# Preface

This, the fifty-sixth volume of the TRANSACTIONS of the American Institute of Electrical Engineers, includes the entire text content of the 12 monthly issues of ELECTRICAL ENGINEERING published during 1937 and a 28-page supplement, immediately preceding the index, which contains two papers not published in ELECTRICAL ENGINEERING.

Fourth in the series of annual volumes initiated under the Institute's unified publication plan, which became effective January 1, 1934, this is the last to be published under that plan. Certain changes in publication policy, approved by the Institute's board of directors October 28, 1937, will become effective January 1, 1938, and consequently will be reflected in the 1938 TRANSACTIONS; these changes in publication policy are outlined on page 1409 of this volume.

Discussions of technical papers, printed in ELECTRICAL ENGINEERING from month to month as they became available, are thoroughly correlated in the comprehensive multientry annual reference index which begins on page 1537 of this volume, immediately following the 28-page supplement. A reference to any of the several subject entries for any technical paper will lead directly to any discussion on that paper that may have been published during 1937. It is of importance to note: first, that, of 1936 papers, this volume contains all discussions published after December 1936; second, that, likewise, the discussions of many of the later 1937 papers will appear in the 1938 TRANSACTIONS.

# Errata

1. Page 60, figure 2*a*, capacitance between surfaces of shell should be indicated as $C'$.

2. Page 65, figure 14, first solid line from bottom should indicate power; second solid line from bottom should indicate power factor.

3. Page 97, figure 11, reproduction correct on page 204.

4. Page 168, first column, lines 16–18 should read: The relation between voltage breakdown $(V/V_0)$ and oil gap spacings $(d/d_0)$ for these curves is closely expressed by $\log (V/V_0) = 0.5 \log (d/d_0)$.

5. Page 170, first column, lines 16–18 should read: The relation between voltage strength $(V/V_0)$ and thickness $(d/d_0)$ over the greater range of the 2 curves for fullerboard is expressed by $\log (V/V_0) = 0.6$ to $0.7 \log (d/d_0)$.

6. Page 334, nomenclature should give $\mathcal{P} = 3.192 \frac{A}{\delta}$.

7. Page 557, table I, should give the following values for 13.8-kv lines:

| Line | Length Line | No. Gaps | No. Structures | Structures With Gaps |
|---|---|---|---|---|
| 13,862<br>13,863 | 0.62 | 90 Ph.<br>8 Gr. | 28 | 15 |
| 13,887<br>13,888 | 3.38 | 426 Ph.<br>71 Gr. | 150 | 71 |
| 13,860<br>13,861 | 3.46 | 240 Ph.<br>40 Gr. | 161 | 40 |

8. Page 615, equations 10 should read:

$$P(s) = V_k(s) \qquad I^k(s) = \hat{V}_\alpha(s) * \hat{I}_\alpha(s)$$

9. Page 622, figure 4, equations in subcaption should read:

$$I_q = \frac{E_q s_2}{\sqrt{r_q^2 + x_q^2 s_2^2}}$$

and

$$I_q = \frac{E_q}{\sqrt{(r_q^2/s_2^2) + x_q^2}}$$

10. Page 1004, equation 1 should read:

$$E_s = E_r \cosh px + I_r Z_0 \sinh px$$

11. Page 1005, equation 5 should read:

$$Z_s = Z_0 \left( \frac{\alpha x}{\cos^2 \beta x} + j \tan \beta x \right) = Z_0 \tan \beta x \left( \frac{Rx}{Z_0 \sin 2\beta x} + j\, 1.0 \right)$$

12. Page 1006, equation 8 should read:

$$R' = \frac{84\sqrt{f}\, 10^{-9}}{r\sqrt{1 - \left(\frac{2r}{D}\right)^2}} = \frac{0.01455}{\sqrt{\lambda}\, r \sqrt{1 - \left(\frac{2r}{D}\right)^2}}$$

13. Page 1009, fourth line following equation 40, $z_0$ should be $Z_0$.

## We Present

# The Easy-Reading Page

IN AN EFFORT to relieve readers of eye-strain, with its attendant fatigue and discomfort, or worse, ELECTRICAL ENGINEERING introduces with this issue some of the indirect results of extensive research by noted illumination and research authorities in the field of "effective seeing"—a hopeful step toward a much-needed "easy-reading page." This issue is printed on new paper of an improved quality, blended and toned scientifically to provide the foundation for an effective non-glare easy-reading page. Typography, too, has been modified in the interests of reader-comfort. Even the ink, which after all makes a periodical out of otherwise blank paper, has been specially compounded to contribute toward the desired results, and in all probability will be improved still further in the future.

Concerning this change, Maurice Holland (A'23, M'30) director, division of engineering and industrial research, National Research Council, has written the following statement:

"I have been advised on good authority that 70 per cent of our current knowledge comes to us through the medium of the printed page. Therefore, especially in view of the recent notable advances in the science and art of electrical illumination, it would seem that we have not carried through to the ultimate conclusion, so far as the reader is concerned.

"Particularly as exemplified in the 'better light, better sight' campaign, much scientific and technical effort has been focused with pronounced success on such modern illuminants as the 'IES lamps.' But all this has had to do with the *source* of the light. Therefore, it seems not only timely, but highly important that thoughtful attention should be given to the question of effective *utilization* of light, particularly with reference to the printed page.

"The advance samples of the January 1937 issue of ELECTRICAL ENGINEERING that I have seen represent the nearest to a scientifically developed easy-reading page that so far has been produced through the media of the graphic arts. It is a definite contribution. It is a definite challenge. An easy-reading page involves not only the paper on which it is printed, but, to be most effective, should represent the co-operative effort of printers, ink manufacturers, type designers, and other elements of the graphic arts."

Frankly an experiment, this step represents ELECTRICAL ENGINEERING's effort to serve its readers in the most effective manner possible. Comments are invited.

# A Million-Cycle Telephone System

ABOUT 2 years ago a new wide-band system for multichannel telephone transmission over coaxial cables was described in an AIEE paper.[1] An experimental system has now been installed between New York and Philadelphia. The various tests and trials which are planned for this system have not been carried far enough to justify a formal AIEE technical paper for presentation and discussion. Meanwhile, the considerable interest that has been aroused in the system has led to this brief statement of its principal features and its general technical performance as so far measured, which has been prepared by M. E. Strieby (M'22) carrier transmission research engineer of the Bell Telephone Laboratories, Inc., New York, N. Y.

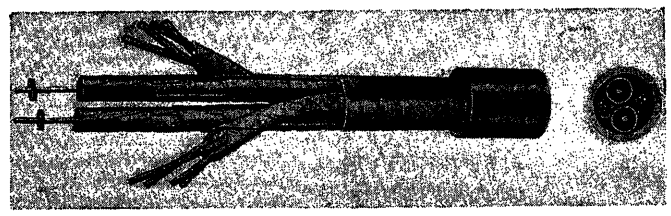

Fig. 1. View showing structure of coaxial cable

The coaxial cable itself has been installed between the long-distance telephone buildings in New York and Philadelphia, a distance of 94.5 miles. It has been equipped with repeaters, at intervals of about 10 miles, capable of handling a frequency band of about 1,000,000 cycles.

This million-cycle system is designed to handle 240 simultaneous 2-way telephone conversations. Only a part of the terminal apparatus has been installed, sufficient in this case to enable adequate tests to be made of the performance of the entire system. A general view of the New York terminal is shown in figure 2. Some preliminary test conversations have been held over the system both in its normal arrangement for providing New York-Philadelphia circuits, and with certain special arrangements whereby the circuit was looped back and forth many times to provide an approximate equivalent of a very long cable circuit. The performance has been up to expectations, and no important technical difficulties have arisen to cast doubt upon the future usefulness of such systems. Much work remains to be done, however, before coaxial systems suitable for general commercial service can be produced.

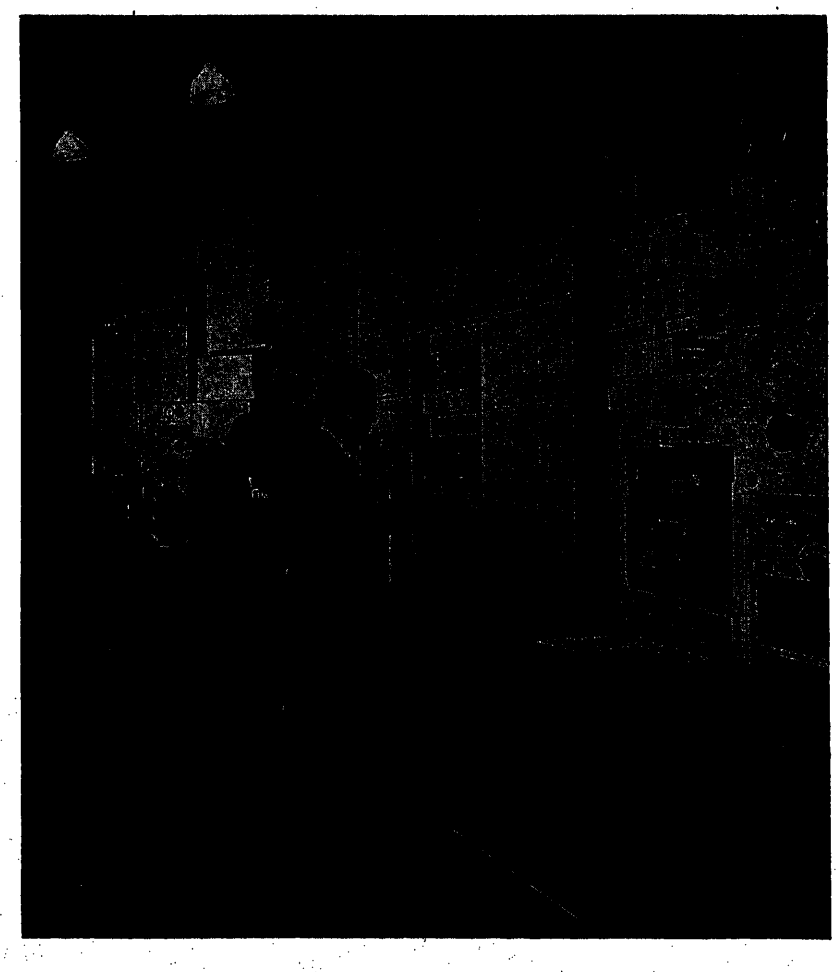
## The Coaxial Cable

Figure 1 shows a photograph of the particular cable used in this installation. It contains 2 coaxial units, each having a 0.265-inch inside diameter, together with 4 pairs of 19-gauge paper-insulated wires, the whole enclosed in a lead sheath having a $^{7}/_{8}$-inch outside diameter. The central conductor of the coaxial units is a 13-gauge copper wire insulated with hard-rubber disks at intervals of $^{3}/_{4}$ inch. The outer conductor is made up of 9 overlapping copper tapes which form a tube 0.02 inch thick; this is held together with a double wrapping of iron tape.

The transmission losses of this coaxial conductor at various frequencies are shown in figure 5. This attenuation is about 4 per cent higher than is calculated for a solid copper tube of the same dimensions and material. Another matter of importance is the shielding obtained from

1. Systems for Wide Band Transmission Over Coaxial Lines, by L. Espenschied and M. E. Strieby, Electrical Engineering (AIEE Transactions), volume 53, 1934, pages 1371–80.

Fig. 2. The New York terminal of the coaxial system



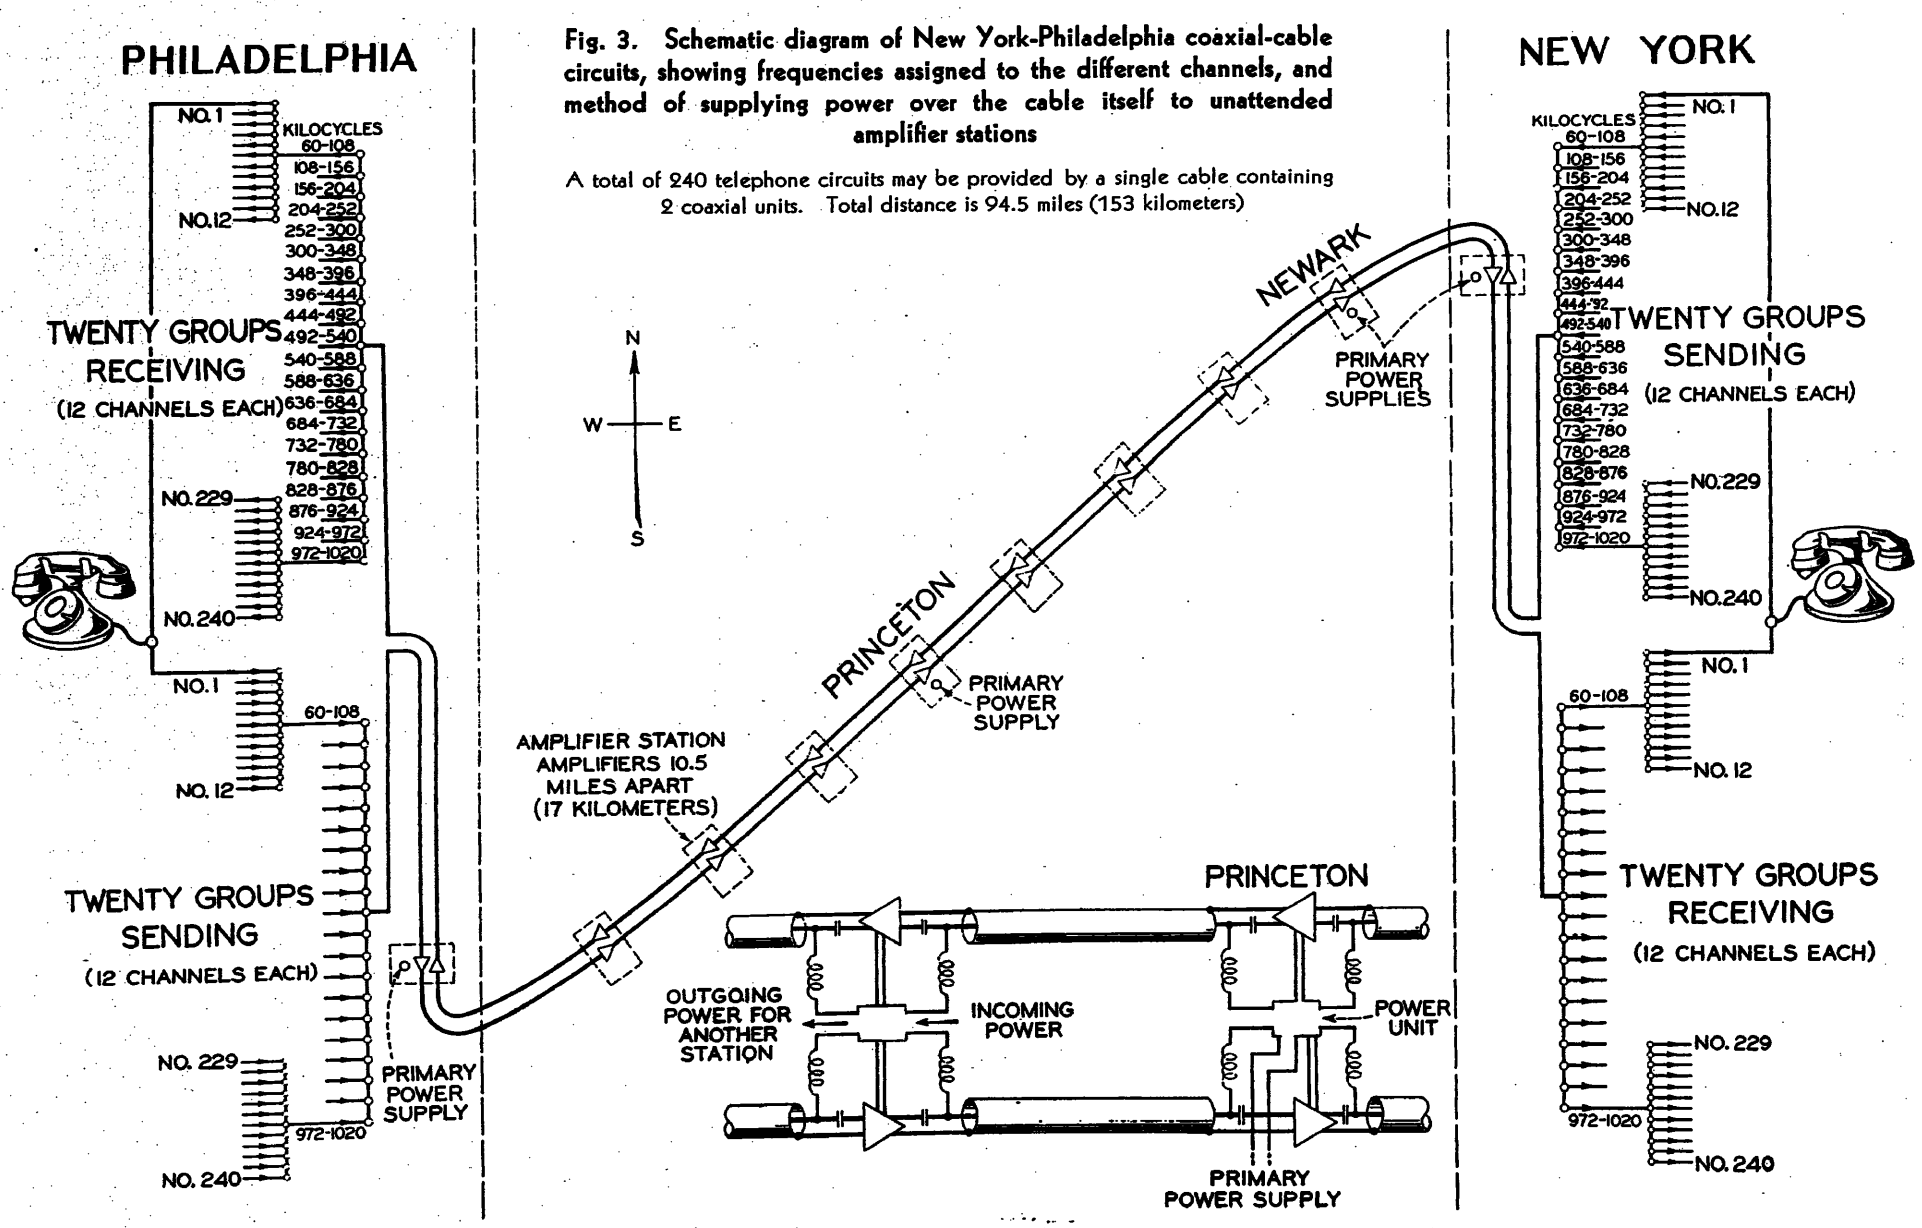


**Fig. 3. Schematic diagram of New York-Philadelphia coaxial-cable circuits, showing frequencies assigned to the different channels, and method of supplying power over the cable itself to unattended amplifier stations**

A total of 240 telephone circuits may be provided by a single cable containing 2 coaxial units. Total distance is 94.5 miles (153 kilometers)

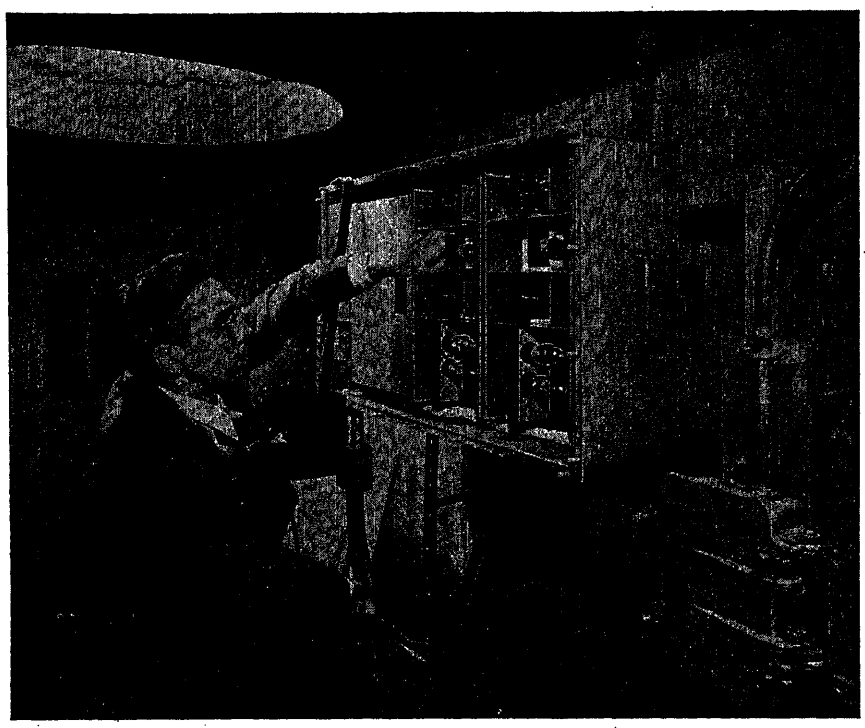

Fig. 4. Million-cycle repeater mounted in a manhole

one conductor to the other or to outside interference. Inasmuch as the most severe requirement is that of cross talk from one coaxial unit to another, this has been used as a criterion of design. Figure 6 shows the average meas-

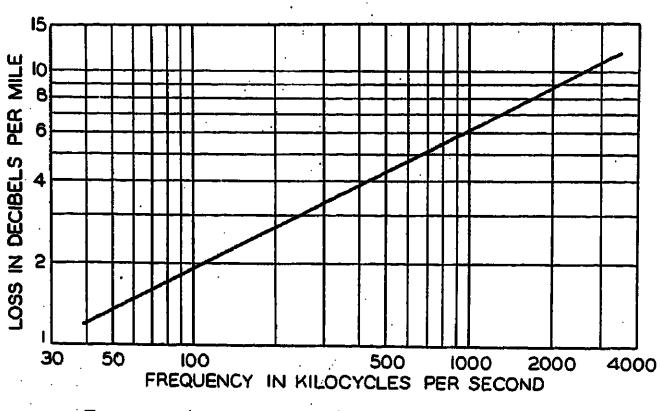

Fig. 5. Attenuation of the coaxial conductor

ured high-frequency cross talk in this particular cable on a 10-mile length without repeaters, both near-end and far-end.

## Repeaters

The amplifiers used in this system were designed for about a 10-mile spacing and a frequency range of 60 to 1,024 kilocycles. A total of 10 complete 2-way repeaters has been provided, including those at the terminals. Two of the intermediate repeaters are at existing repeater stations along the route, the other 6 being at unattended locations along the line. Four of these are in existing manholes, while the other 2 were placed above ground for a test of such operation. Figure 4 shows a manhole repeater with the cover removed for routine replacement of vacuum tubes. Figure 8 shows one of the installations above ground.

The measured gain of a typical repeater is shown by the points on the curve of figure 7. The curve itself is the line loss that the repeater is designed to compensate. Three stages of pentodes are used with negative feedback around the last 2 stages. Attenuation changes due to temperature of the line are compensated automatically by a pilot channel device which has been installed at every second or third repeater. The regulating mechanism uses 4 small tubes and is added to the normal repeater when desired. The amplifiers shown in figure 8 are regulating. As the cable is underground, the temperature changes are very slow and but meager data on the accuracy of compensation are yet available.

## Terminals

The New York and Philadelphia terminals of the cable have each been equipped to handle 36 2-way telephone conversations. As may be remembered, the scheme

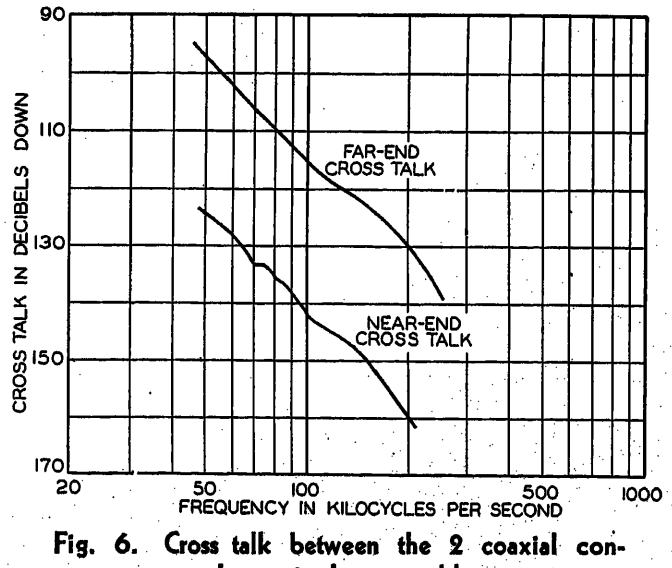

Fig. 6. Cross talk between the 2 coaxial conductors in the new cable

employed involves 2 steps of modulation, the first of which is used to set up a 12-channel group in the frequency range from 60 to 108 kilocycles. Three such groups have been provided in this installation. In order

to transmit at the higher frequencies, a second step of modulation is used in which an entire 12-channel group is moved to the desired frequency location by a "group" modulator. Six such group modulators have been provided at various frequencies throughout the range, including both the top and bottom. Patching facilities have been provided so that any 12-channel group may be transmitted over any one of the high frequency paths. A typical frequency characteristic of one of the channels is shown in figure 9. It may be observed that relatively high quality has been obtained, due largely to the use of crystal filters, even though the channels are spaced throughout the frequency range at 4,000-cycle intervals.

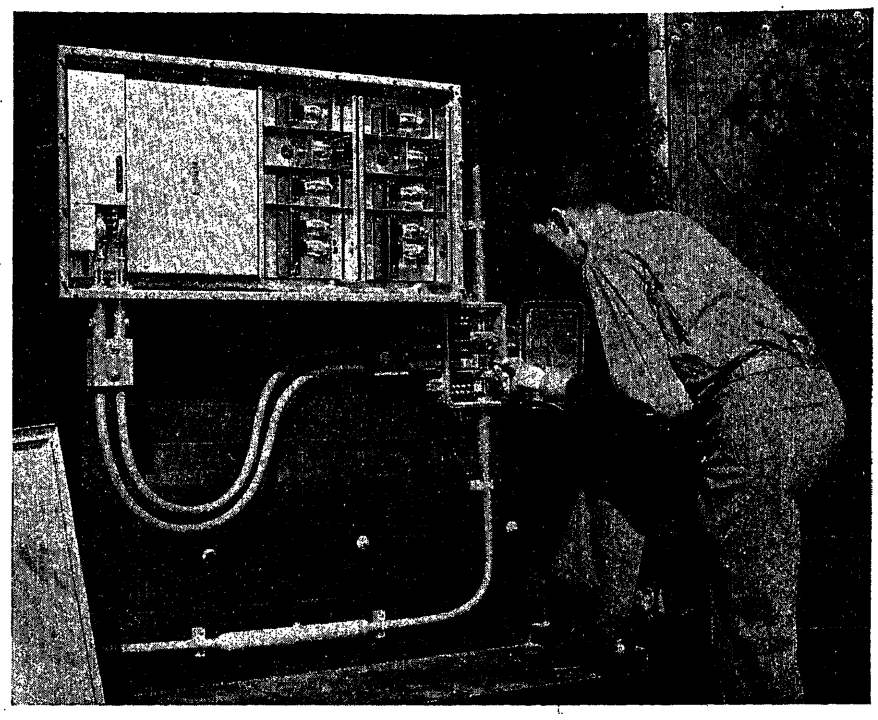

**Fig. 8. Installation of coaxial repeater above ground**

## Preliminary Tests

As already noted, various long circuits have been built up by looping back and forth through the coaxial system. One setup over which conversations were successfully carried out consisted of 5 voice-frequency links in tandem, each link being 760 miles long, giving a total circuit length of 3,800 miles. This setup included, in each direction, 70 stages of modulation and the equivalent of 400 line amplifiers, the transmission passing 20 times through each one of the 20 one-way line amplifiers constituting the 10 2-way repeaters.

This demonstrated that the complete assemblage of

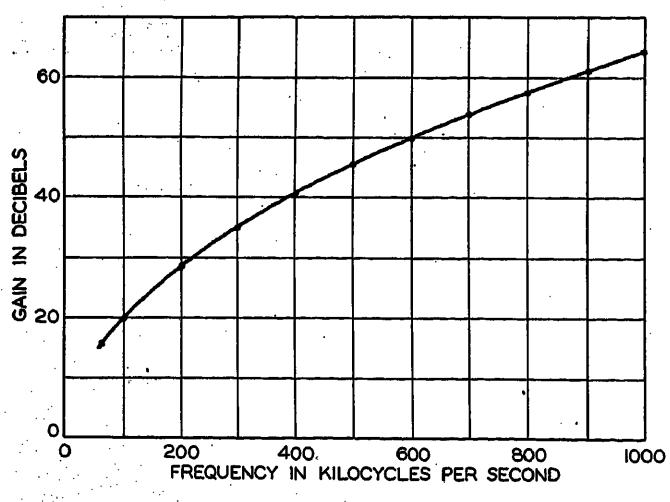

**Fig. 7. Gain-frequency characteristic of coaxial repeater**

parts, including filters which divide the frequency range into the required bands, modulators which produce the necessary frequency transformations, and amplifiers which counteract the line attenuation, introduced very little distortion. Many problems require further consideration, however, before these systems will be ready for design and production for general use. The final systems must have such refinement that they are suitable

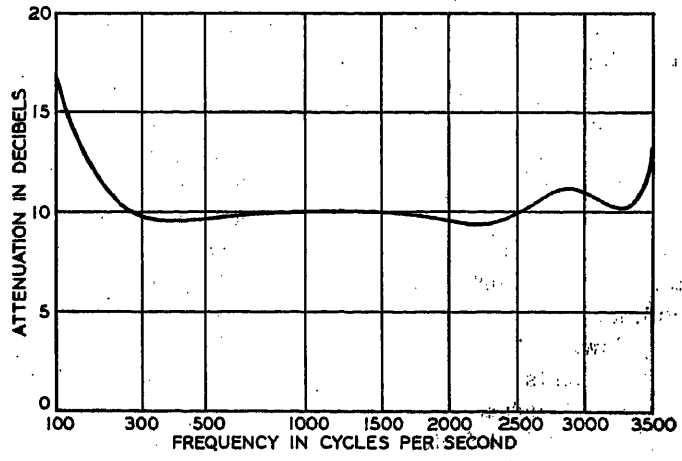

**Fig. 9. Frequency characteristic of a typical speech channel**

for transcontinental distances; the tremendous amplifications needed for such distances must have very precisely designed regulation systems, particularly where aerial construction is involved; noise and cross talk must not accumulate over the long distances; the repeaters must have such stability and reliability that continuity of service will be assured with hundreds of repeaters operating in series and each repeater handling several hundred different communications.

# Abrasion—A Factor in Electrical Brush Wear

By V. P. HESSLER
ASSOCIATE AIEE

**An investigation of the effect of abrasion upon electrical brush wear is reported in this paper. Tests of the rate of wear of anode and cathode brushes, and of brushes carrying current and those that did not, show that abrasion is an important factor in electrical brush wear.**

A BRIEF résumé of the literature on electrical brush wear was reported by the author in a previous paper.[1] A more complete review of this literature has also been reported by the author in another publication.[2] In the interest of brevity, these publications will be assumed to be available to the reader. The investigations reported in this paper represent an extension of the previous work, all of which has been carried on under the auspices of the Iowa Engineering Experiment Station. In the previous investigations the brushes were operated with the anode and cathode brushes (throughout this paper the brush at which the conventional current flow is from the brush to the ring is called the anode brush) on separate paths, for the purpose of obtaining fundamental information concerning the wear of brushes at different polarities. These experiments have been extended to include the condition of brushes tracking and brushes trailing. That is, with brushes tracking, the anode and cathode brushes are both operated on the same path; with brushes trailing, a brush not carrying current is operated on the same path with a current-carrying brush.

The situation of brushes tracking on a drawn copper ring duplicates the arrangement of a d-c commutator rather closely; however, the more important reason for making such a test was to ascertain the effect of the ring surface upon anode and cathode brush wear. The previous investigations indicated a very pronounced polarity effect, but there was nothing in the data to indicate whether the difference in the rates of wear of the anode and cathode brushes was caused by a ring-surface condition, a brush-surface condition, or by the direction of current flow.

The results of the tests with the brushes not tracking and with brushes tracking indicated that abrasion might be an important factor in electrical brush wear; consequently a series of tests was run with brushes trailing, with the hope of evaluating the magnitude of this factor in brush wear. It was assumed that if a brush carrying current were operated on the same ring simultaneously with a brush not carrying current, both might lose material at the same rate as a result of abrasion, while the current-carrying brush would lose additional material as a result of the current flow. This assumption proved to be substantially correct.

## Apparatus Used in the Tests

All of the tests were made upon drawn electrolytic-copper rings. The rings were rolled from strip copper, brazed on the inside of the hoop and pressed upon cast aluminum disks. The rings were turned true and finished with the shaft rotating in its own bearings, so it was possible to maintain the ring eccentricity below 0.0005 inch.

The brush holders were of the radial type. The dimensions of the brushes were 1/2 by 1/2 by 2 inches. It was realized that a brush of these dimensions in a radial brush holder might be subject to chatter, but it caused no apparent difficulty. The brushes were fitted very closely, and the rings were always rotated in the same direction. Double surfaces were observed on the brush faces only during the running-in period. The brush holders were mounted 90 degrees apart on vertical and horizontal diameters. The rings were always rotated in the direction from the lower brush to the upper brush, because the author thought that less of the material abraded from the preceding brush would be carried under the following brush with such an arrangement.

Some of the physical characteristics of the brush materials are given in table I. The tests ordinarily were conducted on 4 rings simultaneously. The 4 pairs of brushes were connected in series and the group connected to an 80-volt d-c generator through a variable resistor. By dropping a large part of the circuit voltage in the variable resistor and operating the generator under conditions corresponding to a point high on its saturation curve it was possible to maintain a constant circulating current through the brushes.

**Table I—Physical Constants of Brush Materials**

| Brush Grade | Resistivity, Ohm-Inches | Hardness (Scleroscope) | Transverse Strength, Pounds Per Square Inch | Normal Current Density, Amperes Per Square Inch | Type of Material |

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted September 28, 1936; released for publication November 27, 1936.

V. P. HESSLER is assistant professor of electrical engineering at Iowa State College, Ames. The author wishes to express his appreciation to the National Carbon Company and the Morganite Brush Company for furnishing the brushes which were used in the tests.

1. For all numbered references see list at end of paper.

The temperature and humidity were maintained constant throughout the tests by means of automatically controlled air-conditioning equipment. The atmosphere was kept as nearly dust free as possible by means of a specially designed dust collector, but no attempt was made to make quantitative measurements of the dust condition.

The rate of wear was determined by measuring the length of the brushes at the beginning and again at the end of a run by means of a micrometer with an electrical contact arrangement. The rate of wear is represented by the ratio of the change in length during the run to the duration of the run. The unit "inches per 100,000 hours" was chosen simply for ease of calculation and presentation of the data. A rate of wear of 11.4 inches per 100,000 hours is equivalent to a life of one year per inch.

The data on contact drop were obtained by means of an auxiliary copper-leaf brush, which was lowered to the ring whenever readings were desired. Each test brush was equipped with a potential lead to eliminate errors caused by the shunt voltage drop, and the contact voltage drop was corrected for the voltage drop through the brush material.

A more complete description of the apparatus is included in a previous paper on brush wear.[1] The same apparatus, except for a few minor changes in brush-holder mountings, was used in these tests.

## Test Procedure

The brushes always were sanded carefully and run for several hours with a nominal current before any readings were taken. The rings were sanded at the beginning of each series of tests and then not cleaned again until the beginning of the next series of tests. The temperature and the relative humidity were held constant at 45 degrees centigrade and 50 per cent, respectively, throughout the

**Fig. 1. Curves showing rate of wear and contact voltage drop with brushes tracking**

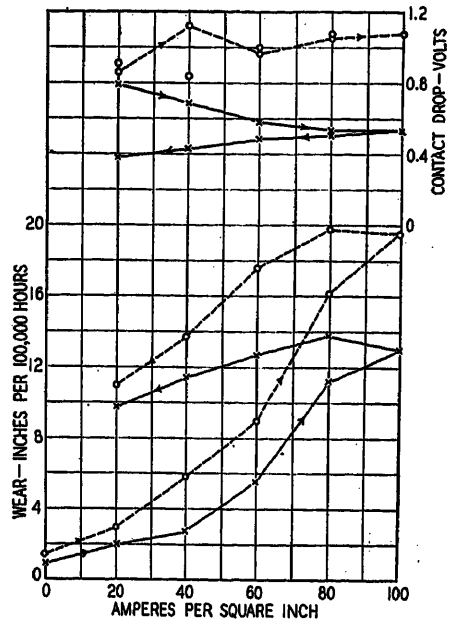

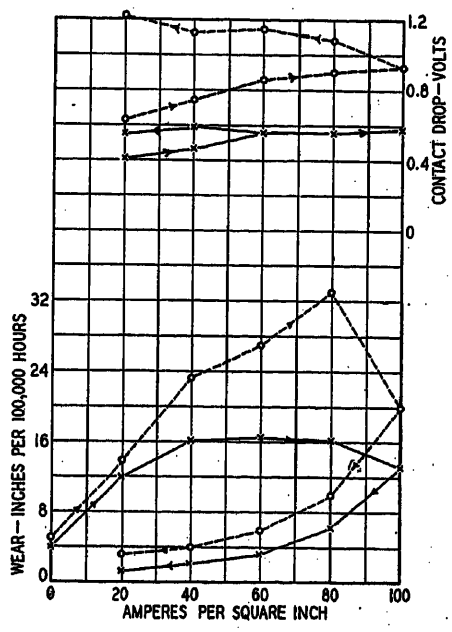

**Fig. 4. Curves showing rate of wear and contact voltage drop with brushes tracking**

Test conditions identical with those of figure 1, except that the brush material was of the grade designated *D* in table I

tests. Ring speed was 3,500 feet per minute and brush pressure 3 pounds per square inch. The curves of contact voltage drop represent the average of several readings taken at intervals throughout the period of operation at a given current density. The equipment was run approximately 24 hours to obtain the data for each point on the wear curves.

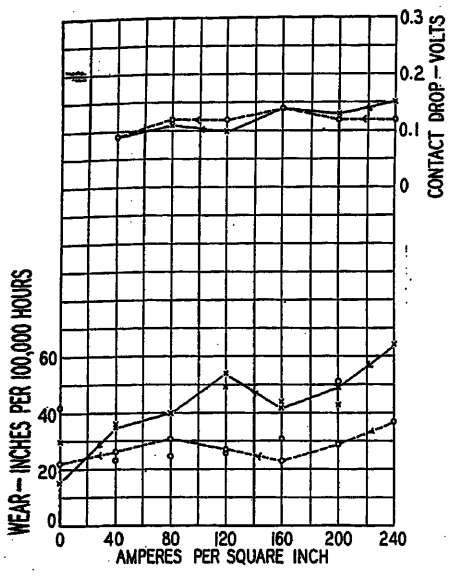

**Fig. 5. Curves showing rate of wear and contact voltage drop with brushes tracking**

Test conditions identical with those of figure 1, except that the brush material was of the grade designated *E* in table I

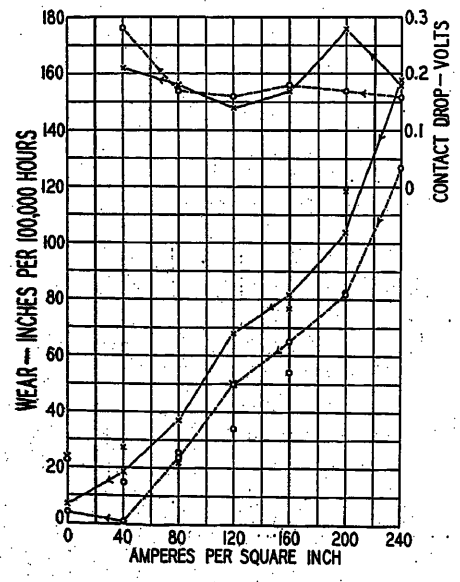

**Fig. 6. Curves showing rate of wear and contact voltage drop with brushes tracking**

Test conditions identical with those of figure 1, except that the brush material was of the grade designated *F* in table I

The experiments with brushes tracking simply consisted of arranging 2 brushes on the same path of a given ring and obtaining wear and contact voltage drop data. The arrangement was somewhat more involved in the case of brushes trailing, for which 4 brushes were mounted on each ring in such a manner that a pair of brushes operated on each of 2 ring paths. The electrical circuit was arranged to carry current through one brush of each pair, to reverse the current through the first 2 brushes, or to connect to the other 2 brushes on a given ring. This arrangement made it possible to observe whether the results obtained were peculiar to a given brush and holder or could be duplicated on other brushes. Also it gave some idea of the time required for changes in film formation to take place. The sequence of readings represents approximately 24-hour periods of operation. In all trailing tests, except for figures 12 and 13, identical brushes were used in all 4 positions on the ring. The tests for figures 13 and 14 were conducted with one metallic brush and one nonmetallic brush on each path, for the purpose of studying whether the higher rate of wear of metallic brushes results from a more abrasive ring path or from the mechanical structure of the metallic brush.

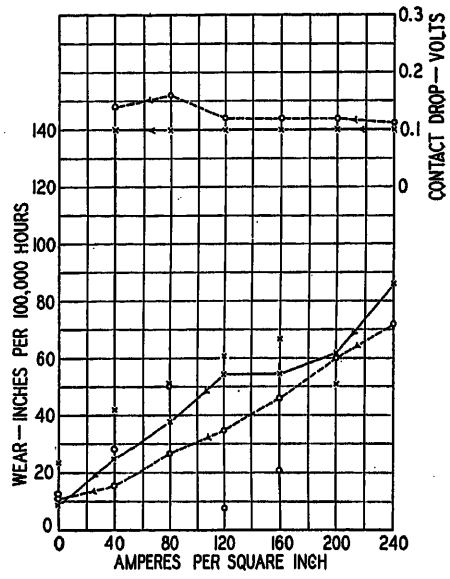

**Fig. 7. Curves showing rate of wear and contact voltage drop with brushes tracking**

## Results of Tests

All of the test results are given in the form of curves in figures 1 to 13. The arrows on the curves of figures 1 to

7 indicate the sequence in which the tests were made. For example, in figure 3, tests were started at zero current; the current was increased to 100 amperes per square inch and reduced to 20 amperes per square inch by 20-ampere increments. For most cases only the descending or ascending curves are shown. The experimental points not connected by curves represent the other values.

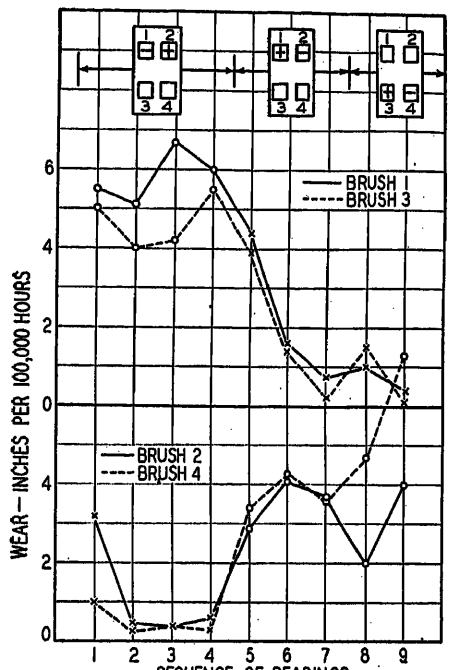

**Fig. 9. Curves showing rate of wear with brushes trailing**

Test conditions identical with those of figure 8, except that the brush material was of the grade designated *I* in table I

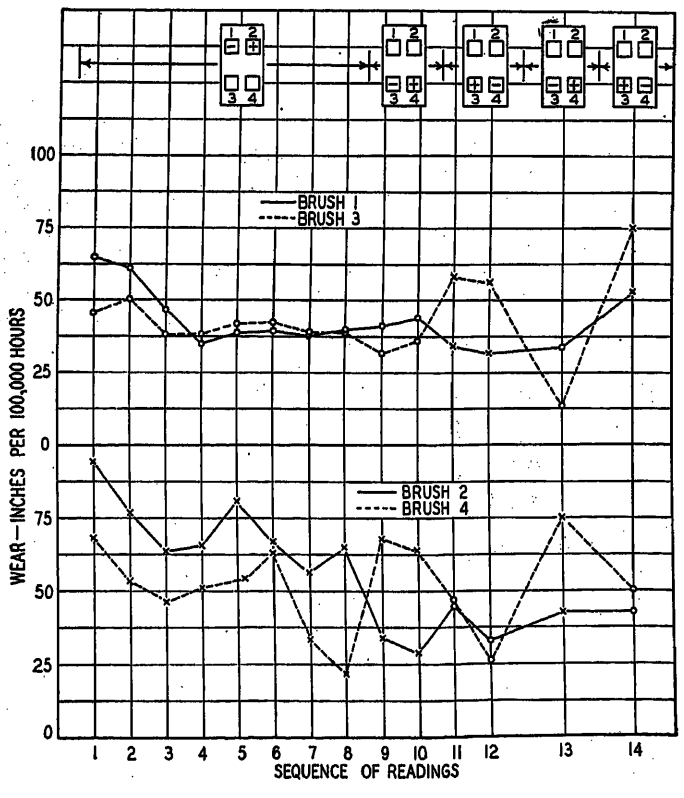

**Fig. 10. Curves showing rate of wear with brushes trailing**

Test conditions identical with those of figure 8, except that the brush material was of the grade designated *E* in table I

Figures 1 to 7 represent the results of the tests with brushes tracking

The results for various brush materials with brushes trailing are given in figures 8 to 13. The boxes at the top of each figure represent the electrical connection and mechanical arrangement of the 4 brushes on a ring. The minus sign indicates the cathode brush and the plus sign the anode brush. For example, the left box in figure 8 indicates that brushes 1 and 3 are operating on the same

path, with brush 1 as the cathode-current-carrying brush, and brushes 2 and 4 are operating on the other path of the same ring with 2 as the anode brush. Readings 1, 2, 3, and 4 were obtained with this arrangement. For readings 5, 6, and 7 the polarity of the current-carrying brushes was reversed. For readings 8 and 9 the current was shifted to the other 2 brushes. As stated previously, the same grade of brush was used in all 4 positions in the tests of figures 8 to 11. The tests of figures 12 and 13 were conducted with one metallic and one nonmetallic brush on each path.

## Interpretation of Results

Even the most casual comparison of figures 1 to 7 with the curves of the previous paper[1] indicates that there is a fundamental difference between operating brushes tracking and not tracking. With brushes of both polarities operating on the same path practically all of the difference in wear which was previously observed disappears. This seems to indicate that the more rapid wear of the carbon or graphite cathode brush was caused by a ring-surface condition set up as a result of current flow. Photomicrographs of ring surfaces show this supposition to be correct. Figure 14*a* and 14*b* show characteristic ring paths as produced by graphite anode and cathode brushes, respectively. The anode-brush path was very smooth, whereas the cathode-brush path was so rough that the peaks and valleys could not be brought into focus simultaneously.

The reader may note that the arrows are reversed on the wear curves of figures 3 and 4. These curves were obtained simultaneously on separate rings mounted upon the same shaft; therefore, any explanation would have to be made in terms of the ring or brush materials. No difference in operation has been observed between the various drawn copper rings used in the tests. Previous tests have shown that the rate of wear of certain brush grades decreases as the brushes are "run in" whereas others increase during the running-in period. In each case the ring may present a satisfactory uniformly polished appearance. No doubt, the same phenomenon has occurred in figures 3 and 4.

The results presented in figures 8 to 13 show definitely that brush wear is largely abrasion resulting from a ring-surface condition set up by current flow. In general, the trailing brush wears at almost the same rate as the current carrying brush. The sequence of readings from 4 to 7 in figure 9 indicates that a surface condition affecting the rate of wear is being established. If the wear were purely electrical, the reversal would take place in a much shorter period.

It is interesting to note that in several instances in figures 10 and 11 the trailing metallic brush wears more rapidly than the current-carrying brush. The sequence of readings from 10 to 14 in figure 11 shows in a very striking manner the polarity effect on metallic brushes.

Figures 12 and 13 show that even for widely dissimilar materials the wear of the trailing brush is governed by the nature and polarity of the current-carrying brush. The decrease in wear from reading 6 to 7 in figure 13 was caused by cleaning the ring.

After showing that brush wear is largely abrasion it was thought that it might be reduced by burnishing or polishing the ring continuously. This was attempted with a cotton tape, which reduced brush wear by about 60 per cent in the first tests. However, it was not possible to obtain these results consistently. An attempt to obtain better results with the aid of certain fine abrasives resulted in tremendously increased rates of brush wear.

The foregoing results suggest using metallic and nonmetallic brushes on the same path to reduce brush wear, but no commercial machine seems to be adaptable to such an arrangement. The metallic brush would not commutate a high-voltage machine and the nonmetallic brush would not have the current-carrying capacity for a low-voltage machine.

An interesting study of brush wear in hydrogen and in air was made by Baker and Hewitt[3] in which they found that brush wear in air was many times that in hydrogen. It would be very instructive to repeat these tests with a trailing brush on each path to ascertain the effect of abrasion in these tests.

# Lightning Protection for Transmission Lines

By A. W. GOTHBERG
ASSOCIATE AIEE

A. S. BROOKES
ASSOCIATE AIEE

**To meet the need for lightning protection on low-voltage transmission lines at moderate cost, and particularly for wood-pole lines, a design is presented in this paper that has high insulation strength and uses, in place of a ground wire, a shielding phase conductor with a lightning protector tube. Lightning currents are drained to ground with a minimum number of tubes of low current rating.**

THE RESULTS of many years of lightning-research work have been applied to steel-tower transmission lines with great improvements in operating results. In general, there has been less accomplished in improving wood-pole line design. The records of the company with which the writers are associated show lightning outages on unprotected wood-pole lines to be 48 per 100 miles of line per year as compared to a rate of 5 for steel-tower lines with 2 ground wires. Such relatively poor performance shows the need for improved protection.

Early investigators attempted to prevent line outages by increasing insulation. Measurements of stroke currents indicate that some outages can be prevented by over-insulation but that obtaining reliable operation by the use of high insulation is costly and impractical.

The most widely used form of protection consists of ground wires to intercept all direct strokes. These are very effective when properly installed with adequate clearances and low-impedance ground connections. In many cases, however, the cost of the extra wire and of enlarging the structures for increased clearances and heavier loading cannot be economically justified. Particularly in the case of wood construction, low-resistance grounds may be difficult and expensive to obtain. In addition, unless special precautions are taken, the ground lead will render useless a portion of the normal wood insulation. The use of additional wires and larger structures naturally increases construction and maintenance costs.

A recent and increasingly popular protection scheme consists in the installation of lightning protector tubes[1,2] to drain surge currents from the phase wires and extinguish the resulting power arc. It is customary to install a tube for each phase on protected structures. Where ground resistances are low, strokes to one wire will cause phase-to-ground faults. Where more than one wire is struck or where ground resistances are high, the tubes will have to interrupt phase-to-phase short-circuit currents. On power systems using neutral resistors or reactors, co-ordination may be difficult since present tubes are effective only within a limited range of short-circuit currents. A given tube will not interrupt currents below its rating and will fail because of excessive internal pressures on currents in excess of its rating. In general, tubes are effective, although a large number are required to secure protection on lines with short span lengths and high ground resistances.

## Summary

Without departing radically from present practices with wood-pole lines, a design is proposed for improved lightning performance. Use is made of wood insulation and a shielding conductor with lightning-protector tubes. Computation methods are shown so that the recommendations may be adapted to local conditions. It may be concluded that:

1. It is possible on low-voltage transmission lines to secure at moderate cost a large reduction in lightning outages.
2. It is possible to secure the advantages of a ground wire without the cost of the additional wires and heavier structures.
3. Protection may be secured by the use of low-rating lightning-protector tubes on one phase of a 3-phase circuit.
4. A method of protection is presented which may be used on higher voltage lines with economies resulting from the elimination of ground wires.
5. With the assumptions used and by using a standard pole top the proposed design shows an estimated reduction in lightning outages of approximately 75 per cent.

## Proposed System of Protection

The proposed design is an attempt to secure at moderate cost a line combining the advantages of the 3 present protection methods as follows:

1. One phase of each circuit is made a shielding conductor by locating it so that the remaining phases will be shielded from direct strokes.
2. Lightning currents are drained from the shielding conductor by means of a lightning-protector tube.
3. The remaining phases are isolated from the shielding conductor and tube ground circuit by insulation sufficient to prevent phase-to-phase faults. This allows the use on each structure of a single tube designed to withstand only phase-to-ground currents which, in general, are much less than phase-to-phase currents.

## Construction Features

Figure 1 shows the described features incorporated in a single-circuit wood-pole top. The location of

A paper recommended for publication by the AIEE committee on power transmission and distribution. Manuscript submitted October 20, 1936; released for publication November 10, 1936.

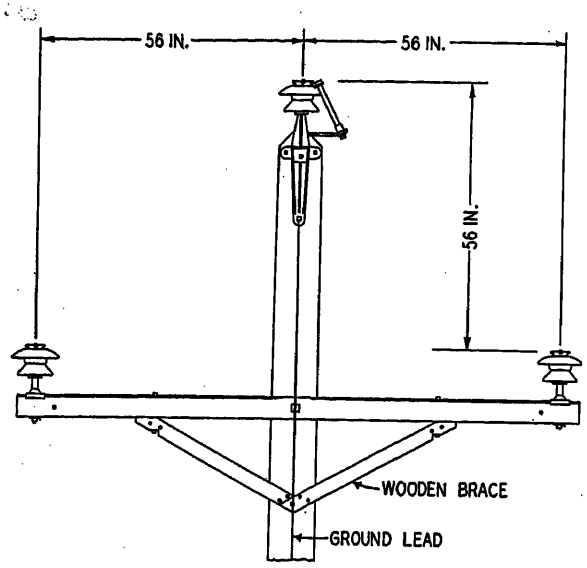

**Fig. 1 (left). Single - circuit pole showing shielding conductor and lightning protector tubes**

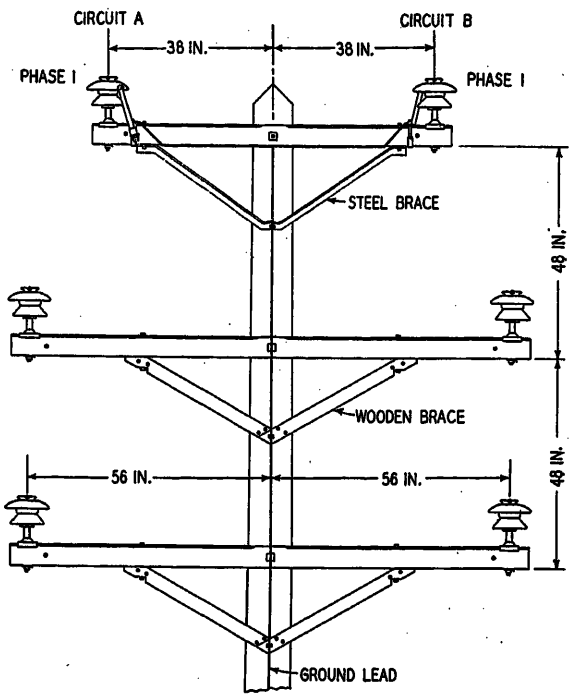

**Fig. 2 (right). Double - circuit pole showing shielding conductor and lightning protector tubes**

the shielding conductor with reference to the other phase wires may be determined by use of the conventional shielding angle[3] or by assuming a cloud height and considering the distances to the line conductors.[4] For a structure of the size shown the shielding-angle method was used as giving the more conservative results.

To prevent flashovers between the tube ground lead and the lower phase wires without excessively close tube spacings requires the use of insulation having high impulse strength. In the design shown this is obtained by the use of wooden crossarm braces. The breakdown strength for the combination shown is 645 kv at 4 microseconds. Insulation values for other desired forms of construction may be obtained from an earlier paper.[5] For most practical designs only the breakdown strength of the insulators and wood need be considered since it is lower than that of the direct path through air.

The tube is placed as shown so as to drain lightning currents from the shielding conductor to ground. The mounting arrangement must be such that the breakdown of the tube and associated gap is at all times less than that of the insulator and the wood between the insulator pin and tube mounting.

The single-circuit pole top may be expanded to provide for an additional circuit as shown in figure 2. The same clearances are maintained and tubes are installed on the 2 top shielding conductors. It is important that the same phase of each circuit be on the top arm so that, in the event of a stroke involving the top 2 conductors, the tubes will not be required to interrupt phase-to-phase currents.

## Distance Between Protected Poles

The expected number of outages and the magnitude of lightning strokes to a line[6] in a territory with an isokeraunic level of 30 are shown in figure 3. While this curve is for a steel-tower line with 2 ground wires, it may be used without serious error for a wood-pole line. This curve is used to find the line performance for an equivalent lightning level. For example, a design for strokes up to 4,000 kv gives an expected

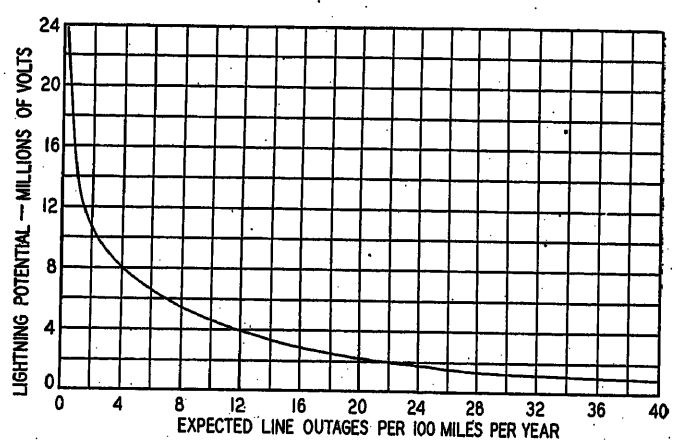

**Fig. 3. Expectancy curve of lightning outages**

outage rate of 12 per 100 miles per year as compared with a rate of 48 for an unprotected line, a reduction in outages of 75 per cent.

Assuming a surge impedance of 200 ohms for the lighting channel and 4,000 kv as the stroke potential, the stroke current is 20,000 amperes. Since the ground current theoretically may reach double this value, it is necessary to use a tube heavy enough to withstand 40,000 amperes surge current.

A computation of the voltages appearing on the shielding conductor for a stroke to a protected pole involves the use of a rate of voltage rise in the stroke. A rate of 1,000 kv per microsecond is believed to be a value which should give conservative results. Neglecting the length of the ground lead, the initial voltage on the shielding conductor $E_L$ at the struck pole is

$$E_L = E_{\text{stroke}} \times \frac{2Y_0}{Y_0 + 2Y_1 + Y_2} = E_s b_0$$

where

$Y_0$ = surge admittance of stroke
$Y_1$ = surge admittance of shielding conductor

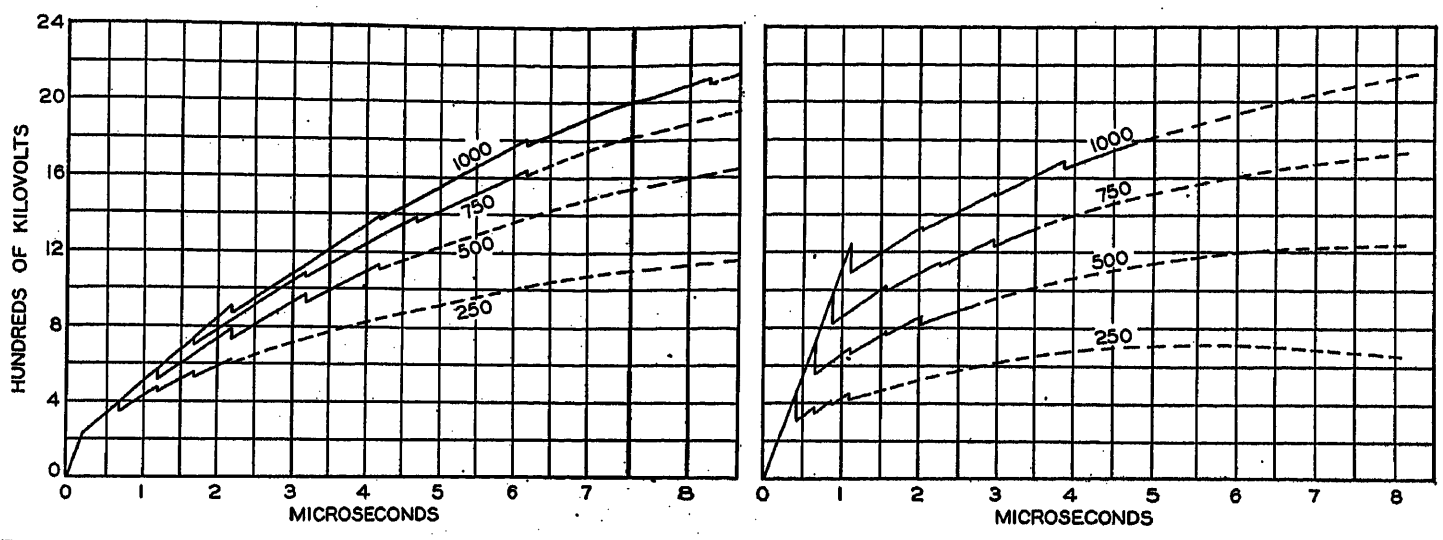
$Y_2$ = surge admittance of ground
$a$ is used for reflection factors
$b$ is used for refraction factors

Sufficiently accurate results are secured by considering only the reflections from the first 2 protected poles on each side of the struck pole. The reflection factor at the struck pole is

$$a_1 = \left(1 - \frac{2Y_1}{Y_0 + 2Y_1 + Y_2}\right)$$

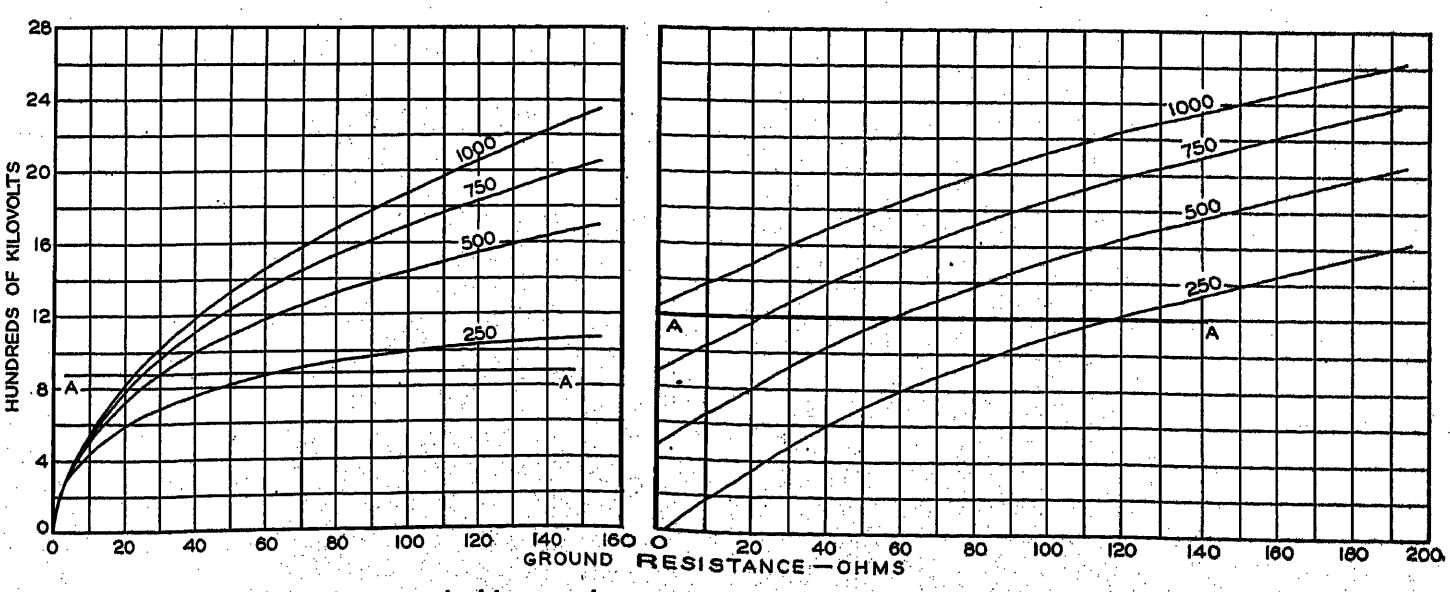
The reflection factors at the first and second protected poles away are

$$a_2 = a_3 = \left(1 - \frac{2Y_1}{2Y_1 + Y_2}\right)$$



Similarly the refraction factors are

$$b_1 = \frac{2Y_1}{Y_0 + 2Y_1 + Y_2} \qquad b_2 = b_3 = \frac{2Y_1}{2Y_1 + Y_2}$$



The reduction factors at the struck pole for successive reflections found by using the lattice method[4] are:

| Reflection | Reduction Factors |
|---|---|
| First | $A = -a_2b_1$ |
| Second | $B = a_2b_1(a_2b_1 - b_2^2 - a_1a_2)$ |
| Third | $C = a_2^2b_1(b_1b_2^2 + b_2^3 - 3a_1b_2^2 - a_2b_2^3 - a_2b_1^2 - a_1^2a_2)$ |
| Fourth | $D = a_2^2b_1(b_1b_2^4 + 4a_1a_2b_1b_2^2 + a_2^2b_1b_2 + a_2^2b_1b_2^2 + a_2b_1^3 + a_1^2a_2^2b_1 + a_1a_2b_2^2 - 2a_2b_1^2b_2^2 - a_1b_2^4 - 3a_1^2a_2b_2^2 - 2a_1a_2^2b_2^2 - a_2^3b_2^3 - a_2b_1b_2^2 - a_1a_2^2b_1^2 - a_1^3a_2^2)$ |

Where the rate of voltage rise $de/dt$ in the stroke equals 1,000 kv per microsecond, $d/1{,}000$ may be used for elapsed time in microseconds after the initial contact of the stroke with the shielding conductor where $d$ is the distance between protected poles (con-

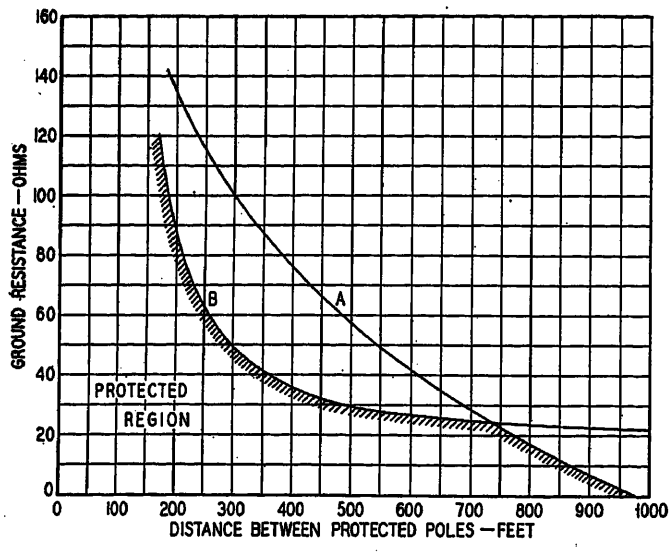

**Fig. 8. Curves showing relation between ground resistance and spacing of protector tubes**

*A*—Limit of protected region, unprotected pole
*B*—Limit of protected region, protected pole

sidering equal spacing) in feet. The voltage at the struck pole is:

$$E_L = \frac{d}{1{,}000} \times \frac{de}{dt} \times b_0$$

At time $t = 2d/1{,}000$

$$E_{2d} = 2E_L$$
$$E_{4d} = 4E_L - 4E_LA$$
$$E_{6d} = 6E_L - 8E_LA - 4E_LB$$
$$E_{8d} = 8E_L - 12E_LA - 8E_LB - 4E_LC$$
$$E_{10d} = 10E_L - 16E_LA - 12E_LB - 8E_LC - 4E_LD$$

With values obtained as shown, figure 4 was plotted for ground resistances of 50 ohms, giving the voltages at the struck pole as a function of time for various spacings of tubes. Curves for other values of ground resistance were calculated in a similar manner. In computing the curves the fact was considered that the voltage at the struck pole must rise to an appreciable value before tube breakdown occurs. This explains the small irregularities in the curves. For all practical purposes, after several reflections the effect of this factor is negligible.

A similar procedure was followed to obtain the voltages on an unprotected pole with a stroke to the shielding conductor at this point. These values are shown in figure 5.

With the assumed rate of voltage rise and a stroke potential of 4,000 kv, the maximum voltage is reached in 4 microseconds. Using values at this time from figures 4 and 5 for ground resistances of 50 ohms and from similar curves for other ground resistances, figures 6 and 7 were plotted to show the voltages appearing on the struck pole for strokes to the protected and unprotected poles. In order to determine the correct ground resistances and tube spacings for the proposed design, the impulse breakdown values of the insulation between the lower phase wires and the ground lead or ground are shown as straight lines on the curves. These values were increased by 30 per cent to allow for coupling between the shielding conductor and other phase wires. The intersections of the straight lines and the curves are plotted in figure 8 to show the maximum ground resistance for safe protection with given tube spacings. Local conditions will dictate whether it is more economical to use closely spaced tubes or to take steps to lower ground resistances.

It is realized that there may be some disagreement in regard to the assumptions made for these calculations but the values chosen are considered sufficiently conservative and accurate to give a co-ordinated installation. Future investigations will probably yield more accurate data but these should affect the figures for expected line performance rather than the fundamental design.

At the present time several 26-kv lines are being rebuilt incorporating the features of this proposed design. It is expected that these lines will be in operation during the coming lightning season so that some field experience will be obtained within a year.

# Abrasion—A Factor in Electrical Brush Wear

(*Continued from page 12*)

## Conclusions and Results

The principal findings are as follows:

1. The wear of brushes on concentric rings is largely abrasion resulting from a ring condition established by the current flow.

2. The abrasive ring condition is caused by the cathode brush for carbon or graphite brush materials, but is caused by the anode brush in the case of metallic brush materials.

3. The abrasive action of the anode metallic brush path is much more pronounced than that of the cathode carbon or graphite brush path.

# Inductive Co-ordination of Common-Neutral Power-Distribution Systems and Telephone Circuits

By J. O'R. COLEMAN
MEMBER AIEE

R. F. DAVIS
ASSOCIATE AIEE

**Early installations of 3-phase 4-wire power distribution systems of the multigrounded or common-neutral type in some cases created noise problems involving neighboring telephone circuits. Operating experience, studies of specific situations and comprehensive co-operative research over a period of years have developed means of largely avoiding difficulties of this character. The relative importance of various features of the power and telephone systems which have been found to affect the noise-induction problems involved is discussed here, and the general co-operative procedures most helpful in conversions to, or extensions of, these types of power distribution systems, are outlined.**

PRIOR to about 1915, delta-connected 2,300-volt 3-phase primary circuits were used extensively for the distribution of electric current. While some distribution networks throughout the country still operate in this manner, the marked increase in load densities, starting about 1915, often made the retention of the 2,300-volt delta system impracticable. In a few instances the development of the particular network was at a point where it was feasible to change from the 2,300-volt delta to a 4,600-volt delta arrangement, but in other cases the existing equipment represented too great an investment for a complete change of this character.

From studies of various methods of caring for the augmented load densities, it was found that the existing equipment could largely be saved and the capacity of the distributing networks substantially increased by converting them to a 2,300/4,000-volt star-connected 4-wire primary system. By about 1925 this system had extended to most of the larger cities and most power companies had found it economical to use in at least some parts of their territories.

In using the 2,300-volt equipment on the 4,000-volt 4-wire system it was necessary to stabilize the neutral conductor in some way. Most of the 4-wire systems had the neutral conductor grounded at the substation only, although sometimes low-voltage lightning arresters were placed on it at various points in the distribution network to aid in its stabilization in case of a break in it. In some instances, at the time of the installation of the 4-wire system, the primary neutral was connected at various points in the network to driven ground rods thus resulting in a multigrounded neutral system. In at least one instance the neutral conductor was not solidly grounded even at the substation, it being connected to ground through lightning arresters.

The experiences of the power companies with the multigrounded neutral were generally favorable. It was found to be more reliable and to embrace some simplifications over other distribution methods. While the early multigrounded neutral arrangements were obtained by making connections to ground along the primary neutral conductor and interconnecting it, at service transformers, to well-grounded secondary neutrals, a further simplification in the arrangement was readily apparent.

It will be noted in figure 1 that this interconnection of the primary and secondary neutrals resulted in 2 grounded neutrals on the pole line in all sections where the secondary neutral existed. In extending the multigrounded neutral arrangement or in reconstructing existing portions of the network, these 2 neutrals were combined into a single well-grounded conductor continuous in all portions of a feeder area and often continuous in all parts of a substation area or of several contiguous substation areas. This arrangement, called the "common-neutral," which was first extensively applied in Minneapolis, Minn., by S. B. Hood, resulted in certain savings in equipment and relief of congested pole heads and in a neutral network most effectively grounded since all secondary neutral grounds were thus made available, in addition to any driven grounds along the pole line.

The operation of this system in Minneapolis showed many advantages in the protection of secondary networks from the effects of voltage rises under abnormal conditions. In addition, a paper presented in 1925 by Mr. Hood[1] pointed out that over a period of 3 years the rate of transformer failure was reduced to $^{8}/_{10}$ of 1 per cent per annum. This excellent performance in transformers arose undoubtedly from the fact that with the "common-neutral" or interconnected neutral arrangements the lightning arresters are connected directly around the transformers. Later studies showed that the connection of the lightning arresters directly between the primary conductors and secondary neutral provides a degree of protection which cannot readily be obtained in any other way.[2–7]

In urban areas, the multigrounded or common-neutral method of distribution introduced, in some instances, noise induction in nearby telephone circuits. In view

A paper recommended for publication by the AIEE committees on (1) communication and (2) power transmission and distribution. Manuscript submitted October 1, 1936; released for publication November 27, 1936.

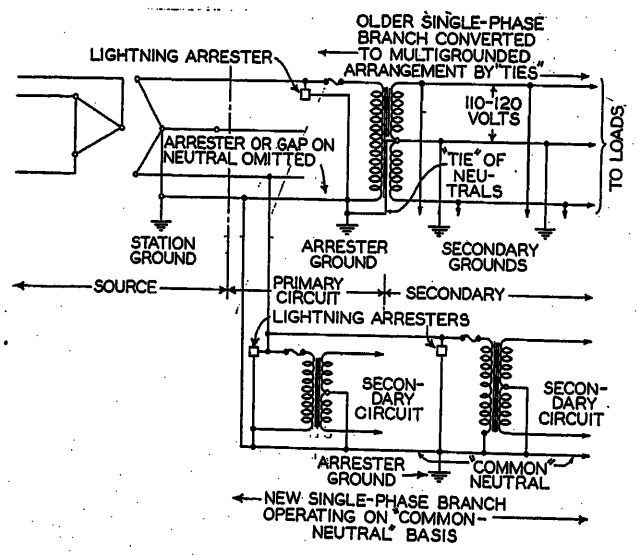

**Fig. 1B. Simplified feeder operating with multiple grounds on primary neutral—older part of feeder having ties between primary and secondary and new extensions being of common-neutral arrangement**

local power distribution systems and telephone systems. A study was carried out in Minneapolis during the years 1924–26 having as its primary objective the determination of the factors involved where the telephone distribution was largely in aerial cable. The investigation was continued in Elmira, N. Y., in 1926–29 to embrace the factors introduced when the exchange telephone plant was of open-wire construction.[8] Supplementing these detailed technical studies, an investigation of certain economic features of various arrangements of power and telephone distributing methods and of their practical application under varying conditions was carried out in California in 1928–29. As a result of these investigations the various factors involved in the co-ordination of multigrounded or common-neutral power systems and telephone distribution systems were determined and certain practices developed for the co-ordination of these systems under various conditions in urban areas.[9]

The purpose of this paper is that of briefly outlining a few of the more important features of power and telephone circuits affecting noise co-ordination. Following such a review there is presented a list of measures which

from the investigations outlined above as these are adequately covered in the references cited.

## Recent Trends

During the past few years there has been extensive conversion from other types of urban power distribution to the multigrounded or common-neutral system of primary distribution. Where there exists a 3-phase 3-wire delta circuit the system is converted by making the secondary neutral network continuous, reinforcing it where necessary, and making the required changes in transformer connections. Where there is a 3-phase 4-wire unigrounded primary system the conversion is, as previously mentioned, made by interconnecting the primary and the secondary neutral at each load transformer, generally removing the primary neutral only at the time of major rebuilding. In either case extensions are usually made using a single neutral in the secondary position.

In the urban areas most of the multigrounded or common-neutral systems are of the 2,300/4,000-volt class, although there are a few instances where 4,600-volt systems have been converted. At the present time there is being constructed a 6,900/12,000-volt common-neutral distribution system at Wichita, Kan.

The distinct trend in power distribution practice has been, in no small measure, influenced by the improved over-all protection features readily obtained by the multigrounded neutral arrangement as well as by certain equipment savings. The recent emphasis placed on the electrification of rural areas and the distinct need for maximum service continuity on rural power circuits have increased the interest in the use of the multigrounded or common-neutral method of distribution in rural areas. The rural systems are generally of the 7,600/13,200-volt class, although 4,600/8,000-volt circuits have been used to some extent.

The factors affecting inductive co-ordination involved in the use of the common-neutral method of distribution in rural areas, are somewhat different from those encountered in urban areas. This is largely due to the lower load densities, the greater lengths of circuits, higher operating voltages and to the somewhat different types of equipment employed in rural telephone distribution. These factors were investigated by the Joint Subcommittee on Development and Research during the summers of 1935 and 1936 and the more important considerations determined.[10]

## Factors Influencing Inductive Co-ordination

In any problem of inductive co-ordination it is convenient to subdivide the factors influencing co-ordination into those relating to the inductive influence of the power circuit, the inductive susceptiveness of the telephone circuit and the inductive coupling between the 2 types of circuits. As far as urban distribution circuits are concerned the load current unbalance of the power circuit is usually the controlling influence factor. For rural distribution circuits the unbalanced charging currents are generally more important than the unbalanced load currents. Likewise, in an exchange telephone circuit the admittance and impedance unbalances of the 2 sides of the circuit are usually the controlling factors in its inductive susceptiveness. As far as coupling between the power and telephone circuits is concerned this is largely controlled by their relative positions and the lengths of the exposure. For urban areas their relative positions are largely fixed by the normal arrangement of conductors and cables on jointly used poles. In rural areas power and telephone circuits are generally at roadway separation although some joint use exists. In urban areas considerable control can often be exercised over the coupling by planning the routes of the main feeds of the 2 services so as to avoid long sections of close exposure. In rural areas

where there are no paralleling routes close together it is generally necessary for both services to use the same roads and therefore the opportunity to control the coupling by the co-operative planning of routes is much reduced. Certain quantitative indications of the extent to which this measure of co-ordination is applicable in the 2 types of areas are shown in the illustrative examples in the appendix.

## Power Circuits

Power systems operate, for the most part, at frequencies of 60 cycles and below. Telephone circuits, on the other hand, depend mainly upon frequencies above about 200 cycles for the transmission of speech. Ordinarily, therefore, the effects of induction from the fundamental-frequency currents and voltages in neighboring power lines are negligible as far as telephone-circuit noise is concerned. It is quite generally recognized, however, that it is impracticable commercially to build rotating machinery and transformers which are entirely free from harmonics. There are, therefore, harmonics present on all operating power systems, and it is the harmonic-frequency components induced into telephone circuits from these power-system harmonics that are of major importance from the noise standpoint.[11]

In any distribution circuit the harmonic currents present will fall within the following classes: load currents, transformer-exciting currents, and line-charging currents. With a uni-grounded neutral the load currents and the transformer-exciting currents are practically entirely confined to the wires of the circuit. Where the neutral is multigrounded, the vector sum of the currents in the phase conductors (residual current) will divide between the neutral conductor and the paralleling earth path as determined by the relative impedances of these 2 paths. While there is some variation in the division of the return current between the neutral and ground paths, for most practical purposes this division may be assumed to be about half in each path at all the frequencies of interest.

As pointed out above, in the case of a line operating with uni-grounded neutral, the earth-return components of the load and transformer-exciting currents are ordinarily negligibly small. However, this is not true of the line-charging current which is chiefly a function of the magnitude and frequency of the impressed voltage, the circuit length, and, at nontriple harmonic frequencies, of the balance of the admittances to ground of the various phase conductors. While multigrounding the neutral ordinarily increases the earth-return components of the load and transformer-exciting currents, it has been found, due to the parallel path provided by the neutral wire, on an average to decrease slightly the amount of charging current in the earth.

In an urban distribution system where the load density is relatively high, the load currents and transformer-exciting currents are relatively large and the line-charging currents are usually negligible. In such a system multigrounding the neutral results in an increase in the current returning through the earth and a consequent increase in the inductive influence of the power distribution system.

In rural areas, however, where the load density is low and the load currents and transformer-exciting currents are relatively small, the line-charging currents become significant. In general, under such conditions the multigrounding of the neutral does not increase the magnitude of the ground-return current at frequencies of interest from the noise-induction viewpoint. Under certain conditions the magnitude of this ground-return current may actually be substantially decreased by the multigrounding of the neutral. This effect is more marked for the higher-voltage circuits.

The harmonics present in a distribution circuit may be divided into: (1) triple harmonics, that is, the third harmonic and odd multiples of it; and (2) nontriple harmonics that is, the odd harmonics, starting with and including the fifth, which are not multiples of 3. The triple harmonics in a 3-phase system are in phase in the 3 line conductors so that their residual value (vector sum) is the arithmetic sum of their magnitudes in the 3 phase wires. The nontriple harmonics are spaced, in time phase, the same as the 60-cycle fundamental, and the magnitude of the residual current (vector sum) for these harmonics is usually much less than their arithmetic sum. If these harmonics were perfectly balanced the residual current for these frequencies would be zero. In exposures involving 3-phase sections of line the balance of the nontriple harmonics between phases is influenced by the degree of balance of the loads and single-phase branches, and therefore has an important effect in reducing the over-all influence of the power system. In exposures involving single-phase extensions, or extensions consisting only of 2 phase wires and a neutral wire, this advantage of the balancing of the nontriple harmonics is, of course, not obtainable.

The extent to which induction from the nontriple harmonic voltages and currents in power-distribution circuits can be controlled by power-circuit transpositions is ordinarily very limited. Usually, due to the large number of exposure discontinuities arising from changes in the power or telephone circuits, the power-circuit transpositions are quite ineffective. This is particularly true in cases where the induction from the ground-return current is controlling. In specific cases where considerable wave-shape distortion exists and the induction from the balanced voltages and currents may therefore be relatively im-

portant, transpositions in power-distribution circuits may be found helpful.

Table I shows the average harmonics present on 3-phase 4-wire industrial and residential feeders under light- and heavy-load conditions. The reduced magnitudes of the nontriple frequencies in the residual current (neutral and ground-return) are evident. The importance of this as regards noise induction is further indicated in the illustrative examples of the appendix.

The triple-harmonic currents present on a feeder supplied from a delta-star substation transformer bank are generally due to the exciting currents of the single-phase load transformers. Under this condition no excessive triples are impressed on the feeder at its source as is sometimes the case where the source is a star-connected grounded-neutral generator directly connected to the feeder. The exciting currents flow from the individual single-phase transformers toward the delta-star transformer in the substation. The presence on the feeder of a large 3-phase star-delta load transformer with its neutral connected to the system neutral, provides a parallel path for supplying part of these triple-harmonic exciting currents as well as part of the unbalanced nontriple and fundamental currents and, under certain conditions, may substantially decrease the over-all inductive influence of a feeder by reducing the ground-return current flowing through an exposure. The effect of such a connection in reducing the noise is dependent upon the location of the bank with respect to the exposure and its relative impedance to the various harmonics as compared to that of the path back to the substation. From the power operating standpoint such a bank tends to supply part of the unbalanced load and also, in case of the interruption of one phase between it and the substation, tends to supply the power to that portion of the phase still connected to it. Under certain conditions, the action of such a bank may prove detrimental to the operation of the power feeder due to its action in attempting to balance the voltages at the point of its connection to the feeder. Under other conditions the neutral of an existing bank can readily be connected to the feeder neutral with distinctly beneficial effects on the inductive influence and with little or no adverse effects on the power-system operation. The tendency of such banks toward noise reduction and toward unbalanced load supply is shown in 2 of the illustrative examples in the appendix.

## Telephone Circuits

The voltages induced into a telephone circuit may be divided into: (1) metallic-circuit induction, that is, a voltage induced between the 2 sides of the circuit with a resultant current flowing around the circuit; and (2) the longitudinal-circuit induction, that is, a

## Table IV—Relative Susceptiveness of Several Types of Station Sets

| General Description of Station Set | Noise in Receiver Branch for 100 Noise Units to Ground—Average Power Wave Shape (One Station on Line—Effect of Set Only) |
|---|---|
| **Class 1—Types of Sets in Most Common Use Today** | |
| (*a*) Side-tone type of party-line set using 8A ringers or equivalents (one end of ringer grounded). (Common-battery talking and signaling) | 350 noise units, approximately |
| (*b*) Same type—local-battery talking | 120 noise units, approximately |
| (*c*) Magneto party-line set (52A ringer or equivalent) | 120 noise units, approximately |
| (*d*) Individual-line set—any type | Negligible |
| **Class 2—Types of Sets Frequently Encountered** | |
| (*a*) Side-tone type of 4-party full-selective or 8-party semiselective set (using relay or cathode tube to connect ringer to circuit during ringing period) | Negligible |
| (*b*) Four-party selective or 8-party semiselective sets employing high impedance ringers or relays connected to ground | About 30 noise units |
| (*c*) Eight-party selective (harmonic ringing) sets employing ringers connected to ground and tuned to 4 different ringing frequencies | Limited data indicate that, depending on frequency for which ringer is tuned, noise will range from about 100 to about 400 units |
| (*d*) Ground-return rural circuits (usually of magneto type and having code ringing) | 3,500 or more noise units |
| **Class 3—Special Types of Sets** | |
| (*a*) Side-tone type of party-line set using split-condenser and higher-impedance ringer (one end of ringer grounded) | About 20 noise units |
| (*b*) Type of party-line set using split-condenser arrangement with 8A ringer or equivalents (one end of ringer grounded) | About 90 noise units |

voltage induced along the conductors such that the resultant current flows in a circuit having the telephone conductors as one side and the earth as the other. This latter voltage may also result in noise, due to its action upon telephone-circuit unbalances, setting up currents in the voice channel (metallic circuit). For either type of voltage, the induction may be "electric," that is, from the voltage on the power circuit, or "magnetic" from the current in the power circuit.

The local telephone circuit may be divided into 3 parts: (*a*) the central-office equipment, (*b*) the line conductors, and (*c*) the subscriber equipment. Interoffice circuits include only the first 2 items.

### (*a*) Central-Office Equipment

The central-office equipment associated with a subscriber circuit consists essentially of 2 elements: (1) line signaling equipment connected to the circuit for indicating to the operator, or to the dial equipment, the desire of a subscriber to start a call; and (2) a linking or switching circuit or circuits for interconnecting 2 subscriber circuits either directly or through intervening trunk circuits and providing supervision during the call.

The line signaling equipment with its associated relay is either bridged across the line or arranged so that when 2 subscriber circuits are interconnected, any ground connections on the line relays are automatically opened. The line signaling equipment is not, therefore, ordinarily a factor in noise considerations. Occasionally, however, the effect on noise of the ground connection on the line signaling equipment requires specific treatment when the longitudinal-circuit induction is sufficiently high. The noise in such instances occurs either during the preanswering period before the line relay is "cut-off" or, in certain types of switchboards, on conversations between 2 persons on the same line (party-line) where the use of a switching circuit in the office is unnecessary.

The linking or switching equipment in the central office may consist of a pair of wires with bridged supervisory relays, as in the case of a magneto office, or may be a complicated arrangement of relays, repeating coils, condensers, etc., as in the case of common-battery offices of the manual or dial type. The necessary ground connections of the latter type of apparatus introduce the possibility of the unbalances in the equipment contributing to the over-all noise when the longitudinal-circuit induction on the outside conductors is impressed on the switching circuits. Ordinarily in urban areas, due either to the frequency make-up of the longitudinal-circuit induction or to the relationships of the various impedances-to-ground, the amount of noise contributed by the central-office equipment is relatively low. This is readily evident from table II which shows, at 500 and 1,000 cycles, the relative proportions of over-all noise due to the action of induced voltages on station, cable, and central-office unbalances. Cases arise, however, quite frequently where the relative circuit impedances or the frequency

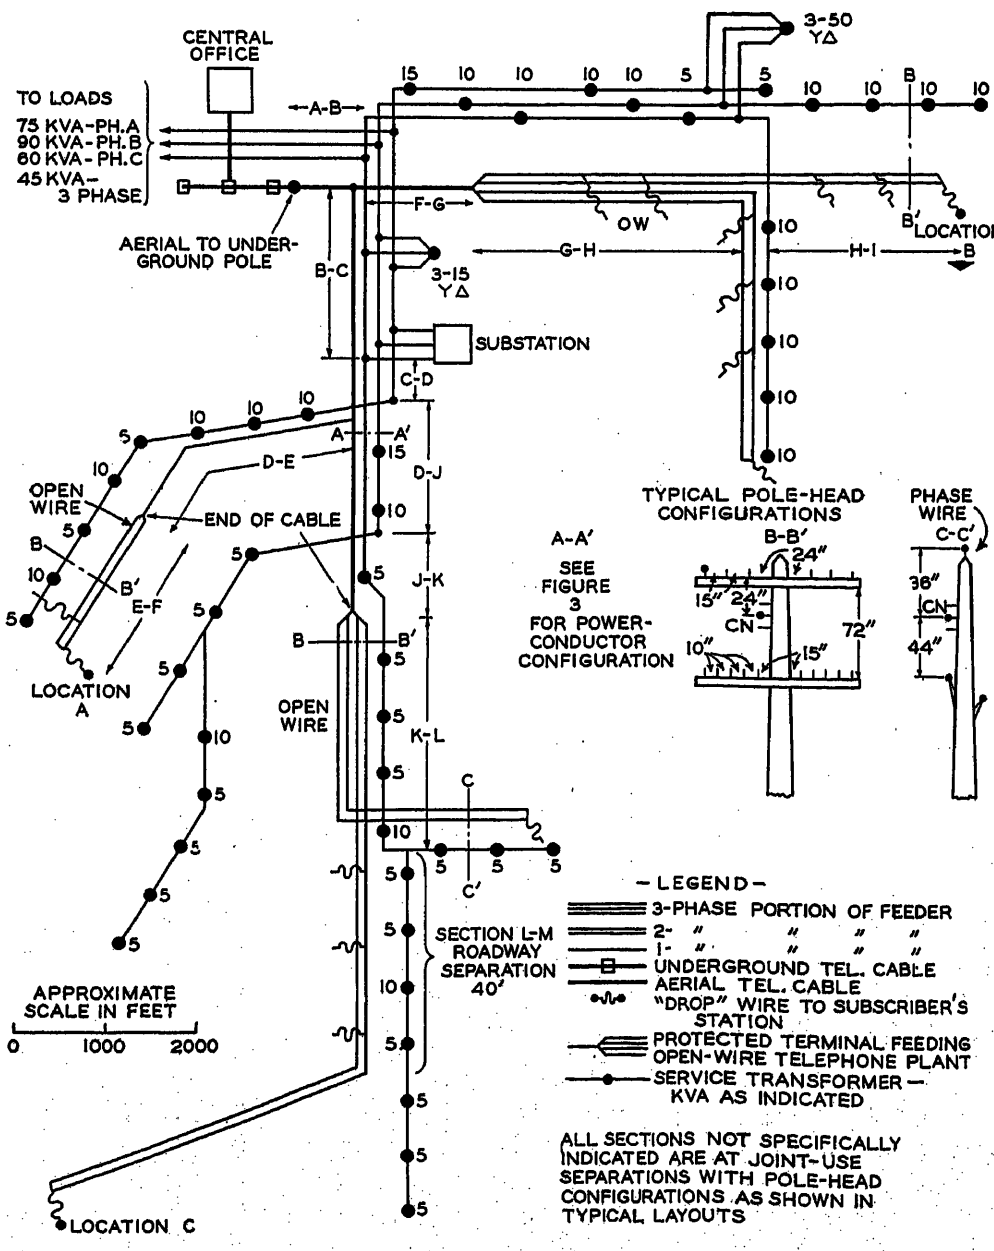

**Fig. 5. Example of exposure conditions between 2,300–4,000-volt distribution feeder and exchange telephone plant in suburban and rural area**

make-up of the induction or both are such that the noise contribution from the unbalances in the central-office equipment becomes important. Such cases usually involve long subscriber or interoffice trunk circuits and particularly where sections of open-wire construction are present. Values of the unbalances in certain types of central-office equipment are given on page 91 of volume I of the Engineering Reports of the Joint Subcommittee on Development and Research.

### (*b*) Line Conductors

Where the telephone line conductors are in open wire, the induced voltage between conductors (metallic-circuit) as well as along these conductors (longitudinal-circuit) must be considered. The direct metallic-circuit induction can be greatly reduced by systematic transpositions in the telephone circuit. Due to the physical limitations in a practical layout of telephone transpositions, the reduction in metallic-circuit induction is, on the average, from 60 to 80 per cent on nonpole pairs and about 90 per cent on pole pairs. Transpositions also tend to lessen the capacitance and inductance unbalances of the 2 sides to ground and to other circuits, thereby reducing the effect of the longitudinal-circuit induction on such unbalances. The improved balance of the mutual impedances between the various telephone conductors is, of course, distinctly beneficial in reducing cross talk, and transpositions are generally used for limiting the cross talk where open-wire telephone circuits extend for substantial distances.

The construction of telephone cables is such that there is inherently very close spacing between the conductors, and they are frequently transposed due to the continuous twisting of the pairs in manufacture. Due to this close spacing and frequent transposing there is practically no voltage induced between the wires of a cable pair or quad (group of 4 conductors). The unbalance to ground of the conductors of the present type of cable is so small that it is not ordinarily a contributing factor to noise induction. It may be noted, however, from table II that in cases where the central-office unbalances are of importance, the effect of shunt or series unbalances in the cables also needs consideration.

The lead sheath of a telephone cable provides practically perfect shielding against induction from power-system voltages when it is grounded at one or more points. The sheath likewise provides substantial magnetic shielding when it is grounded more or less continuously, as in underground construction, or is grounded at both ends of the aerial section or near both ends of an exposure. The degree of magnetic shielding effected varies, depending on the size of the cable and the resistance of the ground connections, reaching optimum values of over 90 per cent. Table III gives the magnitude of this shielding for various selected sizes and lengths of cable. Table III brings out distinctly the variation in the magnetic shielding due to the factors mentioned above. The effect of cable sheath shielding in several typical cases is further indicated in the appendix.

### (*c*) Station Apparatus

Individual-line stations employ a "bridged" ringer connection, that is, the ringer is, in effect, connected between the 2 line conductors. However, for selective signaling purposes party-line stations, frequently have the ringer connected, in effect, between one of the line

conductors and ground. The unbalance of the party-line station equipment is therefore affected by the impedance of the ringer and its point of connection in the station equipment. The relative susceptiveness of several types of station sets to noise-frequency induction is shown in table IV.

Table IV shows that, with advance planning in areas where noise induction is or may likely become a matter of importance, much can be accomplished by the use of station sets of decreased inductive susceptiveness. Where such types of apparatus are substituted in existing plant, except in gradual replacements or in connection with general rearrangement programs, the expense is, naturally, increased.

## Inductive Coupling

As stated above, the inductive coupling between exchange telephone plant and power-distribution circuits in urban areas is largely controlled by such factors as the street layouts and the joint use of poles. However, by co-operative planning of routes it is frequently practicable to secure lower coupling by avoiding long exposures between the main feeds of the 2 plants. As shown by the illustrative examples this procedure is, where applicable, very beneficial.

In rural areas where both distribution services must ordinarily be carried along the highways the opportunity for controlling the coupling between the 2 classes of circuits by co-operative planning of routes is much reduced.

Some benefit may be gained, however, in the case of open-wire construction, particularly at joint-use separations, by arangements of the conductors on the pole so as to avoid excessive spacings. As shown on figure 2, certain arrangements tend to minimize the amount of noise induction arising from the power-circuit voltages and currents. This beneficial effect is, however, much less noticeable at roadway separations.

**Table VIII—Comparison of Effectiveness of Various Remedial Measures (Figure 4)**

| Type of Remedial Measure | Approximate Noise Units on Party-Line Stations (Heavy Power Loads) | |

| | | 26 kva of unbalanced load |
| 5. Cable-sheath shielding—grounding at junction pole and to 1-ohm ground at *X* | 325 | 420 |
| 6. Combinations of measure 3, 4, and 5 | 85 | 245 |

## Summary and Conclusions

Since about 1915 there has been a continued increase in the use of the multigrounded or common-neutral arrangement of power distribution in this country. At the present time, approximately half of the distribution is by 4,000-volt multigrounded or common-neutral circuits. A large part of the higher-voltage rural distribution is also operating with this arrangement.

In general it may be said that for the lower-voltage 2,300/4,000-volt distribution circuits, the use of the multigrounded or common-neutral arrangement may be expected to increase the inductive influence of the power circuits. Unless attention is given to co-operative planning to secure features beneficial from the inductive-co-ordination standpoint, noise problems may result either in restricted or extensive areas. With proper attention to the co-ordination features[9] such noise situations as develop are largely in the nature of isolated cases and can usually be cared for by relatively minor changes or adjustments in either or both plants.

For the higher-voltage (11–13 kv) rural distribution circuits, there seems to be little difference, from the noise-induction standpoint, between the uni-grounded 4-wire system and the multigrounded or common-neutral arrangement.[10] Under many conditions the placing of multiple grounds on the neutral will result in noise reductions due to the effect, previously mentioned, of the multigrounded neutral on the line-charging currents. It is interesting to note that experience to date with the multigrounded or common-neutral circuit in rural areas has shown that many of the measures of co-ordination applicable in urban areas will prove similarly helpful in rural communities.

The measures of co-ordination which investigations

| Location | Type of Telephone Service | Total Noise Units | Contribution (Noise Units) From: Cable Exposures | Contribution (Noise Units) From: Open-Wire Exposures | Remarks |
|---|---|---|---|---|---|
| *A* | 1. Common-battery party-line stations (class 1-*a* table IV) | 225–345 | 220–270 | 45–215 | Open-wire noise dependant on effectiveness of telephone transpositions |
| | 2. Magento party-lines (class 1-*c* table IV) | 85–225 | 75 app. | 40–215 | |
| | 3. Individual line (class 1-*d* table IV) | 40–210 | 25–35 | About 10–210 | Lower values of noise on circuits controlled by effects of station sets — higher values by effectiveness of telephone transpositions |
| *B* | 1 | 170–1,200 | 10–100 | 170–1,190 | |
| | 2 | 75–1,175 | 20– 35 | 70–1,175 | |
| | 3 | 60–1,175 | About 20 | 55–1,175 | |
| *C* | 1 | 400–975 | 285–325 | 275–925 | Noise in cable section due to office and cable unbalances |
| | 2 | 150–870 | 110–125 | 110–860 | |
| | 3 | 100–860 | 60 | 75–860 | |

and operating experiences have shown to be practicable and effective include:

1. Co-operative planning by both parties to avoid not only severe exposure conditions but also types of equipment likely to aggravate the possible noise-induction situation.

2. A reasonable degree of balance of the loads between the 3 phases of the power circuit. In the higher-voltage rural circuits this also includes the lengths of branches consisting of 1 or 2 phase wires and neutral.

3. The avoidance of unnecessarily heavily loaded branches consisting of 1 or 2 phase wires and neutral.

4. The prevention of excessive overexcitation of transformers.

5. The grounding, where necessary, of aerial telephone cables at or near both ends of an exposure to obtain the benefits of magnetic shielding.

6. The use of adequately co-ordinated telephone transpositions on open-wire extensions and the avoidance of severe unbalances in the open-wire conductors.

7. The correction of badly distorted voltage or current wave shape on the power system.

8. The connection of the neutral point of 3-phase star-delta load banks to the system neutral conductor.

9. The use of telephone station apparatus, on party-line service, of lower susceptiveness.

10. Occasionally the use of arrangements or apparatus to minimize the effects from unbalances in central office equipment.

It is, of course, essential in successfully co-ordinating the power distribution and telephone circuits that, as in other co-ordination situations, the power and telephone people view the matter as a mutual responsibilty and fully co-operate in the application of the tools available. Experience over a period of years has now shown that where this is done adequate over-all co-ordination can be readily secured.[12]

## Appendix

For the sake of brevity, the detailed calculations and some of the minor assumptions for the following examples have been omitted.

### Illustrative Example 1

The purpose of this example is to show, for average power-system wave shapes:

1. The noise-induction problem that might be created by the exposure of a reasonably long aerial telephone cable in an urban area with a heavily loaded single-phase feeder. It features:
(*a*) The relative importance of triple and nontriple harmonic induction, and
(*b*) The extent to which planning of routes, grounding of cable sheaths, etc., might improve the situation.

2. The change in the noise magnitudes for the same situation with the various single-phase loads well distributed among all 3 phases. Under this condition, attention is directed to:
(*a*) The change in the relative importance of the triple and nontriple harmonic induction.
(*b*) The amount of reduction obtained by the same remedial measures tried in 1-*b* above.

Figure 3 shows a possible method of supplying the single-phase loads in a rather extensive part of an urban area. The general layout shown in figure 3 is such that all of the current for the feeder area traverses a considerable part of the exposure. Under this quite extreme condition—essentially single-phase supply for a relatively large area—the noise at location *C* under heavy-load conditions would be about as shown in table V.

**Table X—Comparison of Effectiveness of Various Remedial Measures**

| Type of Remedial Measure | Approximate Noise Units at: Location A 1* | A 2 | A 3 | Location B 1 | B 2 | B 3 | Location C 1 | C 2 | C 3 |
|---|---|---|---|---|---|---|---|---|---|
| 1. Before applying measures.. | 225–345 | 85–225 | 40–210 | 170–1,200 | 75–1,175 | 60–1,175 | 400–975 | 150–870 | 100–860 |
| 2. Using special telephone sets. | 40–210 | 40–210 | Neg. change | 60–1,175 | 60–1,175 | Neg. change | 100–860 | 100–860 | Neg. change |
| 3. Avoiding exposure section *B-C* by co-operating planning | 130–250 | 65–220 | Neg. change | Neg. change | | | 350–950 | 115–860 | Neg. change |
| 4. Interconnecting neutral of 150-kva star-delta bank..... | 180–310 | Neg. change | | 150–1,175 | Neg. change | | 370–950 | Neg. change | |
| 5. Average degree of co-ordinated telephone transpositions..... | 250 | 80 | 50 | 200 | 175 | 175 | 340 | 175 | 130 |
| 6. Telephone transpositions + cable - sheath shielding**... | 210 | 70 | 50 | 180 | 175 | 175 | 320 | 165 | 130 |
| 7. Combination of 4, 5, and 6.. | 185 | 65 | 50 | 160 | 155 | 155 | 310 | 160 | 125 |

* Type of station apparatus shown on table IX.
** Cable was assumed to be grounded at junction pole at end of section *F-G* to 2.5-ohm ground; at other junction poles to grounds exceeding 10 ohms.

It is evident from table V that most of the party-line stations fed by the aerial telephone cable would need treatment. It will be noted from table VI that completely replacing the existing party-line stations with special station apparatus will, to a large extent, care for the situation since, in this case, the amount of noise contributed by the cable and central-office unbalances would aggregate less than 150 units. Other measures either singly or in combination, probably more economical in their application, would provide substantial reductions in noise, but would not be adequate for the more severely exposed stations.

Assume, however, that instead of supplying the single-phase loads in the area shown on figure 3 from one phase only, the single-phase loads were distributed reasonably uniformly among the phases. This would be advantageous not only by the noise-reduction possibilities, which will be more fully discussed, but also by the improved regulation attainable on the feeder. Figure 4 shows a possible rearrangement of figure 3 along these lines and table VII shows the noise conditions with the feeder arrangements of figure 4.

A comparison of tables V and VII shows that the noise from the nontriple harmonics has been very materially reduced by the balancing of loads made possible by the more favorable feeder arrangement of figure 4, although that from the triple harmonics has been inappreciably changed. The net effect has been a reduction of nearly 75 per cent in the noise on the party-line stations served by the telephone cable. The reductions afforded by various remedial measures are shown in table VIII.

It is evident from table VIII that, by the application of various of the measures of co-ordination, the need for an extensive rearrangement of either plant is avoided.

### Illustrative Example 2

The purpose of this example is to show the extent to which remedial measures of the type generally applicable in urban areas (see example 1) may be applied in a less thickly settled area where exposures to 2.3/4-kv multigrounded-neutral arrangements are encountered under average conditions of power-system wave shape. In detail the example covers:
(*a*) The extent to which such measures as co-operative planning of routes and use of star-delta load banks may be ineffective.
(*b*) The importance, particularly under joint-use conditions, of noise directly induced into the metallic circuit of open-wire tele-

# Two-Reaction Theory of Synchronous Machines

By S. B. CRARY
ASSOCIATE AIEE

**An extension of the 2-reaction theory of synchronous machines as developed by R. H. Park is given in this paper for machines having capacitance in the armature circuit. General equations for predetermination of the performance under certain abnormal conditions of machines having balanced 3-phase capacitance in the armature circuit are presented.**

THIS PAPER is an extension of the method of analysis by R. H. Park[1,2,3] in that the effect of armature circuit capacitance is included in the general equations for the performance of a salient-pole synchronous machine. These equations are of sufficient generality so that the operation of a synchronous or induction machine having balanced 3-phase capacitance in the armature circuit can be predetermined for the condition of 3-phase short circuit, sudden application of capacitance load, self-excitation, running out of synchronism, hunting, pulling into step, etc. The method of approach is such that the general impedance operators which have been utilized by recent writers[5-10] can also be used in studying the effect of capacitance in the armature circuit. Such impedance operators include the effect of additional rotor circuits. It is believed that a theoretical basis for the study of the performance of synchronous or induction machines as influenced by capacitance is particularly important at this time, with the increased use of series and shunt capacitors for voltage regulation purposes.

An interesting application of the general equations is to the problem of self-excitation of a machine connected to a circuit containing capacitance. Criteria are developed which indicate the regions in which self-excitation may occur for the case of a synchronous machine connected to a capacitance load or through series capacitance to a system.

## List of Symbols

All constants are in per-unit values in terms of normal kilovolt-amperes and voltage, and correspond wherever possible with established nomenclature.

$x_c = 1/c$ = capacitance reactance
$x_d$ = synchronous reactance of direct-axis armature circuit
$x_d'$ = direct-axis transient reactance
$x_d''$ = direct-axis subtransient reactance
$x_d(p)$ = impedance operator relating the direct-axis armature flux linkages with the direct-axis armature current
$x_q$ = synchronous reactance of quadrature-axis armature circuit
$x_q'$ = quadrature-axis transient reactance
$x_q''$ = quadrature-axis subtransient reactance
$x_q(p)$ = impedance operator relating the quadrature-axis armature flux linkages with the quadrature-axis armature current
$G_d(p)$ = operator relating the direct-axis armature linkages with the direct-axis field excitation voltage
$G_q(p)$ = operator relating the quadrature-axis armature flux linkages with the quadrature-axis field excitation voltage
$r$ = armature circuit resistance
$e$ = system voltage
$E_{fd}$ = direct-axis field-excitation voltage
$E_{fq}$ = quadrature-axis field-excitation voltage
$e_d$ = direct-axis armature voltage
$e_q$ = quadrature-axis armature voltage
$e_0$ = zero-sequence armature voltage
$\psi_d$ = direct-axis armature flux linkages
$\psi_q$ = quadrature-axis armature flux linkages
$\psi_0$ = zero-sequence armature flux linkages
$i_d$ = direct-axis armature current
$i_q$ = quadrature-axis armature current
$i_0$ = zero-sequence current
$e_a, e_b, e_c$ = phase voltages
$i_a, i_b, i_c$ = phase currents
$\psi_a, \psi_b, \psi_c$ = phase flux linkages
$T_o$ = open-circuit field time constant in electrical radians
$p$ = $d/dt$
$s$ = slip
$t$ = time in electrical radians; unit time is the time required for the rotor to pass one electrical radian at normal frequency
$\delta$ = angular displacement in electrical radians
1 = Heaviside's unit function

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted October 16, 1936; released for publication November 6, 1936.

S. B. CRARY is in the engineering division of the central-station department, Electric Company, Schenectady, N. Y.

## General Analysis

This analysis is based on the definition of an ideal synchronous machine as given in reference 1. A knowledge of the material in references 1 and 2 by R. H. Park is assumed in the following development.

Park gives the following relations:

$$\left.\begin{aligned} i_d &= \tfrac{2}{3}[i_a\cos\theta + i_b\cos(\theta-120) + i_c(\cos\theta + 120)] \\ i_q &= -\tfrac{2}{3}[i_a\sin\theta + i_b\sin(\theta-120) + i_c(\sin\theta + 120)] \end{aligned}\right\} \quad (1)$$

$$\left.\begin{aligned} e_d &= \tfrac{2}{3}[e_a\cos\theta + e_b\cos(\theta-120) + e_c\cos(\theta + 120)] \\ e_q &= -\tfrac{2}{3}[e_a\sin\theta + e_b\sin(\theta-120) + e_c\sin(\theta + 120)] \end{aligned}\right\} \quad (2)$$

$$\left.\begin{aligned} \psi_d &= \tfrac{2}{3}[\psi_a\cos\theta + \psi_b\cos(\theta-120) + \psi_c\cos(\theta + 120)] \\ \psi_q &= -\tfrac{2}{3}[\psi_a\sin\theta + \psi_b\sin(\theta-120) + \psi_c\sin(\theta + 120)] \end{aligned}\right\} \quad (3)$$

$$\left.\begin{aligned} e_a &= p\psi_a - ri_a \\ e_b &= p\psi_b - ri_b \\ e_c &= p\psi_c - ri_c \end{aligned}\right\} \quad (4)$$

and

$$\left.\begin{aligned}\psi_d &= G_d(p)\,E_{fd} - x_d(p)i_d\\ \psi_q &= G_q(p)\,E_{fq} - x_q(p)i_q\end{aligned}\right\}\ (5)$$

If the effect of armature circuit capacitance is to be included, equations 4 become

$$\left.\begin{aligned}e_a &= p\,\psi_a - \left(r + \frac{x_c}{p}\right)i_a\\ e_b &= p\,\psi_b - \left(r + \frac{x_c}{p}\right)i_b\\ e_c &= p\,\psi_c - \left(r + \frac{x_c}{p}\right)i_c\end{aligned}\right\}\ (6)$$

or

$$\left.\begin{aligned}pe_a &= p^2\psi_a - (p\,r + x_c)\,i_a\\ pe_b &= p^2\psi_b - (p\,r + x_c)\,i_b\\ pe_c &= p^2\psi_c - (p\,r + x_c)\,i_c\end{aligned}\right\}\ (7)$$

Differentiating equations 2,

$$\left.\begin{aligned}pe_d &= \frac{2}{3}\left[\cos\theta\,pe_a + \cos(\theta-120)\,pe_b + \cos(\theta+120)\,pe_c\right] -\\ &\quad \frac{2}{3}\left[e_a\sin\theta + e_b\sin(\theta-120) + e_c\sin(\theta+120)\right]p\theta\\ pe_q &= -\frac{2}{3}\left[\sin\theta\,pe_a + \sin(\theta-120)\,pe_b + \sin(\theta+120)\,pe_c\right] -\\ &\quad \frac{2}{3}\left[e_a\cos\theta + e_b\cos(\theta-120) + e_c\cos(\theta+120)\right]p\theta\end{aligned}\right\}\ (8)$$

Using equations 2 and 7, equations 8 become

$$\left.\begin{aligned}pe_d - e_q p\theta &= \frac{2}{3}\left[\cos\theta\,p^2\psi_a + \cos(\theta-120)\,p^2\psi_b + \cos(\theta+120)\,p^2\psi_c\right] -\\ &\quad \frac{2}{3}r\left[\cos\theta\,pi_a + \cos(\theta-120)\,pi_b + \cos(\theta+120)\,pi_c\right] -\\ &\quad \frac{2}{3}x_c\left[\cos\theta\,i_a + \cos(\theta-120)\,i_b + \cos(\theta+120)\,i_c\right]\\ pe_q + e_d p\theta &= -\frac{2}{3}\left[\sin\theta\,p^2\psi_a + \sin(\theta-120)\,p^2\psi_b + \sin(\theta+120)\,p^2\psi_c\right] +\\ &\quad \frac{2}{3}r\left[\sin\theta\,pi_a + \sin(\theta-120)\,pi_b + \sin(\theta+120)\,pi_c\right] +\\ &\quad \frac{2}{3}x_c\left[\sin\theta\,i_a + \sin(\theta-120)\,i_b + \sin(\theta+120)\,i_c\right]\end{aligned}\right\}\ (9)$$

In order to express equations 9 in terms of direct- and quadrature-axis quantities rather than phase quantities, the following relations will be used. Differentiating equations 3,

$$\left.\begin{aligned}p\psi_d &= \frac{2}{3}\left[\cos\theta\,p\psi_a + \cos(\theta-120)\,p\psi_b + \cos(\theta+120)\,p\psi_c\right] + \psi_q p\theta\\ p\psi_q &= -\frac{2}{3}\left[\sin\theta\,p\psi_a + \sin(\theta-120)\,p\psi_b + \sin(\theta+120)\,p\psi_c\right] - \psi_d p\theta\end{aligned}\right\}\ (10)$$

Differentiating equations 10,

$$p^2\psi_d = \frac{2}{3}\left[\cos\theta\,p^2\psi_a + \cos(\theta-120)\,p^2\psi_b + \cos(\theta+120)\,p^2\psi_c\right] -$$
$$\frac{2}{3}\left[\sin\theta\,p\psi_a + \sin(\theta-120)\,p\psi_b + \sin(\theta+120)\,p\psi_c\right]p\theta +$$
$$p\theta\,p\psi_q + \psi_q p^2\theta \qquad (11a)$$

$$p^2\psi_q = -\frac{2}{3}\left[\sin\theta\,p^2\psi_a + \sin(\theta-120)\,p^2\psi_b + \sin(\theta+120)\,p^2\psi_c\right] -$$
$$\frac{2}{3}\left[\cos\theta\,p\psi_a + \cos(\theta-120)\,p\psi_b + \cos(\theta+120)\,p\psi_c\right]p\theta -$$
$$p\theta\,p\psi_d - \psi_d p^2\theta \qquad (11b)$$

Substituting equations 10 in equations 11,

$$\left.\begin{aligned}&\frac{2}{3}\left[\cos\theta\,p^2\psi_a + \cos(\theta-120)\,p^2\psi_b + \cos(\theta+120)\,p^2\psi_c\right] =\\ &p^2\psi_d - 2p\theta\,p\psi_q - \psi_d(p\theta)^2 - \psi_q p^2\theta -\\ &\frac{2}{3}\left[\sin\theta\,p^2\psi_a + \sin(\theta-120)\,p^2\psi_b + \sin(\theta+120)\,p^2\psi_c\right] =\\ &p^2\psi_q + 2p\theta\,p\psi_d - \psi_q(p\theta)^2 + \psi_d p^2\theta\end{aligned}\right\}\ (12)$$

Differentiating equations 1,

$$\left.\begin{aligned}&\frac{2}{3}\left[\cos\theta\,pi_a + \cos(\theta-120)\,pi_b + \cos(\theta+120)\,pi_c\right] = pi_d - i_q p\theta -\\ &\frac{2}{3}\left[\sin\theta\,pi_a + \sin(\theta-120)\,pi_b + \sin(\theta+120)\,pi_c\right] = pi_q + i_d p\theta\end{aligned}\right\}\ (13)$$

Substituting equations 1, 12, and 13 in equations 9 and simplifying,

$$p(e_d - p\psi_d + ri_d + \psi_q p\theta) + x_c i_d = p\theta(e_q - p\psi_q + ri_q - \psi_d p\theta) \qquad (14)$$

$$p(e_q - p\psi_q + ri_q - \psi_d p\theta) + x_c i_q = -p\theta(e_d - p\psi_d + ri_d + \psi_q p\theta) \qquad (15)$$

The expression for the zero-sequence voltage may be obtained by substituting equations 6 in the equation for the zero-sequence voltage given in reference 2, equation 6. This yields

$$e_0 = p\psi_0 - \left(r + \frac{x_c}{p}\right)i_0 \qquad (15a)$$

where

$$\psi_0 = \frac{1}{3}\left(\psi_a + \psi_b + \psi_c\right)$$

$$i_0 = \frac{1}{3}\left(i_a + i_b + i_c\right)$$

Equations 14, 15, and 15*a* can be used directly in place of equations 8, 9, and 10 of reference 2 in order that the effect of balanced armature circuit capacitance can be included in determining the performance of a synchronous machine. It may be noted that if $x_c = 0$, the case when $c = \infty$, the solution of equations 14, 15, and 15*a* is that given by equations 8, 9, and 10 of reference 2.

In the following are applications of equations 14 and 15 to problems involving the performance of a synchronous machine and balanced capacitance.

## Application to Self-Excitation of a Synchronous Machine

The phenomenon of self-excitation of a synchronous machine connected to a capacitive load or to a system through series capacitance is evidenced by the building up of machine armature voltage to values which are limited by machine or circuit saturation, it being impossible to control completely the terminal voltage by variation in the field-excitation voltage. A common cause for the occurrence of the

phenomenon is the connection of a synchronous machine to a transmission circuit whose line-charging kilovolt-amperes exceed the line-charging capacity of the generator. The following analysis indicates the regions in which this phenomenon will and will not occur. Saturation can be neglected in such an analysis as its effect is chiefly to limit the voltage of self-excitation and not to alter the values of circuit constants which cause it to occur, except for the case when the initial excitation is high enough to produce appreciable saturation.

Consider the case of a machine running at constant speed with constant excitation voltage and connected to a balanced shunt capacitive load or through a balanced series capacitance to an infinite bus, $p\theta = (1-s)$, $\Delta E_{fd} = \Delta E_{fq} = 0$. Substituting equations 5 in equations 14 and 15 for these conditions and simplifying,

$$pe_d-(1-s)e_q = \{[(1-s)^2-p^2]x_d(p)-pr-x_c\}i_d+(1-s)[2px_q(p)+r]i_q \quad (16)$$

$$pe_q+(1-s)e_d = -(1-s)[2px_d(p)+r]i_d+\{[(1-s)^2-p^2]x_q(p)-pr-x_c\}i_q \quad (17)$$

Solving equations 16 and 17 simultaneously for the currents $i_d$ and $i_q$,

$$i_d = -\frac{\{[p^2+(1-s)^2]Z_q(p)+px_c\}e_d+\{[p^2+(1-s)^2](1-s)x_q(p)-(1-s)x_c\}e_q}{A(p)} \quad (18)$$

$$i_q = \frac{\{[p^2+(1-s)^2](1-s)x_d(p)-(1-s)x_c\}e_d-\{[p^2+(1-s)^2]Z_d(p)+px_c\}e_q}{A(p)} \quad (19)$$

where

$$A(p) = [p^2+(1-s)^2][Z_d(p)Z_q(p)+(1-s)^2x_d(p)x_q(p)]+x_c[pZ_d(p)+pZ_q(p)-(1-s)^2x_d(p)-(1-s)^2x_q(p)+x_c] \quad (20)$$

and

$$Z_d(p) = px_d(p)+r \qquad Z_q(p) = px_q(p)+r$$

The currents $i_d$ and $i_q$ will increase indefinitely if any of the roots of the denominator of the operational expression for $i_d$ and $i_q$, which is obtained by rationalizing $A(p)$, have positive real values. Therefore, the criterion of Hurwitz[11] or of Routh,[12] for determining if a positive real root exists, can be used for testing whether or not self-excitation will occur for a given set of machine and circuit constants.

Equation 20 is a general expression which may be used for determining if self-excitation will occur in a salient pole or a symmetrical rotor machine having any number of rotor circuits.

Using the roots of the denominator to determine if self-excitation will occur is similar to the method employed by M. Takahashi.[4] He analyzed quite completely the case of a symmetrical rotor machine with a single rotor winding and to a limited extent a salient-pole machine with a single field winding. When the same special cases were studied the results obtained from equation 20 were found to be in general agreement with his work.

An analysis by Rudenberg[13] based on graphical methods describes the chief aspects of the phenomenon and can be used for determining the effect of saturation in limiting the voltage of self-excitation. The graphical method of analysis is limited, however, in that it cannot be used for a quantitative determination of the effect of additional rotor circuits on the regions of self-excitation.

Consider the special case of a salient-pole machine running at synchronous speed, with no rotor circuits other than the direct-axis field circuit. For this case, $s = 0$,

$$x_d(p) = \frac{x_d'T_op+x_d}{T_op+1}$$

and

$$x_q(p) = x_q$$

Substituting these values in equation 20 and rationalizing, the operational expression for the denominator of the currents is

$$D(p) = x_qx_d'T_op^5+[x_dx_q+rT_o(x_d'+x_q)]p^4+[2x_qx_d'T_o+r(x_d+x_q)+T_ox_c(x'_d+x_q)+T_or^2]p^3+[2x_qx_q+rT_o(x_d'+x_q)+x_c(x_d+x_q)+r^2+T_o2rx_c]p^2+[x_qx_d'T_o+r(x_d+x_q)-T_ox_c(x_d'+x_q)+2rx_c+T_o(x_c^2+r^2)]p+[x_dx_q-x_c(x_d+x_q)+x_c^2+r^2] \quad (21)$$

Self-excitation will occur if any of the roots of $D(p)$, equation 21, have a positive real value.

For the numerical case of

$x_d = 1.0$, $x_d' = 0.30$, $x_q = 0.6$, $T_o = 1{,}000$, and $T_o = 0$

the regions of self-excitation are shown on figure 1. The shaded area is a region of self-excitation for the case of $T_o = 1{,}000$ as well as for the case when $T_o = 0$, indicating that the phenomenon of self-excitation is possible in a salient-pole machine for the condition when the field circuit is open. For normal values of armature resistance, $r$, when the field circuit is closed, self-excitation occurs for values of $x_c$ between $x_d$ and $x_d'$.

*Armature Resistance Neglected.* For the case of $r = 0$, equation 21 reduces to

$$D(p) = x_d'x_qT_op^5+x_dx_qp^4+T_o[2x_d'x_q+x_c(x_q+x_d')]p^3+[2x_dx_q+x_c(x_q+x_d)]p^2+T_o[x_d'x_q-x_c(x_q+x_d')+x_c^2]p+[x_dx_q-x_c(x_q+x_d)+x_c^2]p \quad (22)$$

By applying Routh's criterion the following array is obtained (common coefficients which are positive in value are omitted following the first 2 rows):

| | | |
|---|---|---|
| $x_d'x_qT_o$ | $T_o[2x_d'x_q+x_c(x_q+x_d')]$ | $T_o[x_d'x_q-x_c(x_q+x_d')+x_c^2]$ |
| $x_dx_q$ | $[2x_dx_q+x_c(x_q+x_d)]$ | $[x_dx_q-x_c(x_q+x_d)+x_c^2]$ |
| $x_q$ | $[x_c-x_q]$ | |
| $x_q[3x_d+x_c]$ | $[x_d-x_c][x_q-x_c]$ | |
| $[x_c-x_q]$ | | |
| $[x_c-x_q][x_d-x_c][x_q-x_c]$ | | |

Therefore, self-excitation occurs when

$$x_c < x_q \quad \text{and} \quad x_q < x_c < x_d \quad \text{or} \quad x_c < x_d \quad (23)$$

Accordingly, with zero resistance the phenomenon of self-excitation can occur for any value of capacitance less than that corresponding to the direct-axis synchronous reactance. Practically, however, as shown in figure 1, only a small amount of resistance decreases the range of self-excitation from ($x_d$ to 0) to $x_d$ to $x_d'$).

*Field Switch Open.* For the case of $T_o = 0$, equa-

tion 21 yields the following array when Routh's criterion is applied:

$$x_d x_q \qquad 2x_d x_q + x_c(x_d + x_q) + r^2 \qquad x_d x_q - x_c(x_d + x_q) + x_c^2 + r^2$$

$$r(x_d + x_q) \qquad r(x_d + x_q) + x_c^2 \qquad 0$$

$$\left\{ \begin{matrix} (x_d + x_q)x_d x_q + \\ x_c(x_d^2 + x_q^2) + r^2(x_d + x_q) \end{matrix} \right\} \qquad \left\{ \begin{matrix} (x_d + x_q)x_d x_q - x_c(x_d + x_q)^2 \\ + (x_c^2 + r^2)(x_d + x_q) \end{matrix} \right\}$$

$$\left\{ \begin{matrix} 2(x_d + x_q)^2 + 2r^2(x_d + x_q) \\ + x_c(x_d - x_q)^2 \end{matrix} \right\}$$

$$[x_d x_q - x_c(x_d + x_q) + (x_c^2 + r^2)]$$

Therefore, the values of $x_c$ which will result in self-excitation when the field circuit is open are

$$\frac{x_d + x_q - \sqrt{(x_d - x_q)^2 - 4r^2}}{2} < x_c < \frac{x_d + x_q + \sqrt{(x_d - x_q)^2 - 4r^2}}{2} \quad (24)$$

If $x_d = x_q$, which is the case of a machine with laminated cylindrical rotor, self-excitation cannot occur when the field circuit is open. Equation 24 describes the region of self-excitation for values of $x_c$ between $x_d$ and $x_q$ as shown in figure 1.

*Infinite Field Time Constant.* For the case of $T_o = \infty$ equation 21 yields a similar expression to that obtained for the case when $T_o = 0$ except $x_d'$ replaces $x_d$. Accordingly, the values of $x_c$ which will result in self-excitation when $T_o = \infty$ are

$$\frac{x_d' + x_q - \sqrt{(x_d' - x_q)^2 - 4r^2}}{2} < x_c < \frac{x_d' + x_q + \sqrt{(x_d' - x_q)^2 - 4r^2}}{2} \quad (25)$$

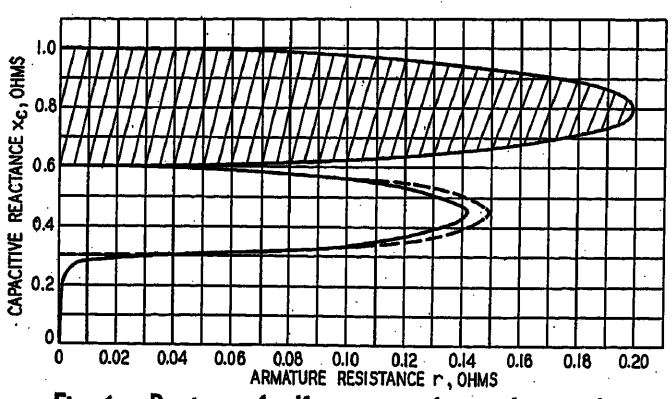

**Fig. 1. Regions of self-excitation for a salient-pole synchronous machine**

$x_d = 1.0$ $\qquad x_d'' = x_d' = 0.30$
$x_q'' = x_q' = x_q = 0.60$ $\qquad T_o = 1{,}000$
Shaded area applies for field circuit opened or closed
Dotted line applies for $T_o = \infty$ (approximate solution)

Equation 25 is a good approximation to the actual case when $T_o$ is large for the region between $x_q$ and $x_d'$ as shown by figure 1.

This section may be summarized as follows:

1. For a machine having rotor circuits additional to the field circuit, the regions of self-excitation can be determined by numerical substitution in equation 20.

2. For most practical purposes the regions of self-excitation can be determined by equations 24 and 25 for the case of a synchronous machine without an amortisseur winding.

3. For normal values of armature circuit resistance, values of capacitive reactance between $x_d$ and $x_d'$ for a machine without an amortisseur will result in self-excitation.

4. A value of series armature resistance greater than both $(x_d - x_q)/2$ and $(x_q - x_d')/2$ will prevent the phenomenon from occurring, for a machine without an amortisseur.

5. The above results are a theoretical explanation of the difficulties sometimes encountered (*a*) when a capacitance shunt load greater than the line charging capacity is connected to a synchronous machine and (*b*) when a synchronous machine is connected to a source of voltage through a series capacitance.

## Applications to a 3-Phase Fault

Equations 14 and 15 will be applied to the case of a 3-phase fault on a synchronous machine running at synchronous speed initially open-circuited having capacitance in its armature circuit. This is also equivalent to suddenly throwing on a capacitive load. The currents $i_d$ and $i_q$ for this case can be determined by substituting $e_d = 0$, $e_q = -e_{q0}1$, and $s = 0$ in equations 18 and 19. This yields

$$i = \frac{(p^2 + 1)x_q(p) - x_c}{A(p)} e_{q0}1 \quad (26)$$

$$i_q = \frac{(p^2 + 1)Z_d(p) + px_c}{A(p)} e_{q0}1 \quad (27)$$

where $A(p)$ is given by equation 20 with $s = 0$.

Equations 26 and 27 are operational expressions for the currents $i_d$ and $i_q$ which can be solved by means of Heaviside's expansion theorem, the roots of the denominator being determined by means of Graeffes[14] root-squaring method. Having determined the current $i_d$ and $i_q$, the phase currents $i_a$, $i_b$, and $i_c$ are obtained by substituting in equation 14 of reference 2.

The general solution of the operational expressions for the current, particularly when the effect of more than one rotor circuit is considered, involves a great deal of algebraic work. However, considerable information as regards the phenomena being studied can be obtained by making use of certain simplifying assumptions. The following is an example to illustrate this.

Suppose that it is required to determine the maximum possible voltage which may occur across the terminals of a synchronous machine when it is suddenly thrown on to a very large capacitive load. This also corresponds to the case of a short circuit occurring on the system side of the capacitance of a machine having series capacitors in its armature circuit. Let the machine and capacitor constants be as follows:

$x_d = 1.0$, $x_q = 0.60$, $x_d' = 0.35$, $r = 0.05$, $T_o = 1{,}000$, $x_c = 0.20$

From the values chosen it is apparent that the value of capacitance of 0.20 does not lie between $x_d'$ and $x_d$ and therefore it will be assumed that self-excitation does not occur for these constants. Practically, for this assumption to be valid, $x_c$ should be definitely less than $x_d'$ by a small amount, as the effect of saturation, which has been neglected, is to reduce the effective value of transient reactance.

The maximum short-circuit current can be calculated on the basis that $T_o = \infty$ and $r = 0$, which neglects the decrements in current and voltage. This results in a fair approximation for the current and voltage during the first few cycles after the fault is

applied and in a considerable simplification in the algebraic work. For these conditions equations 26 and 27 yield

$$i_d = \frac{0.60\,p^2 + 0.40}{0.21\,p^4 + 0.61\,p^2 + 0.06}\,1$$

$$i_q = \frac{0.35\,p^3 + 0.55\,p}{0.21\,p^4 + 0.61\,p^2 + 0.06}\,1$$

which gives

$$i_d = 6.67 - 0.81\cos 1.67\,t - 5.83\cos 0.32\,t$$
$$i_q = 0.452\sin 1.67\,t + 2.82\sin 0.32\,t$$

Substituting the values of $i_d$ and $i_q$ in

$$i_a = i_d\cos(t+\alpha) - i_q\sin(t+\alpha)$$

and simplifying,

$$i_a = 6.67\cos(t+\alpha) - 0.63\cos(0.67\,t-\alpha) - 4.33\cos(0.68\,t-\alpha) - 0.18\cos(2.67\,t+\alpha) - 1.51\cos(1.32\,t+\alpha)$$

The voltage across the capacitor is

$$V_a = \frac{1}{c}\int i_a\,dt$$

$$= 1.33\sin(t+\alpha) - 0.01\sin(2.67\,t+\alpha) - 0.23\sin(1.32\,t+\alpha) - 1.29\sin(0.68\,t-\alpha) - 0.19\sin(0.67\,t-\alpha)$$

indicating a possible maximum transient voltage across the capacitor of 3 times normal. The actual maximum voltage across the capacitor would be somewhat less because the effect of armature circuit resistance, which was neglected, would be to damp out the components having frequencies other than normal frequency. The voltage across the capacitor immediately after the armature circuit transients have died away corresponds to that given in the first term of the above expression for voltage.

From these results, the conclusion is reached that during the first few cycles immediately following the short circuit, the voltage across the capacitor will be from 1.3 to 3.0 times normal line-to-ground voltage, depending upon the value of armature circuit resistance.

The sustained voltage is

$$V_a = \frac{0.20\times 1}{1.0 - 0.20}\times\sin(t+\alpha) = 0.25\sin(t+\alpha)$$

By these comparatively simple calculations, it is evident that the transient voltage across the capacitance will be considerably greater than that corresponding to the sustained voltage, and that the maximum possible voltage is approximately 3.0 times normal.

*Approximate Field Time Constant.* An approximate value for the time constant of the field circuit under the condition of capacitive load can be determined by dividing the coefficient of $p^1$ by the coefficient of $p^0$ in equation 21. This yields, when terms in the coefficient for $p^1$ which do not include $T_o$ are neglected,

$$T_d' = \frac{(x_d - x_c)(x_q - x_c) + r^2}{(x_d' - x_c)(x_q - x_c) + r^2}\,T_o \qquad (28)$$

This time constant is valid only when $T_d'$ and $T_o$ are comparatively large. Although approximate, it does indicate with good accuracy the values of $x_c$ which will cause $T_d'$ to become negative and accordingly produce self-excitation.

## Application to Small Angular Oscillation

Park gives for the change in electrical torque for small changes in angular displacement of a synchronous machine connected to an infinite bus (equation 60, reference 1)

$$\Delta T = [\psi_{d0} + i_{d0}x_q(p)]\,\Delta i_q - [\psi_{q0} + i_{q0}x_d(p)]\,\Delta i_d \qquad (29)$$

By substituting the following relations in equations 14 and 15, $\Delta i_d$ and $\Delta i_q$ can be determined:

$$\psi_d = \psi_{d0} + \Delta\psi_d \qquad e_d = e_{d0} + \Delta e_d \qquad i_d = i_{d0} + \Delta i_b$$
$$\psi_q = \psi_{q0} + \Delta\psi_q \qquad e_q = e_{q0} + \Delta e_q \qquad i_q = i_{q0} + \Delta i_q$$
$$p\theta = 1 + p\Delta\delta$$

This yields,

$$\left.\begin{aligned} e_{q0} &= \psi_{d0} + x_c i_{d0} - r\,i_{q0} \\ e_{d0} &= -\psi_{q0} - x_c i_{q0} - r\,i_{d0} \end{aligned}\right\} \qquad (30)$$

and

$$\left.\begin{aligned} &p\Delta e_d - \Delta e_q - e_{q0}p\Delta\delta = p^2\Delta\psi_d - 2p\Delta\psi_q - 2\psi_{d0}p\Delta\delta - \Delta\psi_d - \psi_{q0}p^2\Delta\delta - rp\Delta i_d + r\Delta i_q + ri_{q0}p\Delta\delta - x_c\Delta i_d \\ &p\Delta e_q + \Delta e_d + e_{d0}p\Delta\delta = p^2\Delta\psi_q + 2p\Delta\psi_d - 2\psi_{q0}p\Delta\delta - \Delta\psi_q + \psi_{d0}p^2\Delta\delta - rp\Delta i_q - r\Delta i_d - ri_{d0}p\Delta\delta - x_c\Delta i_q \end{aligned}\right\} \qquad (31)$$

$$\left.\begin{aligned} \psi_{d0} &= E_{fd} - x_d i_{d0} \\ \psi_{q0} &= -x_q i_{q0} \end{aligned}\right\} \qquad (32)$$

Substituting equations 32 in equations 30 and solving for the initial currents,

$$i_{d0} = \frac{E_{fd}(x_q - x_c) - (x_q - x_c)e\cos\delta_0 - r\,e\sin\delta_0}{(x_d - x_c)(x_q - x_c) + r^2} \qquad (33)$$

$$i_{q0} = \frac{E_{fd}\,r - e\,r\cos\delta_0 + (x_d - x_c)\,e\sin\delta_0}{(x_d - x_c)(x_q - x_c) + r^2} \qquad (34)$$

From equation 28 of reference 1,

$$e_d = e\sin(\delta_0 + \Delta\delta) \qquad e_q = e\cos(\delta_0 + \Delta\delta)$$

Since $\Delta\delta$ is small,

$$\Delta e_d = e\cos\delta_0\,\Delta\delta \qquad \Delta e_q = -\,e\sin\delta_0\,\Delta\delta$$

Also from equations 5,

$$\Delta\psi_d = -\,x_d(p)\,\Delta i_d \qquad \Delta\psi_q = -\,x_q(p)\,\Delta i_q$$

Substituting these relations in equations 31,

$$\left.\begin{aligned} &[-e\cos\delta_0 - 2\psi_{q0}p + \psi_{d0}p^2 - ri_{d0}p]\,\Delta\delta = [2px_d(p) + r]\,\Delta i_d + [p^2x_q(p) - x_q(p) + rp + x_c]\,\Delta i_q \\ &[-e\sin\delta_0 - 2\psi_{d0}p - \psi_{q0}p^2 + ri_{q0}p]\,\Delta\delta = [p^2x_d(p) - x_d(p) + rp + x_c]\,\Delta i_d - [2px_q(p) + r]\,\Delta i_q \end{aligned}\right\} \qquad (35)$$

Equations 35 can be solved for $\Delta i_d$ and $\Delta i_q$ and substituted in equation 29 for the incremental torque. Therefore,

$$\Delta T = f(p)\,\Delta\delta$$

The response to a sudden change in the electrical angular displacement, $\Delta\delta 1$, may be determined by

(*Concluded on page 36*)

# Proposed Transformer Standards

By J. E. CLEM
MEMBER AIEE

**During the past 2 years the AIEE transformer subcommittee* has proposed changes in the AIEE transformer standards; this paper is presented to bring these changes before the Institute.**

## 1—Transformer Insulation Levels

DURING previous years the transformer subcommittee established insulation levels for transformers connected to circuits operating at standard voltages. These requirements have been passed on to the ASA sectional committee on transformers (V. M. Montsinger, chairman), and on to the standards sub-committee (W. M. Dann, chairman). The ASA transformer standards subcommittee has taken these insulation levels and incorporated them in the standards with slight modifications not affecting the fundamental requirements. A memorandum of the proposed ASA standards was submitted to the transformer subcommittee and approved with minor changes and recommended for immediate use. These proposed standards follow and are essentially as given in the proposed ASA transformer standards as material in Sections II, III, and IV.

### A—Standards Common to Transformers, Regulators, and Reactors

*Insulation Level.* Table I gives the relations between established rated circuit voltages, limits of rated apparatus voltages, and required basic insulation levels, for transformers and other induction apparatus covered by the standards. Column 1 gives the values of established circuit voltages. Column 2 gives the limits of rated apparatus voltages permissible for the corresponding insulation levels. Columns 3 and 4 give the required standard insulation levels in terms of the spacings of rod gaps used in making impulse tests, and of the low-frequency dielectric test.

A bank of modern large transformers

Table I

| Rated Circuit Voltage—Volts | Limit of Rated Apparatus Voltage—Kv | Basic Insulation Level: Impulse Test Gap Spacing—Inches | Basic Insulation Level: Alternating Voltage Dielectric Test—Kv |
|---|---|---|---|
| 120 | | | |
| 240 | | | |
| 480 | | | |
| 600 | 1.2 | 0.8 | 10 |
| 2,400 | | | |
| 2,500 | 2.5 | 1.6 | 15 |
| 4,160 | | | |
| 4,330 | | | |
| 4,800 | 5.0 | 2.2 | 19 |
| 6,900 | 8.66 | 3.3 | 26 |
| 11,500 | | | |
| 13,800 | 15.0 | 4.5 | 34 |
| 25,000 | 25.0 | 7.1 | 51 |
| 34,500 | 34.5 | 10.2 | 70 |
| 46,000 | 46.0 | 13.5 | 93 |
| 69,000 | 69.0 | 20.6 | 139 |
| 92,000 | 92.0 | 27.5 | 185 |
| 115,000 | 115.0 | 34.7 | 231 |
| 138,000 | 138.0 | 42.1 | 277 |
| 161,000 | 161.0 | 49.0 | 323 |
| 196,000 | 196.0 | 60.0 | 393 |
| 230,000 | 230.0 | 70.4 | 461 |
| 287,500 | 287.5 | 88.0 | 578 |
| 345,000 | 345.0 | 105.6 | 691 |

Note 1—When apparatus is suitable for wye connection, the name plate shall be so marked and the circuit (line-to-line) voltage rating shall determine the required basic insulation level and bushing requirements. For example, if a transformer is designed for a high voltage of 6,900/11,950Y the name plate shall be marked accordingly and the transformer will be in the 15-kv insulation class.

Note 2—Exceptions to these standards will be found in the specific sections.

### B—Standards for Distribution and Power Transformers

In the ASA standards for distribution and power transformers the same introductory paragraphs and the table will be reproduced, with footnotes essentially as follows:

Note 1—When transformers are suitable for wye connection the name plate shall be so marked and the circuit (line-to-line) voltage rating shall determine the insulation level. For example:
Single-phase transformers for 8,660 volts or below shall be suitable for connection in star (wye) and shall be capable of withstanding tests as shown in table II.

### C—Standards for Instrument Transformers

In the ASA standards for instrument transformers the introductory paragraph on insulation level is again reproduced, with suitable wording to make it apply to instru-

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted September 16, 1936; released for publication November 25, 1936.

J. E. Clem is electrical engineer in the central station department of the General Electric Company, Schenectady, N. Y.; he was chairman of the transformer subcommittee* of the AIEE committee on electrical machinery, 1934–36.

* Personnel of Transformer Subcommittee of AIEE Committee on Electrical Machinery, 1935–36: J. E. Clem, *chairman;* G. M. Armbrust, F. F. Brand, E. S. Bundy, F. A. Lane, A. C. Monteith, L. C. Nichols, J. R. North, H. J. Scholz, E. D. Treanor, and F. J. Vogel.

## Table II

| Transformer Voltage Rating | Impulse Test Gap Spacing—Inches | Alternating Voltage Dielectric Test—Kv |
|---|---|---|
| Single-phase transformers | | |
| 2,400 delta/4,160 star | 2.2 | 19 |
| 4,800 delta/8,320 star | 3.3 | 26 |
| 6,900 delta/11,950 star | 4.5 | 34 |
| 3-phase transformers | | |
| 2,400 delta or star | 1.6 | 15 |
| 4,800 delta or star | 2.2 | 19 |
| 6,900 delta or star | 3.3 | 26 |

(The reference to table II appears as a note in the main table opposite 1.2–2.5–5.0–8.66 kv transformer voltages.)

Note 3—*Exception*—Transformers designed to permit star-connected operation on circuits of 92,000 volts and above with the neutral solidly grounded, may be designed, when so specified, to be capable of withstanding only an induced-voltage test corresponding to that required for the next lower rated circuit voltage class.

Note 4—Transformers may be provided with regulation taps for voltages not exceeding 10 per cent above the rated circuit voltage.

## Table III

| Transformer Voltage Rating | Impulse Test Gap Spacing—Inches | Alternating Voltage Dielectric Test—Kv |
|---|---|---|
| Single-phase transformers | | |
| 2,400 delta/4,160 star | 2.2 | 19 |
| 4,800 delta/8,320 star | 3.3 | 26 |
| 6,900 delta/11,950 star | 4.5 | 34 |
| 3-phase transformers | | |
| 2,400 delta or star | 1.6 | 15 |
| 4,800 delta or star | 2.2 | 19 |
| 6,900 delta or star | 3.3 | 26 |

(The reference to table III appears as a note in the main table opposite 1.2–2.5–5.0–8.66 kv transformer voltages.)

Note 3—The next-lower insulation level may be specified when it is adequate. For example:

(*a*) For potential transformers for 15 kv or below when exposure to impulse voltage is low.
(*b*) *Exception*—Transformers designed to permit star-connected operation on circuits of 92,000 volts and above with the neutral solidly grounded, may be designed, when so specified, to be capable of withstanding only an induced voltage test corresponding to that required for the next lower rated circuit voltage class.

Note 4—Voltage ratings of current transformers are the maximum voltages for which they are applicable. For co-ordinated insulation, current transformers having the same test-gap ratings as other apparatus in the circuit should be selected.

ment transformers, together with the table, and the footnotes are essentially as follows:

Note 1—When potential transformers are suitable for wye connection, the name plate shall be so marked and the circuit (line-to-line) voltage rating shall determine the insulation level. For example: Single-phase potential transformers for 8,660 volts or below shall be suitable for connection in star (wye) and shall be capable of withstanding tests as shown in table III.

## 2—Impulse Tests on Transformers

Initially the impulse test code required 5 tests to be made. In the "Recommended Transformer Standards" by Putman and Clem, published in ELECTRICAL ENGINEERING, December 1934, this was changed to require 3 tests. Since that time the wording designating the tests has been changed to the following:

(*a*) Apply a wave just sufficient to cause flashover of the specified test gap under existing conditions of humidity and air density.
(*b*) Apply a wave sufficient to cause flashover of the bushing. For this test the applied voltage must be at least 5 per cent in excess of the standard minimum flashover voltage for the standard bushing under standard conditions of humidity and air density.

Note—When oversized bushings are used they shall be equipped with suitable gaps to provide the same standard minimum impulse flashover as for the standard bushing.

(*c*) Apply a wave having a crest not less than 90 per cent of the standard minimum flashover voltage of the standard bushing under existing conditions of humidity and air density. No flashover of the bushing shall occur during the test.

Standard atmospheric conditions for these tests are a temperature of 25 degrees centigrade, air density corresponding to 760 millimeters of mercury and a humidity corresponding to a vapor pressure of 15.46 millimeters.

These changes in wording are the result of changes made from time to time to make the test requirements more explicit.

## Table IV—Insulation Requirements for Current Limiting Reactors

| Limit of Rated Apparatus Voltage—Kv | Low-Frequency Dielectric Test Applied Voltage—Kv | |
|---|---|---|
| | Oil Insulated | Air Insulated |
| 1.2 | 12 | 20 |
| 2.5 | 17 | 25 |
| 5. | 21 | 30 |
| 8.66 | 29 | 40 |
| 15.0 | 36 | 60 |
| 25.0 | 58 | 85 |
| 34.5 | 80 | 115 |
| 46.0 | 106 | |
| 69.0 | 157 | |
| 92 | 209 | |
| 115 | 261 | |
| 138 | 312 | |
| 161 | 364 | |
| 196 | 444 | |
| 230 | 520 | |
| 287.5 | 648 | |
| 345 | 780 | |

## 3—Insulation Requirements—Current Limiting Reactors

There are, in general, 2 types of construction for current-limiting reactors—oil insulated and air insulated. The insulation has in practice departed somewhat from former Institute standards and the ASA sectional committee has modified these values in accordance with table IV and the AIEE transformer subcommittee recommends that these values be put into immediate use.

## 4—Transformer for Mercury Arc Rectifiers

The transformer subcommittee does not agree with the present recommendations of the mercury arc rectifier. Subcommittee for the insulation of mercury-arc-rectifier transformers. It recommends higher test voltages based

## Table V

| D-C Voltage —Volts | Limit of Rated Apparatus Voltage —Kv | Alternating Voltage Dielectric Test —Kv |
|---|---|---|
| 0– 700 | 1.2 | 10 |
| 701– 1,500 | 2.5 | 15 |
| 1,501– 3,000 | 5.0 | 19 |
| 3,001– 5,000 | 8.66 | 26 |
| 5,001– 8,750 | 15.0 | 34 |
| 8,751–15,000 | 25.0 | 51 |
| 15,001–20,000 | 34.5 | 70 |

on voltage classifications which agree with those for other transformers.

It is reasonable to insulate primaries of rectifier transformers according to conventional transformer practice. The secondaries of these transformers are not, as a rule, exposed to lightning directly, and, accordingly, the next lower insulation level might be considered. However, the secondaries are exposed to overvoltages inherent in the operation of the rectifying equipment, so that a reduction in the low-frequency dielectric test does not seem advisable. Accordingly, the insulation of the secondary windings of these transformers should also follow conventional transformer practice after the proper insulation class of the transformer secondary winding has been agreed upon. However, the impulse tests for other transformers have been set up with overvoltages for lightning in mind. Rectifier transformers are subject only to overvoltages inherent in their operation which may be different in their character and frequency of occurrence, and, therefore, it seems advisable to study the question of the proper impulse test further.

There might be some question as to the secondary voltage rating to be used in selecting the insulation level on account of the variation in connections used to obtain the same d-c voltage. This occurs because the transformer secondary voltage for the same d-c voltage may be different for different schemes of connections. It appears reasonable that the most consistent results would be obtained if the d-c voltage was made the basis for determining the voltage class. It was agreed that the voltage class should be determined by the formula:

$$\text{Voltage class} = 2 \times \frac{\text{Rated d-c voltage}}{1.17}$$

The rated d-c voltage divided by 1.17 gives the corresponding open-circuit voltage to neutral of the rectifier

## Table VI—Bushing Characteristics

Transformers Larger than 500 Kva (Power). Transformers 500 Kva and Smaller (Distribution)

| Rated Circuit Voltage—Kv (1) | Maximum Rated Apparatus Voltage—Kv (2) | Power Transformers: Equivalent Rod Gap—Inches (3) (4) | Power Transformers: Impulse Flashover Kv (5) (6) | Power Transformers: 60-Cycle Flashover Dry—Kv (6) (8) | Power Transformers: 60-Cycle Flashover Wet—Kv (7) (8) | Distribution Transformers: Equivalent Rod Gap—Inches (3) (4) | Distribution Transformers: Impulse Flashover Kv (5) (6) | Distribution Transformers: 60-Cycle Flashover Dry—Kv (6) (8) | Distribution Transformers: 60-Cycle Flashover Wet—Kv (7) (8) |
|---|---|---|---|---|---|---|---|---|---|

For circuit voltages 92 kv and above use power transformer bushing values.

1. Column 1 gives the values of rated circuit voltages recommended in the NEMA-NELA report on preferred voltage ratings dated October 1928, for the purpose of establishing values to be used in designing and testing electrical apparatus.

Note: Rated circuit voltages of 92,000, 196,000, and 287,500 volts have been added to the NEMA-NELA list.

2. Column 2 gives the maximum rated apparatus voltages permissible for the corresponding insulation levels.

3. The equivalent rod gap for distribution transformer bushings is based on the transformer subcommittee recommendation standardizing the minimum impulse flashover for bushings at 5 per cent above the flashover of the test gap. The equivalent rod gap for power-transformer bushings for voltage classifications 69 kv and below represents existing practice. These values are minimum and must be met.

4. When bushing and equivalent rod gap are tested in parallel at minimum gap flashover with the 1.5 x 40 microsecond positive wave. 50–50 flashover of the equivalent gap and bushing should occur at minimum flashover voltage.

5. Average minimum flashover voltage with the 1.5x40 microsecond positive wave. Based on curves and tolerance of rod-gap flashover data agreed upon by the NEMA-EEI subcommittee on correlation of laboratory data, September 26, 1935. The tolerance applies to the recorded flashover voltage only (see note 3).

6. Flashover voltages are average values and are given for standard conditions of air density and humidity.

7. Wet flashover voltages are average values based on 0.1-inch precipitation per minute at an angle of 45 degrees with water having a resistivity of 12,000 ohms per centimeter cube and at standard air density.

8. The tolerance on the 60-cycle dry- and wet-flashover voltages shall be 5 per cent under standard conditions of air density and humidity.

9. All flashover values are based on the revised sphere-gap calibration data agreed upon by the sphere gap calibration subcommittee of the instruments and measurements committee. See ELECTRICAL ENGINEERING, page 783, July 1936.

transformer for any half wave 3-phase connection or double-Y connection with interphase. For the same d-c voltage, 6 or more phase half-wave connections have slightly lower corresponding transformer open-circuit voltages; single-phase connections, which are not common in power sizes, have somewhat greater open-circuit voltages. Commutation effects will, in general, result in a slightly higher a-c/d-c voltage ratio than at open circuit. Twice the maximum a-c voltage to neutral of the transformer secondary winding is equal to or greater than the maximum a-c voltage between secondary bushings and so is used to define the voltage class.

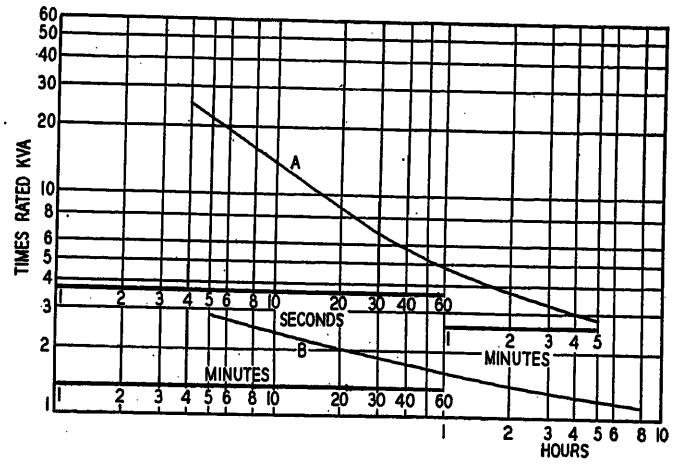

Fig. 1

| Duration of Load | Load in Multiples of Continuous Rating | Curve |
|---|---|---|
| 4 seconds | 25 | A |
| 10 seconds | 13.7 | A |
| 30 seconds | 6.7 | A |
| 60 seconds | 4.75 | A |
| 5 minutes | 2.8 | A |
| 30 minutes | 1.85 | B |
| 60 minutes | 1.6 | B |
| 2 hours | 1.4 | B |
| 5 hours | 1.2 | B |

Application of this formula gives the following, with some slight rounding off of values:

### Required Insulation Level of Transformers for Mercury Arc Rectifiers

PRIMARY WINDINGS

The primary windings of rectifier transformers shall be insulated in accordance with standard transformer requirements.

SECONDARY WINDINGS

The secondary windings of rectifier transformers shall be insulated in accordance with table V. It is recommended that this practice be put into immediate use.

## 5—Bushing Standards

Due to recent changes in the sphere-gap calibration curves it became necessary to modify the 60-cycle flashover data of transformer bushings. In addition the NEMA-EEI laboratory subcommittee on correlation of laboratory data revised the rod-gap flashover data which in turn required a slight change in the tabulation bushing impulse-flashover voltages. The standard bushing characteristics with these changes shown in table VI was approved and is recommended for immediate use.

Tests to verify the flashover of bushings should be made on the basis of the new calibration curve and the new flashover values. If, however, it is required to verify the old flashover values then the old calibration curves shall be used.

## 6—Use of Sphere-Gap Calibration Curves

Since the subcommittee of the instruments and measurements committee on sphere gap calibration has revised the sphere-gap calibration curves, it is recommended that these new calibrations be put into immediate use in the testing of transformers. The new calibration curves have been published on page 783 of the July 1936 issue of ELECTRICAL ENGINEERING.

The new calibration curves are given only for the case of one sphere grounded. It was recommended that these same curves also be used for the case of nongrounded spheres, providing the ratio of gap spacing to sphere diameter does not exceed $1/4$. A review of the data has indicated that with this precaution the error will be quite small.

## 7—Short-Time Heating and Overloading of Distribution Transformers

The subcommittee's report on the short time overloading of oil-immersed power transformers were given in a paper entitled "Overloading of Power Transformers" by V. M. Montsinger and V. M. Dann, ELECTRICAL ENGINEERING, October 1934, page 1353. Since that time the subcommittee has drawn up a guide for the short-time heating and overloading of certain sizes of distribution transformers. These curves apply to transformers 100 kva and smaller below 15,000 volts, and to network transformers 500 kva and smaller. Other distribution transformers are covered by the paper just mentioned.

## Guide—Short-Time Heating and Overload—Distribution Transformers

Distribution transformers operate under varying load-time curves, generally with relatively low load factor. It is possible to apply higher than rated load for short periods without encroaching too seriously on the life of the insulation or the oil. Since the shape of the load curve is variable from day to day and from season to season, and is not subject to easy control, there is no exact method of calculating the correct size of transformer for a given location.

The deterioration of insulation proceeds at different rates, depending upon the temperature, and the end point is not definite unless some characteristic is arbitrarily chosen. Calculations of the life on the basis of assumed

load curves are therefore of somewhat uncertain value. Many such calculations integrating the effect of time and temperature have been made, however, and they tend to check data from experience which in itself is not exact, but this agreement gives some foundation for setting up a curve which should prove a useful guide in overloading distribution transformers without materially affecting the length of life which has been obtained in the past.

Such a curve representing the magnitude and duration of permissible daily overloads starting at no-load temperature has been compiled and is shown as that portion of figure 1 for times longer than 5 minutes, curve *B*. This section of the curve should be of value in the application of distribution transformers, particularly in determining the economic size of transformer required to carry the expected load, with due regard for short-time peak overloads.

The short-time portion of the curve, that is, for times less than 5 minutes, curve *A*, is based on what may be termed, in general, short circuits, whose occurrence is accidental and not premeditated as with a daily recurrent load. They may occur at any time, and hence the worst condition—occurrence after full load—must be assumed. The frequency with which they occur can only be estimated. This portion, curve *A*, of the curve will be useful in the application of primary fuse links or network transformer fuses to meet thermal protective requirements. This portion of the curve is essentially a time-current curve of distribution transformers based on not reducing their normal expected life. A fuse link to provide thermal protection for such a transformer should lie below and to the left of the transformer curve. The inherent thermal ability of fuse links is much smaller than that of the transformer windings and therefore it cannot be expected that such links will provide thermal protection for periods exceeding approximately 5 minutes.

The short-time portion, curve *A*, of the curve may also be used to determine the ability of distribution transformers to operate as grounding transformers only, and to indicate the required time and current settings of protective devices used in the neutral of such transformers to clear them in the case of sustained faults. If distribution transformers connected as grounding transformers are also required to carry load, it should be recognized that the probable more frequent occurrence of line-to-ground faults will result in a shorter life than if the transformers were operated as normal distribution units subjected to occasional secondary faults. In addition, the normal impedance of distribution transformers is usually too low for them to function as grounding transformers unless additional external impedance is added, thus requiring a study of each particular case.

These 2 proposed curves are blended to form a composite continuous curve based on the limiting condition of a 30-degree daily average ambient. For lower ambients the same increase of load may be permitted as has been standardized for use on power transformers, one per cent for each degree below 30 degrees centigrade, but no further increase shall be made below a temperature of zero degrees centigrade.

Continuous duty on distribution transformers in high ambients is so unusual as to constitute a special situation which should be presented when transformers for such service are purchased.

---

## Two-Reaction Theory of Synchronous Machines

(*Continued from page 31*)

evaluating $f(p)$ by Heaviside's expansion theorem.

In the manner shown by Park[3] the synchronizing and damping component of electrical torque can be determined for any sinusoidal angular oscillation by introducing a system of vectors rotating at $s$ per unit angular velocity, where

$\Delta\delta = [\Delta\delta] \sin st$

$T_s =$ real part of $f(jS)$

$sT_d =$ imaginary part of $f(jS)$

In using the method outlined in this section for the study of sustained hunting or oscillation of a synchronous machine connected through capacitance to a system, it was found that the capacitive reactance could be subtracted from the external inductive reactance and the problem analyzed in the usual manner with good approximation, for those cases when the natural oscillation frequency of the machine being studied was small compared with normal frequency of the terminal voltage.

# Sealed-Off Ignitrons for Welding Control

By DAVID PACKARD
ASSOCIATE AIEE

J. H. HUTCHINGS
ASSOCIATE AIEE

**Accurate control of high currents for resistance welding may be obtained by igniter-type mercury-cathode tubes capable of conducting 7,000 amperes in impulses of from less than 0.01 second to several seconds duration. This paper describes design principles and manufacturing technique for tubes of the sealed-off type.**

IN THE PROCESS of resistance welding, parts to be welded are placed between high-conductivity electrodes, pressure is applied, and an impulse of current passed through the electrodes and work. The region of highest resistance, where most of the heat is developed when the current flows, is the point of contact between the pieces being welded.

When making large welds, very high currents are required to produce sufficient heat to melt the metals. It is desirable to accomplish this heating and subsequent cooling very quickly so that the melted zone does not travel from the joint through the pieces to their outer surfaces. In this way short weld timing leaves a bridge of cooler metal adjacent to each electrode, thus minimizing oxidation and deformation. This short timing, if coupled with high accuracy of current and time control, simplifies the welding of metals otherwise very difficult to weld. Thus there are encountered 2 principal requirements of any device used to control current to a resistance welder:

1. Ability to pass very high currents. Welding depends upon high currents to develop the necessary heat.

2. Quick response. The device must respond quickly if it is to follow the signal impulses and so give the desired short and accurate timing.

## The Ignitron

These requirements have been satisfied by the ignitron,[1,2,3] which may be either a sealed-off tube or a continuously pumped tank, the fundamentals of operation being the same in both cases. The ignitron is a mercury-arc rectifier having a special control electrode or igniter used for initiating the arc. Once the arc is established by passing an impulse of current through the igniter, it continues for the remainder of that half-cycle during which the anode is positive with respect to its cathode. During the negative half-cycle the arc is completely extinguished and control is regained. When the anode again becomes more positive than the cathode the arc may be re-established if desired by passing another impulse of current through the igniter. In this way alternating voltage enables one to regain control every cycle. Thus the ignitron and thyratron effect similar control over the flow of current.

In welding service, 2 ignitrons are connected "back to back" in series with the welding transformer primary as shown in figure 1. By energizing the igniter of each unit at the proper instant during each conducting cycle, 2-way or alternating conduction of current is permitted. Each ignitron passes current during half of each conducting cycle, and so control is regained every half-cycle. When the weld has been completed, conduction is stopped by removing excitation from the igniters. Two ignitrons thus act as a quickly responding contactor.

The ignitron satisfies the 2 requirements previously stated for the following reasons:

1. Use of a mercury-pool cathode makes possible the conduction of extraordinarily high instantaneous currents. Cathode life at these high currents should be very long.

2. Quick and accurate response is attained through use of the igniter electrode. When the proper impulse of current is applied to the igniter, the arc starts in less than 100 microseconds. Conduction stops at the instant an anode becomes negative, thus all conducting periods end at approximately the same point on the voltage wave.

It is therefore evident that the ignitron is sufficiently responsive for use in the welding field. If it is coupled with some suitable igniter firing circuit the necessary degree of over-all timing accuracy may be obtained.

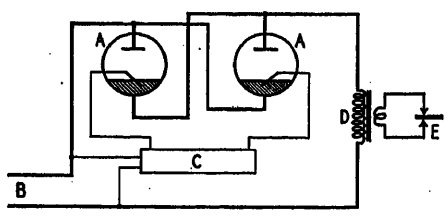

**Fig. 1. Schematic diagram of "back to back" connection**

A synchronous thyratron control[4] panel is commonly used with ignitrons in welding installations to supply this igniter firing control. This control panel or "brain" of the device makes possible initiation of the arc at any predetermined point on the voltage wave. Very short timing may be attained by firing only one ignitron and doing so just before the end of the positive half cycle. This procedure makes possible a conduction period much

A paper recommended for publication by the AIEE committees on electric welding and electronics. Manuscript submitted October 28, 1936; released for publication November 25, 1936.

DAVID PACKARD is a test engineer for the General Electric Company, Schenectady, N. Y. J. H. HUTCHINGS is an electrical engineer in the vacuum tube engineering department of the same company.

1. For all numbered references see list at end of paper.

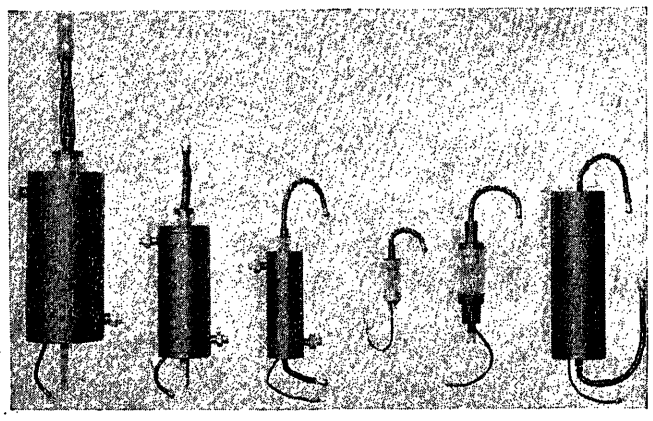

**Fig. 2. Sealed-off ignitrons of the water-cooled (3 at left) and air-cooled (3 at right) types**

shorter than one-half cycle. By uniformly starting the arc at one point on the voltage wave, the variability of current transients and hence of welds is minimized.

## Design Problems of the Sealed-Off Tube

In the development of a line of sealed-off ignitrons the design problems appear in the following natural divisions:

1. The igniter must be properly designed and located in each tube if reliable ignition of the arc is desired.

2. A current path through the tube of good conductivity must be provided to carry the high current. Peak, average, and root-mean-square currents must all be considered.*

3. Heat removal must be sufficiently effective to limit cathode, arc stream, and anode temperatures to values at which reliable operation and good life result.

4. Manufacturing technique must be such that a vacuum-tight product is obtained. This is of course essential if the unit is to be sealed off and still maintain its vacuum over an extended period of life.

The igniter is the "firing pin" of the tube. The design that has been adopted consists of a small rod of treated silicon carbide with the part dipping in the mercury pointed to a logarithmic shape.[5] The igniter is mounted on an insulating bushing in the mercury pool, making it possible to have terminals at the ends of the tube only.

The electron current from the cathode comes from a number of small spots on the pool of mercury.[6] The first spot is started by a spark from the igniter, and it divides into more spots as the current demand is increased until at high currents the emission comes from a great many small spots, each supplying from 5 to 15 amperes. One condition for determining pool size is satisfied by providing sufficient area so that the cathode spots, starting at the igniter, do not travel to the edge of the pool and anchor on the envelope in the time allotted to a single conduction interval. If this occurs, material may be sputtered from the metal walls of the tube. This requirement is easily fulfilled in normal operation since the arc has only one-half cycle during which to travel. Another consideration at the cathode is to provide large contact area between the pool and the cathode lead for the dual purpose of current and heat conduction.

The cross-sectional area of the tube influences the maximum peak current the tube will conduct without failure. As the current density in the arc stream is increased above a certain value the voltage drop in the tube, and consequently the loss per unit current, increases rapidly. This and other considerations set a current density above which it is not practical to operate. In 550-volt welder service successful operation has been obtained with arc stream current densities exceeding 500 amperes per square inch. The envelope sizes have been selected from a preferred number series of standard seamless steel tubing, thus tending to cause peak current capacities to fall in a similar series.

The anode size is determined by both the average and root-mean-square or effective currents. The heat generated at the surface depends upon the average current. The heat generated in the conducting parts is a function of the effective current. Thus both the area and the conduction cross section must be considered. The anode lead must be designed to conduct the effective current.

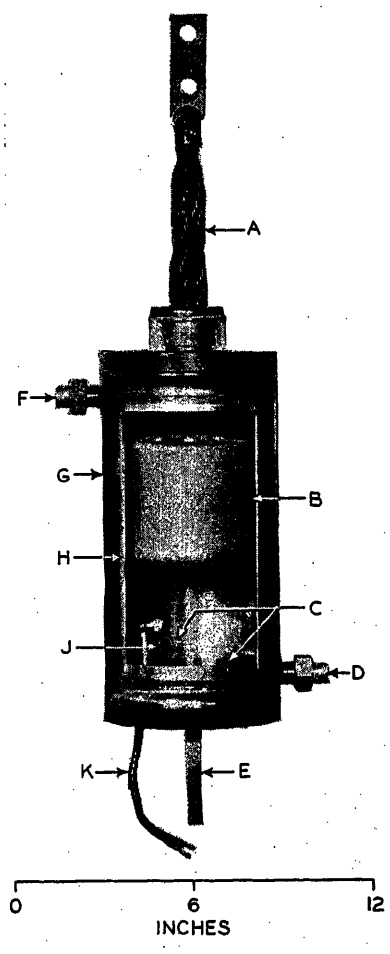
## Heat Removal

When conducting, a gas-filled tube has a voltage drop from anode to cathode of the same order of magnitude as the ionization potential of the gas. This voltage is roughly independent of the current being carried by the arc and in the case of these mercury-pool tubes is approximately 15 volts. This drop causes power loss which appears as heat within the tube.

A mercury-pool tube of any one design and operating under certain current and voltage conditions will perform satisfactorily only when the temperatures of the various parts lie below definite limiting values. It is particularly important to limit the mercury-vapor pressure in the tube. This pressure is determined by the temperature of the cooler parts. If the temperature limits are exceeded, current may be carried in either direction when the igniter is not energized and conduction is not desired. Bad welds may result from such failures. A tube which fails by carrying current in the forward direction is commonly said to "shoot through." One which carries current in the reverse direction is said to "arc back."

The limiting condensed-mercury temperatures of ignitrons now available lie between 50 and 125 degrees centigrade. This means that relatively small temperature differences, between some tube parts and cooling medium, are available for removal of heat.

In the case of low-power ignitrons, air cooling of both ends has been accomplished by providing good paths for conduction of heat from anode and cathode to larger and cooler external parts. An example of this type of



*The highest instantaneous value of current conducted will be referred to hereafter as peak anode current or simply peak current. Large welds require high peak currents.
Average anode current per tube is obtained by averaging the instantaneous values over the rated averaging period. This period is usually sufficiently long to include several welds and the intervening off periods. Both the size of the welds and the frequency at which they are made determine the average current.
Root-mean-square current, as referred to in this paper, is measured or calculated in the usual manner considering both the time of current flow and the time off included in the rated averaging period of the tube.

cooling is seen in the 2 smaller tubes shown in figure 2. Radiation and forced ventilation are utilized to remove the heat from tubes of intermediate size. Parts of the tube, the anode in particular, are allowed to operate at high temperatures and so radiate effectively. Parts controlling mercury temperature, such as those parts in the region of the pool cathode, are cooled mainly by forced ventilation. An example of this class of ignitron is the tube on the right side of figure 2.

The amount of heat generated at the cathode of a high-current tube cannot easily be transmitted by conduction through the mercury pool and other cathode parts. It is also difficult to conduct this heat through glass side walls. Temperature drop along either of these paths may be sufficiently great to give inner or effective temperatures higher than are allowable even though the outside of the tube is kept at low temperature. This fact has caused the adoption of metal construction for higher power tubes.

Coupling the metal design with water cooling, as shown in figure 3, results in the cooling water and arc stream being separated only by about $^1/_{16}$ inch of metal, the thickness of the inner envelope. As shown in this illustration, the sides of the ignitron are cooled over their entire length by use of a water jacket. Rather close spacing between the 2 cylinders forming the jacket is used to increase water velocity and so provide better heat transfer.

**Fig. 3. Cutaway view of a large water-cooled ignitron**

*A*—Anode connection
*B*—Anode
*C*—Space for mercury pool
*D*—Water inlet
*E*—Cathode connection
*F*—Water outlet
*G*—Water jacket
*H*—Tube envelope
*J*—Igniter
*K*—Igniter connection

In order to avoid air pockets and to keep coolest water in contact with the pool cathode, water enters at the bottom of the jacket and flows out at the top.

The top seal and the central part of the mercury pool are kept cool by use of heavy tube-end pieces, or headers, welded to the cooled envelope. In one tube of large diameter, these ends are over $^1/_8$ inch thick, thus providing a good path for heat conduction. In this way effective cooling, and hence effective control of mercury-vapor pressure, has been attained.

## Corrosion and Hydrogen Diffusion With Water Cooling

Water cooling, though it solved many problems, introduced the new ones of corrosion and hydrogen diffusion.

Early developmental tube models employed ordinary steel envelopes and water jackets. Passage of water through the cooling chamber caused considerable rusting. In addition, many of the hydrogen ions* present in the water filtered through the steel envelope into the tube and soon rendered it gassy and inoperable. Ordinary steel is no effective barrier to the hydrogen ion, and while the water may be treated to prevent corrosion and diffusion this does not appear at present to be economical in welding applications. While this seepage of hydrogen through the envelope might be tolerated if the unit were being pumped continuously, it obviously cannot be permitted in sealed-off tubes.

These difficulties of corrosion and hydrogen diffusion were overcome by the use of stainless steel envelopes and jackets. This material is practically impervious to the hydrogen ion at operating temperatures. Since water comes in contact only with stainless steel and the brass pipe fittings, corrosion should be extremely slow, thus permitting very long tube life from this consideration.

## Metal Tube Manufacturing Technique

Initially ignitrons were made of glass by adopting the technique then used in making hot-cathode rectifiers and thyratrons. A new glass-to-metal seal, utilizing an alloy called "fernico," and the application of thyratron control to welding introduced an entirely new technique which is now utilized in ignitron manufacture. Fernico, which is an alloy of iron, nickel, and cobalt, has an expansion characteristic which closely matches that of certain glasses.[7] It can be drawn, machined, and welded. This material makes possible strain-free glass-to-metal seals which are relatively easy to manufacture and free from leaks. All of the insulating bushings of these sealed-off ignitrons are made with such seals. The anode bushing of a large water-cooled tube is shown in figure 4.

This figure also shows some of the important welds. The fernico cup on the top is welded onto the anode lead which is designed to carry 1,500 amperes, effective value. The fernico piece on the bottom is welded onto

* Ordinary tap water has a hydrogen concentration of roughly $1 \times 10^{-7}$ mole per liter.

the steel head which forms the end of the tube. This head is seam welded into a piece of seamless steel tubing forming the envelope. If a water jacket is desired, the tube envelope is flared out at each end beyond the header and a longer cylinder is seam welded on the outside as shown in figure 3. Welding machines equipped with thyratron control, using ignitron or thyratron power tubes, make these vacuum-tight welds and other welds where consistent high quality is essential. Thus ignitrons are an important part of ignitron manufacture.

Even the air-cooled tubes made mainly of glass have been manufactured with metal tube technique. The essential difference in this case is that a larger piece of glass is used between the 2 fernico seals, for the glass is the insulating bushing and tube envelope as well. Although this glass construction has been quite popular, metal tubes are being made in all except the smaller sizes where the glass involved is of about the same size as the anode bushing of a larger tube. Figure 5 shows the smallest ignitron tube before being evacuated beside an anode bushing of a larger ignitron. This tube is made from parts of a similar but larger bushing.

This new technique used in ignitron manufacture has many advantages over older methods:

1. The vacuum-tight seals are mechanically strong and provide good support for heavy anodes and leads required by high current capacity.

2. The metal construction provides good heat transfer and simplifies water cooling.

3. The manufacturing processes may be closely controlled and do not require highly skilled labor, therefore they are less costly.

4. The metal construction gives a product more accordant with industrial psychology.

Some of these construction features have promise of use in other fields. The metal-to-glass seals may be used as insulating bushings in other apparatus. The stainless-steel seam-welded water-jacket construction offers a simple cooler for heat transfer in other devices, and the welding used throughout the line exemplifies what can be done with modern welding technique.

## Performance of the Tubes

These general design principles have been applied to ignitrons for a wide range of applications. All of the smaller tubes are air-cooled, and are used where the welds are either small or are made infrequently. The smallest tube is $1^1/_2$ inches in diameter and 3 inches long, yet it will control currents up to several hundred amperes. With this tube small welds such as are used in jewelry manufacture may be controlled. The demand for larger air-cooled tubes has been met with several other sizes, the largest of which will pass peak currents up to several thousand amperes, and can be used to time large welds which are not made in rapid succession.

Application of water cooling to tubes of intermediate rating has brought a great reduction in size and cost. An example is the small water-cooled unit shown in figure 6 which has a slightly higher capacity than the large air-cooled tube shown in the same picture.

Large sealed-off water-cooled tubes are now practical for controlling peak currents of 7,000 amperes or more and average currents, at lower peaks, as high as 250 amperes per tube. They are applied where either high peak current, high average current, or both are encountered.

# Contributions to Synchronous-Machine Theory

By A. S. LANGSDORF
FELLOW AIEE

**In this paper the 2-reaction theory of synchronous machines is extended, for steady-state conditions, to present some new deductions apparently not previously known.**

IT HAS long been known that the cylindrical-rotor theory, based essentially upon the concept that the synchronous impedance is a constant for all loads and for all positions of the armature winding relative to the rotor, leads to gross inconsistencies when applied to salient-pole machines. The Blondel 2-reaction theory, and its extension by Doherty and Nickle,[1] have pointed the way to numerous improvements which bring the theory much more nearly into accord with the facts, but the conclusions thus far published have stopped short of a complete presentation of some exceedingly interesting deductions. It is the purpose of this paper to point out some features, apparently not previously known, which follow quite simply and naturally from the 2-reaction theory. This treatment is here limited to steady-state operation, perhaps not as important as the transient case of sudden short circuit, but the results are nevertheless of fundamental interest.

It is desirable, partly by way of introduction, but mainly to facilitate future comparisons, to review briefly the essential features of the cylindrical-rotor theory, as applied to the case of a synchronous motor; the extension to the case of the generator then follows directly. Thus, in figure 1, let

$V$ = terminal voltage
$E$ = counter electromotive force or excitation voltage
$I$ = armature current
$Z_s$ = synchronous impedance
$X_s$ = synchronous reactance
$R_a$ = effective resistance
$\varphi_s = \tan^{-1} X_s/R_a$
$\varphi$ = angle of phase displacement between $V$ and $I$

all of these quantities referring to one phase of the winding.

The power (per phase) developed by the machine, including core loss, friction, and windage, is

$$P = VI \cos \varphi - I^2 R_a \tag{1}$$

whence

$$I^2 - \frac{V}{R_a} I \cos \varphi = -\frac{P}{R_a} \tag{2}$$

Adding to both sides of this equation the constant term $(V/2R_a)^2$, it becomes

$$I^2 + \left(\frac{V}{2R_a}\right)^2 - 2\left(\frac{V}{2R_a}\right) I \cos \varphi = \left(\frac{V}{2R_a}\right)^2 - \frac{P}{R_a} \tag{3}$$

The quantity $V/(2R_a)$ is obviously a current in phase with $V$, and it is a constant. Consequently the equation states that the sum of the squares of $I$ and $V/(2R_a)$, minus twice their product times the cosine of the included angle, is a constant, provided $P$ is constant. This suggests the ordinary cosine law of trigonometry, and indicates the well-known construction, figure 2, for the circular current locus subject to the condition of constant power.

The vector diagram, figure 1, shows further that

$$(IZ_s)^2 = V^2 + E^2 - 2VE \cos \delta \tag{4}$$

where $\delta$ is the variable torque angle, whence

$$I^2 = \left(\frac{V}{Z_s}\right)^2 + \left(\frac{E}{Z_s}\right)^2 - 2\left(\frac{V}{Z_s}\right)\left(\frac{E}{Z_s}\right) \cos \delta \tag{5}$$

Here $V/Z_s$ is a constant current lagging behind $V$ by angle $\varphi_s$, as in figure 3, and $E/Z_s$ is a constant provided the excitation is held fixed. The same cosine law then shows that the current locus for a fixed excitation is a circle, figure 3, having its center at $D$, and it is readily shown that $D$ is a point on the zero-power circle. It is to be particularly noted that this construction points to the conclusion that an unexcited motor ($E = 0$) can develop no power, which is not in accord with experimental facts.

## Equivalent Impedance, 2-Reaction Theory

Applying the 2-reaction theory, the vector diagram takes the form of figure 4, where, as usual, $\psi$ is the phase displacement between the armature current and the component $(-E)$ of the impressed voltage which balances the counter electromotive force. In this diagram

$$I_q = I \cos \psi \tag{6}$$
$$I_d = I \sin \psi$$

represent, respectively, the components of armature current in the transverse (cross) axis and in the direct axis of the machine; also

$$X_q = X_q' + X_l \tag{7}$$
$$X_d = X_d' + X_l$$

where $X_q'$ and $X_d'$ are the reaction reactances in the 2 axes; and $X_l$ is the true leakage reactance, assumed to be the same in both axes.

From the diagram it is seen that

$$V \sin \delta = I_q X_q + I_d R_a \tag{8}$$

$$E - V \cos \delta = I_d X_d - I_q R_a \tag{9}$$

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted September 8, 1936; released for publication November 30, 1936.

A. S. LANGSDORF is dean of the schools of engineering and architecture at Washington University, St. Louis, Mo.

1. For all numbered references see list at end of paper.

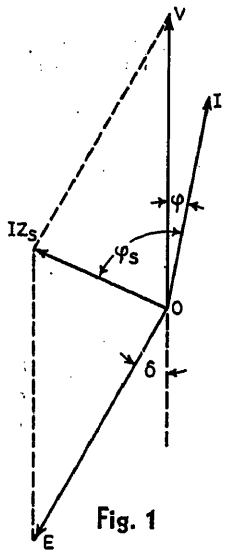

Fig. 1

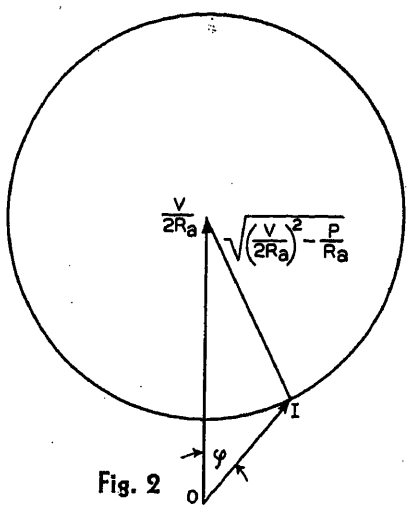

Fig. 2

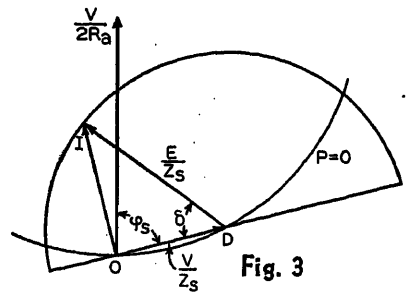

Fig. 3

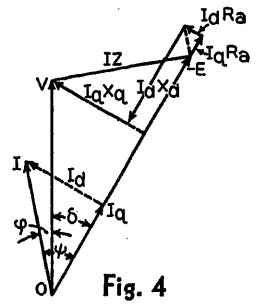

Fig. 4

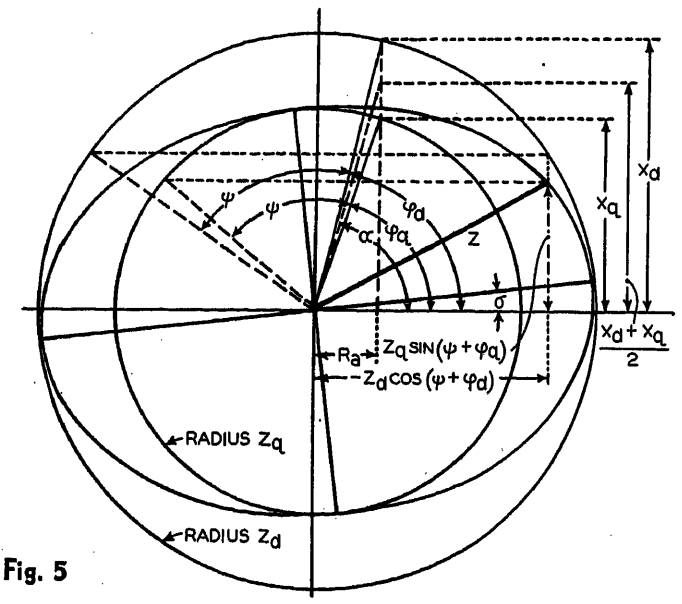

Fig. 5

which may be written in the form

$$V \sin \delta = I(X_q \cos \psi + R_a \sin \psi) = IZ_q \sin (\psi + \varphi_q) \tag{10}$$

$$E - V \cos \delta = I(X_d \sin \psi - R_a \cos \psi) = -IZ_d \cos (\psi + \varphi_d) \tag{11}$$

where

$$\left.\begin{aligned} Z_q &= \sqrt{R_a^2 + X_q^2} \\ Z_d &= \sqrt{R_a^2 + X_d^2} \\ \varphi_q &= \tan^{-1} \frac{X_q}{R_a} \\ \varphi_d &= \tan^{-1} \frac{X_d}{R_a} \end{aligned}\right\} \tag{12}$$

It is also plain from figure 4 that the equivalent impedance drop in the machine is the vector sum of $V$ and $E$, that is, $IZ$, and

$$(IZ)^2 = (V \sin \delta)^2 + (E - V \cos \delta)^2 \tag{13}$$

Substituting equations 10 and 11 in equation 13,

$$Z^2 = [Z_q \sin (\psi + \varphi_q)]^2 + [-Z_d \cos (\psi + \varphi_d)]^2 \tag{14}$$

which is at once recognizable as the polar equation of an ellipse with $Z$ and $\psi$ as the dependent and independent variables.

The graph of $Z$ as a function of $\psi$ may be quite simply constructed as in figure 5. The positions of the major and minor axes, which define the maximum and minimum values of $Z$, are found by differentiating equation 14 with respect to $\psi$ and setting the result equal to zero; thus

$$\frac{d}{d\psi}(Z)^2 = -Z_d^2 \sin 2(\psi + \varphi_d) + Z_q^2 \sin 2(\psi + \varphi_q) = 0 \tag{15}$$

which, when solved for $\psi$, gives

$$\tan 2\psi = \frac{Z_q^2 \sin 2\varphi_q - Z_d^2 \sin 2\varphi_d}{Z_d^2 \cos 2\varphi_d - Z_q^2 \cos 2\varphi_q} \tag{16}$$

On substituting in equation 16 the relations grouped as equation 12, this reduces to

$$\tan 2\psi = \frac{2 \tan \psi}{1 - \tan^2 \psi} = \frac{R_a}{\frac{1}{2}(X_d + X_q)} = \cot \alpha \tag{17}$$

or

$$\tan \psi = -\frac{\frac{1}{2}(X_d + X_q)}{R_a} \pm \sqrt{1 + \left(\frac{\frac{1}{2}(X_d + X_q)}{R_a}\right)^2} \tag{18}$$

thus defining 2 values of $\psi$, 90 degrees apart, one of which corresponds to the maximum, the other to the minimum, value of $Z$. It may be noted in passing that the major axis of the ellipse is tipped up from the horizontal axis of reference at an angle $\sigma$ such that

$$\tan \sigma = \frac{Z_q \sin \left(\frac{\pi}{4} + \frac{\alpha}{2} - \varphi_q\right)}{Z_d \cos \left(\frac{\pi}{4} + \frac{\alpha}{2} - \varphi_d\right)}$$

The maximum and minimum values themselves are most simply determined by transforming equation 14 to the form

$$Z^2 = \frac{Z_d^2 + Z_q^2}{2} + \frac{Z_d^2}{2} \cos 2(\psi + \varphi_d) - \frac{Z_q^2}{2} \cos 2 (\psi + \varphi_q) \tag{19}$$

which, when expanded and rearranged, using equation 12, becomes

$$Z^2 = \frac{Z_d^2 + Z_q^2}{2} - (X_d - X_q)\sqrt{R_a^2 + \left(\frac{X_d + X_q}{2}\right)^2} \times \sin (2\psi + \alpha) \tag{20}$$

where the angle $\alpha$, defined by equation 17, has the meaning indicated in figure 5.

The variation of the equivalent impedance $Z$ as a function of $\psi$ may be studied in another way by observing from figure 5 that its complex value may be written

$$Z = -Z_d \cos(\psi + \varphi_d) + jZ_q \sin(\psi + \varphi_q)$$
$$= \left(-R_a + j\frac{X_d + X_q}{2}\right)\epsilon^{-j\psi} - j\frac{X_d - X_q}{2}\epsilon^{j\psi} \qquad (21)$$

This equation has the simple geometrical interpretation shown in figure 6; that is, when $\psi = 0$, $Z$ is made up of the directed magnitude $OA = \left(-R_a + j\frac{X_d + X_q}{2}\right)$ combined with the directed magnitude $AB = -j\frac{X_d - X_q}{2}$, giving as resultant $Z_{\psi=0} = OB = -R_a + jX_q$. For any arbitrary value of $\psi$, $OA$ swings clockwise, to $OA'$, while $AB$ swings in a counterclockwise direction to $A'B'$, thus giving $Z = OB'$ for the particular value of $\psi$ indicated in the diagram. It will be noted that the angle between $OA'$ and $A'B'$ is always $2\psi - \alpha'$, where $\alpha'$ is the complement of the constant angle $\alpha$ that appears in figure 5 and which is defined by equation 17. Finally, therefore, the variation of $Z$ may be illustrated by the extremely simple diagram, figure 7, from which

$$Z^2 = (OC)^2 + (CP)^2 - 2(OC)(CP)\cos(2\psi - \alpha')$$
$$= \frac{Z_d^2 + Z_q^2}{2} - (X_d - X_q)\sqrt{R_a^2 + \left(\frac{X_d + X_q}{2}\right)^2} \times \cos(2\psi - \alpha') \qquad (22)$$

which is the same as equation 20.

The variation of $Z$ as a function of $\psi$ may now be shown as in figure 8, which is constructed from figure 7 by assigning various values to $\psi$ and plotting the results in rectangular co-ordinates. It is seen that $Z$ passes through 2 complete cycles of values for each cycle in the value of $\psi$, but the curve is not a simple harmonic function of $\psi$ as might at first glance be supposed to be the case; it fluctuates between limits equally spaced on either side of the ordinate $\sqrt{R_a^2 + (X_d + X_q)^2/2}$, but the upper loops are slightly longer than the lower ones, as may be seen from the fact that in figure 7 the arc through $C$, having $O$ as center, divides the small circle into 2 unequal parts, so that $a > b$ in figure 8.

Otherwise expressed, when the square root of such an expression as equation 22 is evaluated by means of the binomial theorem, terms appear that involve the ascending powers of the term $\cos(2\psi - \alpha')$, which means that the curve of figure 8 really consists of a fundamental (of double frequency) and a series of higher harmonics.

It has long been known that the reactance of a salient-pole machine varies cyclically when measured at a series of successively different positions of the field poles relatively to the winding, but it has heretofore been assumed[2] that the reactance is expressible as

$$X = X_{aver} + X' \cos(2\theta + \gamma)$$

where $X_{aver}$ is the average value over an arc of one pole pitch, $X'$ is the maximum deviation from the average, and $\theta$ is the angle, in electrical degrees, measured from an arbitrarily selected reference point on the armature surface. The analysis here presented shows conclusively that this assumption is not strictly correct, though it becomes very nearly so if $X_d$ and $X_q$ are not greatly different.

## Current Locus, Constant Excitation

Equations 8 and 9, when solved for $I_q$ and $I_d$, yield the following relations:

$$I_q = \frac{VX_d \sin\delta - R_a(E - V\cos\delta)}{X_dX_q + R_a^2} = \frac{VZ_d \cos(\delta - \varphi_d) - ER_a}{X_dX_q + R_a^2} \qquad (23)$$

$$I_d = \frac{VR_a \sin\delta + X_q(E - V\cos\delta)}{X_dX_q + R_a^2} = \frac{VZ_q \sin(\delta - \varphi_q) + EX_q}{X_dX_q + R_a^2} \qquad (24)$$

The form of these 2 expressions suggests a simple geo-

Fig. 6

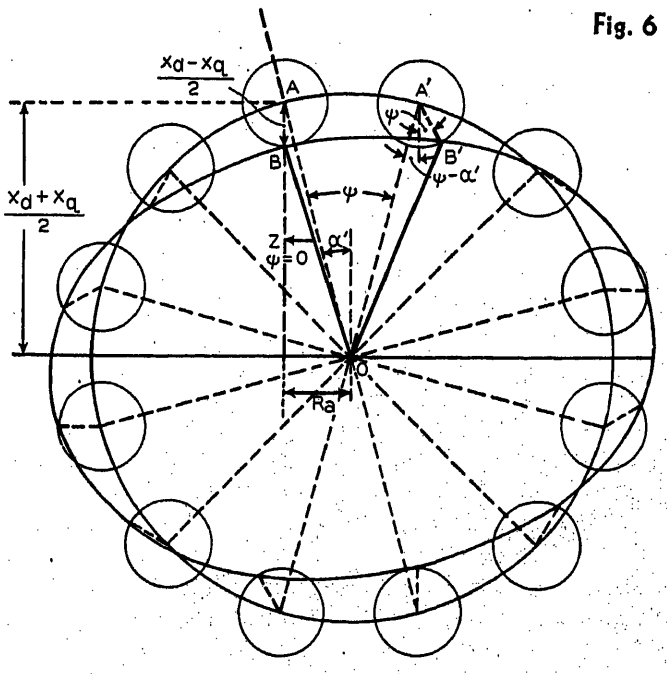

Fig. 7 (right)

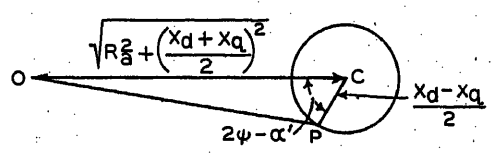

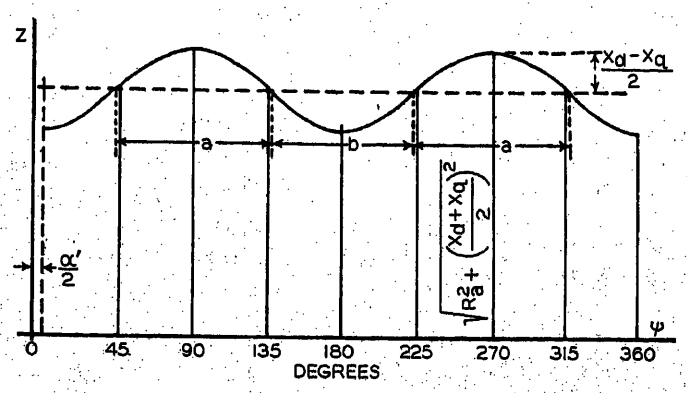

Fig. 8 (below)

metrical construction for the current locus if $E$ is maintained constant. Thus, in figure 9, $OV$ represents the fixed terminal voltage and $-OE$ is the excitation voltage, fixed as to magnitude, but displaced from $OV$ by the variable torque angle $\delta$. The lines $OD = (VZ_d)/(X_dX_q + R_a^2)$ and $OC = (VZ_q)/(X_dX_q + R_a^2)$, representing the constant coefficients that appear in equations 23 and 24, are drawn at the fixed angles $\varphi_d$ and $\varphi_q$, respectively, with $OV$. Accordingly, when perpendiculars are dropped from the points $D$ and $C$ upon the line $OE$, it follows that

$$OK = \frac{VZ_d}{X_dX_q + R_a^2} \times \cos(\delta - \varphi_d)$$

and

$$GC = \frac{VZ_q}{X_dX_q + R_a^2} \times \sin(\delta - \varphi_q)$$

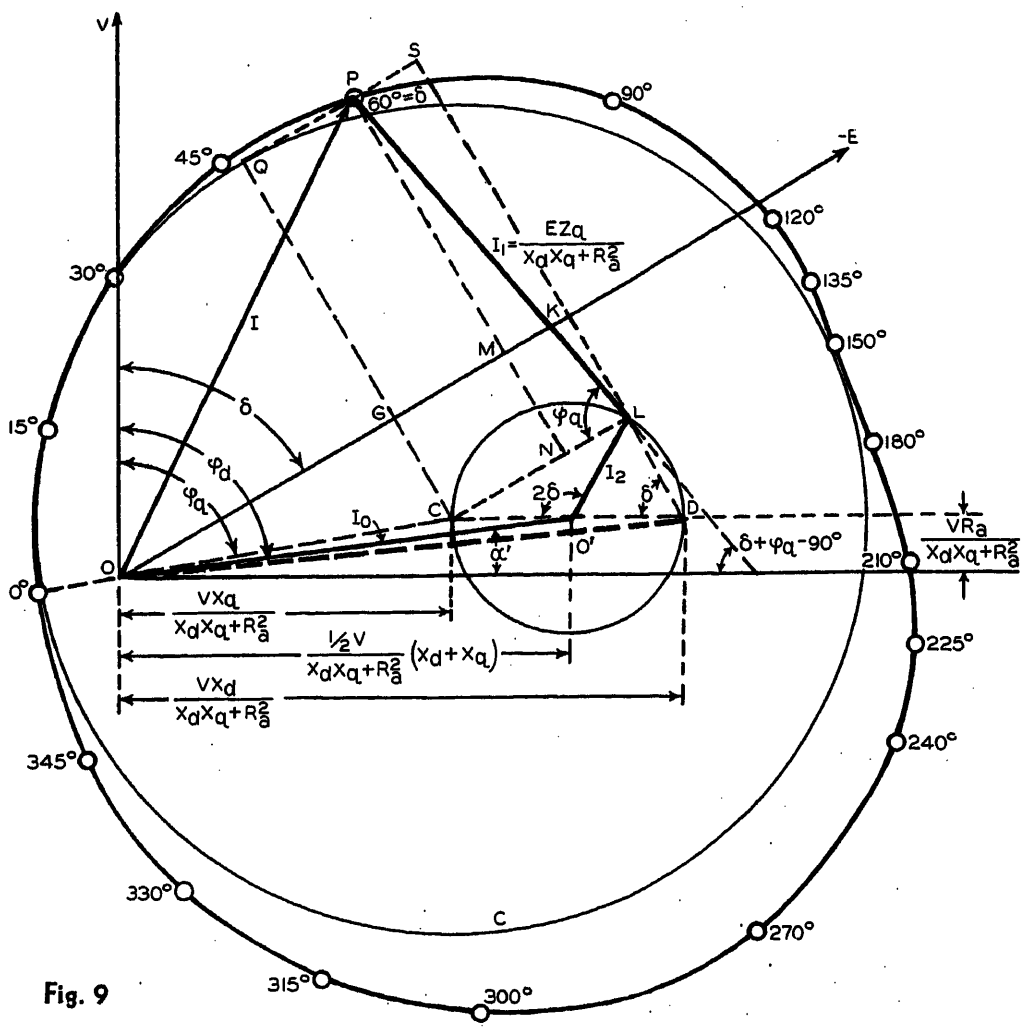

Fig. 9

On subtracting from $OK$ the fixed length

$$KM = LN = \frac{ER_a}{X_dX_q + R_a^2}$$

and adding to $GC$ (which must be considered negative in the diagram since $\delta < \varphi_q$) the fixed length

$$CQ = NP = \frac{EX_q}{X_dX_q + R_a^2}$$

it is clear that in accordance with equations 23 and 24

$$OM = I_q$$
$$MP = I_d$$

and

$$OP = \sqrt{(OM)^2 + (MP)^2} = I$$

Now it is apparent from figure 9 that no matter what value is assigned to $\delta$, the angle $CLD$ is necessarily a right angle, hence its locus is a circle having $CD$ as a diameter. The magnitude and position of $CD$ are readily fixed in terms of the co-ordinates of points $C$ and $D$ as indicated on the diagram, from which it appears that $CD$ is perpendicular to $OV$ and that

$$CD = \frac{V(X_d - X_q)}{X_dX_q + R_a^2}$$

The center of the circle $CLD$ is at $O'$, which has the co-ordinates

$$\left(\frac{V}{X_dX_q + R_a^2} \cdot \frac{X_d + X_q}{2}, \frac{VR_a}{X_dX_q + R_a^2}\right)$$

consequently the line $OO' = I_0$ is fixed in length and is tipped up from the horizontal by the same angle $\alpha'$ that appears in figure 6. Since the angle $CDK = \delta$ by construction, it follows that the radius vector $O'L = I_2$ is inclined to $O'C$ at an angle $2\delta$. Finally, the vector

$$LP = I_1 = \sqrt{\left(\frac{ER_a}{X_dX_q + R_a^2}\right)^2 + \left(\frac{EX_q}{X_dX_q + R_a^2}\right)^2} = \frac{EZ_q}{X_dX_q + R_a^2}$$

is also fixed in length so long as $E$ remains constant, and it is inclined to the horizontal at an angle $(\delta + \varphi_q - 90)$, as indicated in figure 9.

So there develops the remarkably interesting fact that the current vector $OP = I$ is the vector sum of 3 components, 2 of which, $I_0$ and $I_2$, are permanently constant in magnitude, and the third component, $I_1$, is constant for a fixed excitation; for different excitations $I_1$ is directly proportional to the excitation. But while the 3 components are constant in magnitude (for a given value of $E$), they are linked together at phase angles which change with $\delta$ in an interesting manner, with the result that the current locus has the irregular form shown in

figure 9, which has been drawn for the condition $E = (5/4)V$, and $Z_d/Z_q = 5/3$.

Expressed in complex notation,

$$I = I_0 + I_2 + I_1 \tag{25}$$

where

$$I_0 = \frac{V}{X_d X_q + R_a^2}\sqrt{R_a^2 + \left(\frac{X_d + X_q}{2}\right)^2}\epsilon^{j\alpha'} = I_0(\cos\alpha' + j\sin\alpha') \tag{26}$$

$$I_2 = -\frac{V}{X_d X_q + R_a^2}\cdot\frac{X_d - X_q}{2}\epsilon^{-j2\delta} = -I_2(\cos 2\delta - j\sin 2\delta) \tag{27}$$

$$I_1 = -j\frac{EZ_q}{X_d X_q + R_a^2}\epsilon^{-j(\delta+\varphi_q)} = -I_1[\sin(\delta+\varphi_q) + j\cos(\delta+\varphi_q)] \tag{28}$$

These results may at this point be compared with those of the cylindrical rotor theory. To do so it is only necessary to impose the condition that $Z_d = Z_q = Z_s$, or $X_d = X_q = X_s$. When this is done, the vector $I_2$ vanishes; the points $O'$ and $D$, figure 9, coalesce with point $C$, which then has the co-ordinates

$$\frac{VX_s}{X_s^2 + R_a^2} = \frac{V}{Z_s}\sin\varphi_s$$

and

$$\frac{VR_a}{X_s^2 + R_a^2} = \frac{V}{Z_s}\cos\varphi_s$$

which are the same as those of point $D$, figure 3; and the irregular current locus of figure 9 degenerates to a simple excitation circle of the type shown in figure 3. This circle is indicated in figure 9 as curve $C'$, having its center at $C$ and a radius equal to $LP$.

To construct the current loci corresponding to different values of the excitation voltage $E$, it is only necessary to modify the dimensions of triangle $LPN$ in the desired ratio; otherwise all construction lines remain the same as in figure 9. The effect of varying $E$ from zero to $(7/2)V$, by steps of $V/2$, is shown in figure 10.

Figure 10 brings out vividly some extremely interesting characteristics. One of them, known to be an experimental fact, is that an unexcited motor ($E = 0$) is capable of carrying a theoretical maximum load corresponding to the power circle $P_1$, drawn tangent to the small circle $E = 0$. The remaining power circles, indicated as $P_2$, $P_3$, . . . $P_8$, are all drawn tangent to the curves of constant excitation, and the points of tangency have as their loci the curve marked "stability limit."

Another point of interest is the shape of the excitation curves, which bulge outward to the left, and descend below the zero power circle more than they rise within it. This is a natural consequence of the difference between the action of the machine as a generator (outside the circle $P = 0$) and the action as a motor within the circle $P = 0$. On the right, beyond the stability limit, the curves are flattened when $E$ is large, they develop a concave depression as $E$ becomes smaller, and finally, for sufficiently small values of $E$, this depression becomes a re-entrant loop.

The nature of this re-entrant loop is shown somewhat more clearly in figure 11, where the points $O$ and $O'$ and the small circle on $CD$ as a diameter have the same meaning as in figure 9. The small triangle shown in successive positions in figure 11 is the same as triangle $LPS$, figure 9; for values of $\delta$ from zero to 150 degrees, inclusive, the triangle is cross-hatched; in the remaining positions it is left blank to avoid confusion.

The interesting linkage of the vectors $OO'$, $O'L$, and $LP$ of figure 9 led to the construction of a working model in which the 2 movable vectors were ruled with India ink on strips of transparent sheet celluloid, suitably pivoted together. Placing these links in the positions corresponding to $\delta = 0$, and then moving them bit by bit as the torque angle was gradually increased from zero to 360 degrees, it was possible to photograph the model in successive positions, thereby yielding a film suitable for use in a moving-picture projector. It is quite interesting to observe this animated vector diagram, which has been

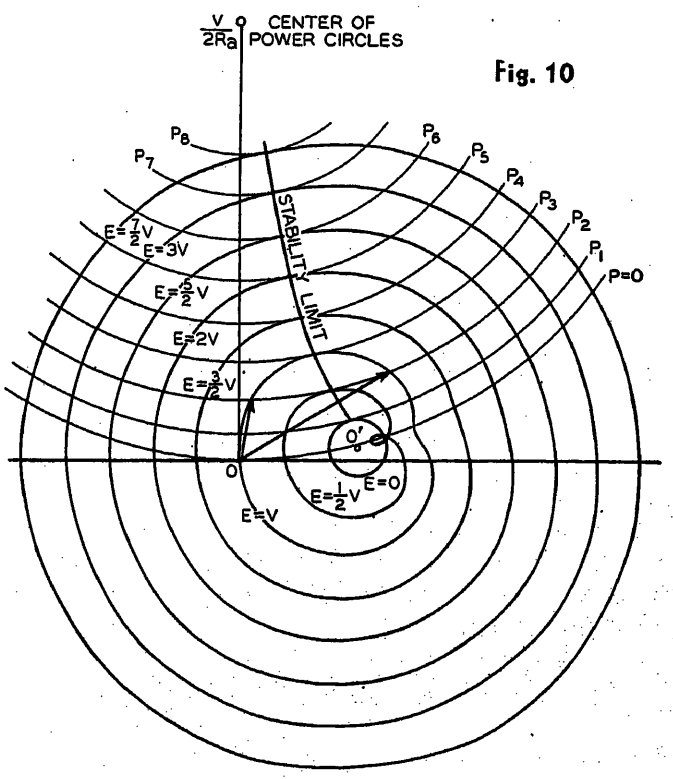

Fig. 10

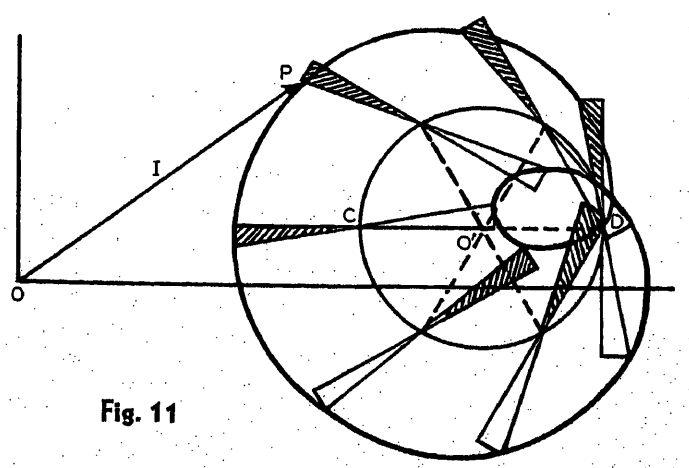

Fig. 11

so made that the excitation locus is drawn as the vectors move.

While no particular importance attaches to the fact, it may be noted that the excitation which marks the point of division between those excitation loops wholly exterior to circle $CD$, and those which lie partly inside it, is determined by the consideration that

$$I_1 = \frac{EZ_q}{X_dX_q + R_a^2} = CD = \frac{V(X_d - X_q)}{X_dX_q + R_a^2}$$

or

$$E = \frac{V(X_d - X_q)}{Z_q} \qquad (29)$$

and that the point of osculation between this limiting loop and the circle occurs at a value of $\delta$ such that $\delta = 180 - \alpha'$.

When the armature current $I(= OP)$, figure 11, is plotted in rectangular co-ordinates as a function of the torque angle $\delta$, curve 1 of figure 12 results. For the sake of comparison, there has been drawn on the same diagram, as curve 2, the variation of armature current when $E = 0$, the ordinates being taken directly from the circle $CD$ of figure 11. Curve 2 will be recognized in terms of the now familiar slip test; it is the envelope of an oscillogram of the armature current taken with the field unexcited and the rotor turned at a speed differing slightly from synchronism.* Curve 1 of figure 12 is then the envelope of the armature current oscillogram taken in the same manner but with the field magnetized to a small fraction of normal excitation. It can be seen from figure 10 that in the case of both curves 1 and 2 the machine is acting as a motor for somewhat less than half of the interval corresponding to slipping a double pole pitch, and is a generator the remainder of the time; but in the case of curve 1, whose polar equivalent has the re-entrant loop projecting outside the zero power circle, the initial motor action is followed by a brief period of generator action, then by another short motoring interval, before the full period of generator action sets in.

One additional feature worthy of consideration is the effect of negative excitation, that is, of reversing the field polarity. It is obvious that if $E$ is reversed in sign, the effect is to reverse the phase of vector $LP$, figure 9; but figure 11 shows that for any position of vector $O'L$ the excitation triangle $LPS$ necessarily appears in 2 diametrically opposite positions, hence the excitation loci with reversed excitation are identical in form with those shown in figures 10 and 11, but the sequence of values is reversed. In any case the locus passes through a region lying within the zero-power circle and motor action is possible.

## The $V$-Curves

The $V$-curves constructed from figure 10 are just as distinctively different from those usually derived from the cylindrical rotor theory as are the excitation curves of figure 10 in comparison with the customary circles (figure 3). The $V$-curves are shown in figure 13, and it will be seen that those portions lying below the stability line $H_2$ resemble quite closely the curves determined by actual test. Curve $H_1$, passing through the lowest points of the curves, defines the condition for unity power factor; unlike the corresponding curve derived from the cylindrical-rotor theory, it does not have a point of minimum excitation at a value of armature current greater than zero; on the contrary, the minimum excitation consistent with unity power factor occurs when $E = V$.

While it is quite true that any discussion of the $V$-curves lying above the stability curve $H_2$ is academic in the sense that these portions of the curves are beyond the practical limits of operation, they still possess several points of theoretical interest. One of them is that the curve corresponding to zero power lies partly *inside* a curve corresponding to a positive amount of (motor) power. This result, when first encountered, was quite unexpected, but it is a consequence of the fact that the

* The slip test seems to have been first developed and used by K. H. Haga; see *L'Eclairage Electrique*, 11, IX, 1909; also article by J. A. Schouten, *Elektrotechnische Zeitschrift*, volume 81, page 877, 1910.

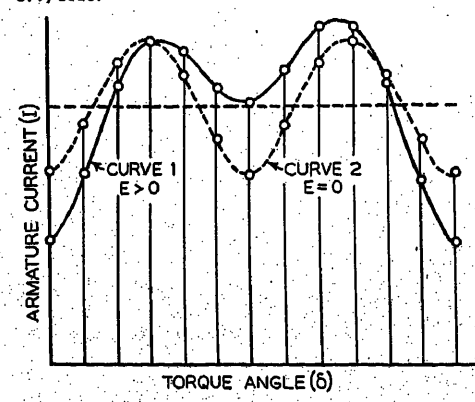

Fig. 12

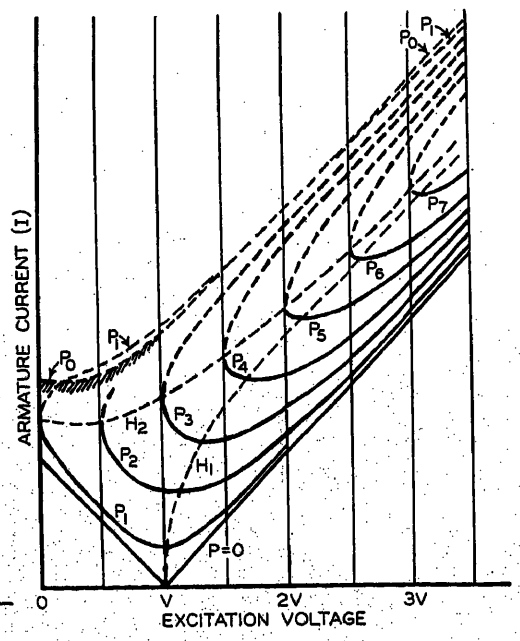

Fig. 13

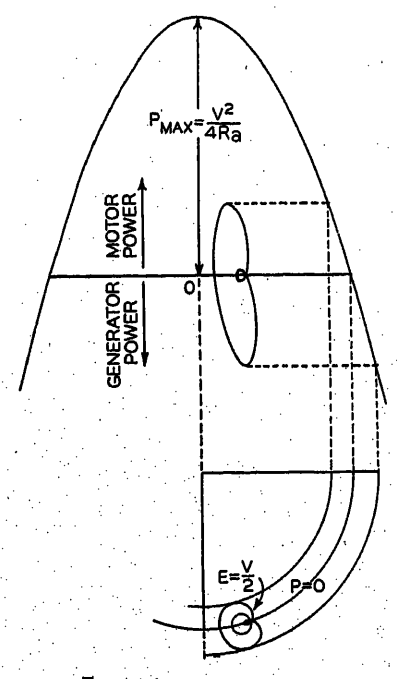

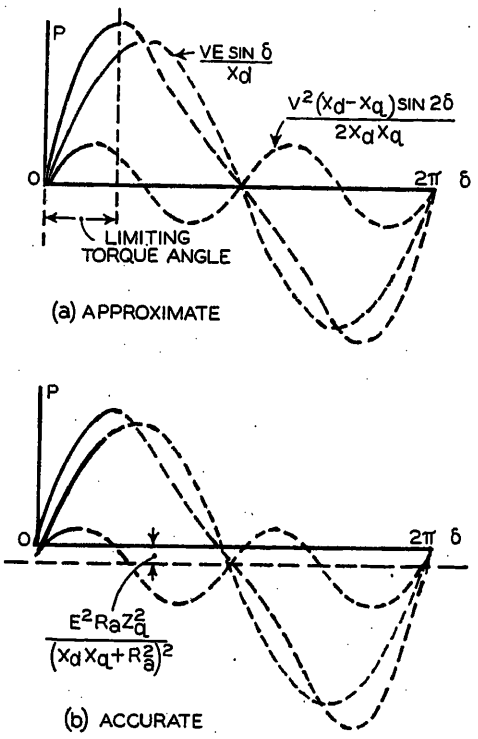

Fig. 14

Fig. 15

excitation loops of figure 10 are indented for values of the torque angle approaching 180 degrees; some indication that this phenomenon actually occurs is to be found in the experimental curves published[3] by Douglas, Engeset, and Jones; the effect is likewise indicated by J. F. H. Douglas's closing remarks in the discussion of that paper.

Perhaps the simplest way to visualize the relations represented by the $V$-curves is to regard them as contour lines of a surface which has as co-ordinates the dependent variable $I$ and the 2 independent variables $E$ and $P$. When this idea is carried back to figure 10, it follows that the power circles $P = 0$, $P_1$, $P_2$, . . . etc., are likewise contour lines of a surface which will be shown to be a paraboloid of revolution; and that the excitation loops are sections of general cylinders having their axes perpendicular to the plane of figure 10. The intersections of the paraboloid and the cylinders then define the armature current and fix the shape of the $V$-curve.

The proof that the power circles of figure 10 are sections of a paraboloid follows immediately from equation 1, which is the equation of a parabola having $I$ and $P$ as the dependent and independent variables, all other quantities, including the phase angle $\varphi$, being constant. The condition $\cos \varphi = 1$ obviously defines the diametral section of the paraboloid, which is shown as figure 14. The vertex of the paraboloid, corresponding to the theoretical maximum power that the machine can develop as a motor, is defined by the condition that the right-hand member of equation 3 cannot become negative, whence $P_{max.} = V^2/(4R_a)$. The base of the paraboloid corresponds to zero motor power ($P = 0$), but the paraboloid extends indefinitely below this particular section, and in that region represents generator power. It is therefore quite simple to visualize conditions when the excitation loops of figure 10 pass outside the zero-power circle; the geometrical meaning is that the excitation cylinder intersects the power paraboloid below the "base" of the latter. The curve of intersection corresponding to $E = (1/2)V$ is shown in vertical projection in figure 14.

## Condition for Unity Power Factor

Inspection of figure 4 shows that when $\varphi = 0$ (i. e., $\cos \varphi = 1$), $\psi = \delta$. Consequently equations 10 and 11 become

$$V \sin \delta = IZ_q \sin (\delta + \varphi_q) \tag{30}$$

$$E - V \cos \delta = -IZ_d \cos (\delta + \varphi_d) \tag{31}$$

from which

$$\sin \delta = \frac{EIX_q}{(V - IR_a)^2 + I^2X_dX_q} \tag{32}$$

$$\cos \delta = \frac{E(V - IR_a)}{(V - IR_a)^2 + I^2X_dX_q} \tag{33}$$

Now it will be seen from figure 9 that when the current vector $I(= OP)$ is in phase with $V$ the algebraic sum of the quadrature components of $I_0$, $I_2$, and $I_1$ is zero. Hence, from equations 26, 27, and 28,

$$I_0 \cos \alpha' - I_2 \cos 2\delta - I_1 \sin (\delta + \varphi_q) = 0 \tag{34}$$

and

$$I \cos \alpha' = \frac{V}{X_dX_q + R_a^2} \cdot \frac{X_d + X_q}{2} \tag{35}$$

$$I_2 = \frac{V}{X_dX_q + R_a^2} \cdot \frac{X_d - X_q}{2} \tag{36}$$

$$I_1 = \frac{EZ_q}{X_dXq + R_a^2} \tag{37}$$

From equations 30 and 31 it is now possible to express $\cos 2\delta$ and $\sin (\delta + \varphi_q)$ in terms of $E$, $I$, and the machine constants, and on substituting all these relations in equation 34 the final result is

$$[(V - IR_a)^2 + I^2X_dX_q]^2 = E^2[(V - IR_a)^2 + I^2X_q^2] \tag{38}$$

which is the complete equation of curve $H_1$, figure 13. It is obviously an equation of the fourth degree, but if it may be assumed that $IX_d$ and $IX_q$ are not large in comparison with $(V - IR_a)$ it is a reasonable approximation to write

$$E^2 = (V - IR_a)^2 + I^2X_dX_q$$

or

$$E^2 = V^2 + I^2X_dX_q \tag{39}$$

which is a hyperbola.

## Condition for Stability

The stability limit indicated in figure 10 (drawn for the region of motor action only), and its counterpart, curve $H_2$ of figure 13, are defined by the condition that the machine is developing the maximum power consistent with the excitation. Hence the stability limit may be found by imposing the condition $dP/d\delta = 0$.

In order to express without any simplifying approximations the power developed ($P$) as a function of the torque angle ($\delta$), use may be made of the concept underlying the 2-reaction theory that the armature winding is subjected to the action of 2 fictitious sets of field poles in addition to the actual poles. One of these fictitious sets of poles lines up with the actual poles and either magnetizes or demagnetizes the latter depending upon the phase conditions; the other fictitious set of poles lies midway between the actual poles. The cross-magnetizing component of armature current, $I_q$, reacts directly with the net flux in the direct axis to produce torque and power, while the direct component of current, $I_d$, reacts directly with the transverse flux. Referring to the particular phase conditions represented in figure 4, it follows that the power developed is given by

$$P = (E - I_dX_d)I_q + (I_qX_q)I_d$$
$$= EI_q - I_qI_d(X_d - X_q) \tag{40}$$

Substituting for $I_q$ and $I_d$ the values given by equations 23 and 24, the complete expression for the power is found to be

$$P = \frac{VEZ_dZ_q^2\cos(\delta-\varphi_d) + VER_aZ_q(X_d-X_q)\sin(\delta-\varphi_q) - V^2Z_dZ_q(X_d-X_q)\sin(\delta-\varphi_q)\cos(\delta-\varphi_d) - E^2R_aZ_q^2}{(X_dX_q+R_a^2)^2} \tag{41}$$

whence the accurate expression for the stiffness or coupling factor is

$$\frac{dP}{d\delta} = \frac{VER_aZ_q(X_d-X_q)\cos(\delta-\varphi_q) - VEZ_dZ_q^2\sin(\delta-\varphi_d) - V^2Z_dZ_q(X_d-X_q)\cos(2\delta-\varphi_d-\varphi_q)}{(X_dX_q+R_a^2)^2} \tag{42}$$

If, in equations 41 and 42 the approximation is made that terms involving $R_a$ may be neglected, and that correspondingly $\varphi_d = \varphi_q = 90$ degrees, they reduce to

$$P = \frac{VE}{X_d}\sin\delta + \frac{V^2(X_d-X_q)}{2X_dX_q}\sin 2\delta \tag{43}$$

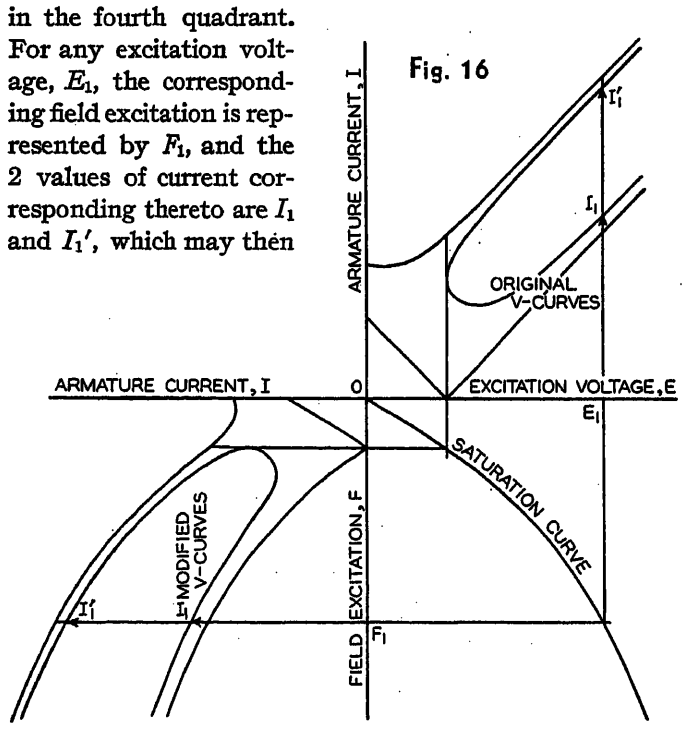
$$\frac{dP}{d\delta} = \frac{VE}{X_d}\cos\delta + \frac{V^2(X_d-X_q)}{X_dX_q}\cos 2\delta \tag{44}$$

which are the same as those derived by Doherty and Nickle by a somewhat different procedure, but which has the disadvantage that it masks some of the finer points of the theory. The differences between the accurate and the approximate expressions are shown graphically in figure 15.

## Effect of Saturation

The full effect of saturation of the magnetic circuit is apparently beyond the scope of any reasonably simple analysis. Approximate methods have been proposed by Doherty and Nickle,[1] and also by Blondel.[4,5] Ordinarily it is sufficiently accurate to assume that the saturation in the armature iron and in the path of the cross field is negligible, and that the significant saturation occurs in the pole cores.[1] These assumptions lead to the conclusion that the reactances $X_d$ and $X_q$ may be treated as constant, from which it follows that in figure 9 the only component vector which is affected by saturation is $LP = (EZ_q)/(X_dX_q + R_a^2)$. Analytically, it is fairly accurate to write Froehlich's equation

$$E = \frac{aF}{b+F} \tag{45}$$



where $a$ and $b$ are constants, and $F$ is the excitation in ampere-turns, which is equivalent to the assumption that the saturation curve of the machine is a hyperbola.

Writing equation 45 in the form

$$F = \frac{bE}{a-E} \tag{46}$$

$F$ may be computed for any assigned value of $E$, and it then becomes possible to correct the $V$-curves of figure 13. The same procedure may be effected quite simply by a purely graphical method in the manner indicated in figure 16. A portion of one of the $V$-curves of figure 13 is reproduced in the first quadrant of figure 16, and the saturation curve is drawn in the fourth quadrant. For any excitation voltage, $E_1$, the corresponding field excitation is represented by $F_1$, and the 2 values of current corresponding thereto are $I_1$ and $I_1'$, which may then be laid off to the left of $F_1$ in the third quadrant. The effect is seen to be to stretch the $V$-curves, the amount of stretch increasing rapidly as the field excitation becomes greater, provided the saturation is sufficient to yield a definite knee to the saturation curve.

# Synchronous Machine with Solid Cylindrical Rotor

By C. CONCORDIA
ASSOCIATE AIEE

H. PORITSKY
Member Am. Math. Soc.

**In this paper a rigorous mathematical analysis of a synchronous machine with solid cylindrical rotor is presented. The analysis embodies a departure from the usual method of considering machine performance by means of circuit theory, and presents an attack from the point of view of field-distribution theory. Such an analysis is desirable, for it provides a definite means of considering the effect of eddy currents in the solid iron rotor.**

IN this paper are presented the development and application of the equations of a cylindrical-rotor synchronous machine, taking into account the eddy currents in the solid iron rotor. The equations for the electromagnetic field in the rotor and air gap due to stator and rotor currents are set up in terms of the magnetic vector potential. These field equations are then related to the circuit voltage equations of a symmetric 3-phase stator winding and a single field winding. The final expressions are solved for the case of symmetric 3-phase currents and constant speed and applied to the calculation of 3-phase short-circuit current, field-current build-up, and flux decay.

In previous treatments of electrical machines, circuit analysis has been the predominant tool. Some of the machine constants have been computed with the aid of coefficients found from flux plots, or by taking into account nonuniform distribution of current in conductors, or the actual circuits replaced by equivalent sinusoidally distributed windings, but always the actual analysis has been of a circuit. In this paper a departure is made by considering the behavior of solid-rotor synchronous machines from the point of view of field-distribution theory. This is particularly desirable since no definite circuit in which the rotor eddy currents must flow presents itself in the actual machine. Previous analyses of solid-rotor machine performance have represented the rotor by an equivalent circuit computed from steady-state eddy-current relations. The present treatment by going back to fundamentals and avoiding the short cuts of the ordinary engineering circuit theory thus presents an opportunity to test the validity of such representation for calculations of transient phenomena. The differential equations governing the field distributions are set up from Maxwell's equations. These are expressed in terms of a magnetic vector potential, introduced in order to correlate them for the rotor and stator, since as ordinarily expressed in terms of electric intensity they are valid only for systems at rest.

## Assumptions

The analysis is based on the following assumptions:

1. The rotor permeability is a constant.
2. The stator permeability is infinite.
3. The presence of slots is neglected in both rotor and stator, a uniform equivalent gap being used.
4. The machine is so long that end effects may be neglected; thus the field is 2-dimensional.
5. The circuit conductors are of negligible depth and are distributed on the rotor and stator surfaces (see also assumption 3).
6. The rotor and stator surface curvatures are small compared to the air gap length.
7. To take account of the end effects and slot leakage, provisional corrective terms (so-called leakage inductances) are included in the circuit equations. In correlating the calculations with test results these terms are found to be very important and it is intended to investigate the effect of eddy currents in the leakage fluxpaths as the next step in the development of the theory.

It may be stated broadly that the present purpose is to compute correctly the effect of eddy currents in the main flux path. The results are here compared to similar calculations for a laminated rotor machine, so that the effect of the solid rotor body may be seen directly.

## The Field Equations

Maxwell's equations for the electromagnetic field, for the present case, and for axes fixed in the medium, are

$$\nabla \times H = 0.4\pi i \tag{1}$$

$$\nabla \times E = -10^{-8} \frac{\partial}{\partial t} B = -\mu 10^{-8} \frac{\partial}{\partial t} H \tag{2}$$

$$\nabla \cdot B = 0 \quad (\nabla \cdot H = 0), \quad \nabla \cdot E = 0 \tag{3}$$

where all quantities are in practical cgs units.

In conducting regions they yield

$$\nabla^2 E = 4\pi\mu 10^{-9} \frac{\partial}{\partial t} i \tag{4a}$$

or, since

$$i = \lambda E, \tag{4b}$$

$$\nabla^2 E = 4\pi\lambda\mu\, 10^{-9} \frac{\partial}{\partial t} E = \beta^2 \frac{\partial}{\partial t} E = \beta^2 pE \tag{5a}$$

while in nonconducting regions

$$\nabla^2 E = 0 \tag{5b}$$

At surfaces (such as the rotor and stator surfaces) where current sheets are flowing, the last equations are replaced

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted October 20, 1936; released for publication December 3, 1936.

C. CONCORDIA is an engineer in the central station department of the General Electric Company, Schenectady, N. Y. H. PORITSKY is in the engineering general department of the same company.

1. For all numbered references, see list at end of paper.

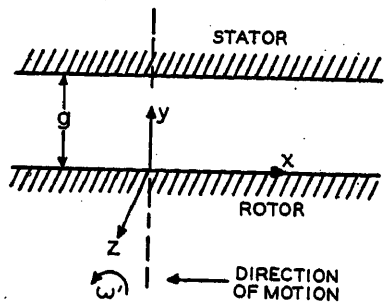

**Fig. 1. Orientation of co-ordinate system in the rotor**

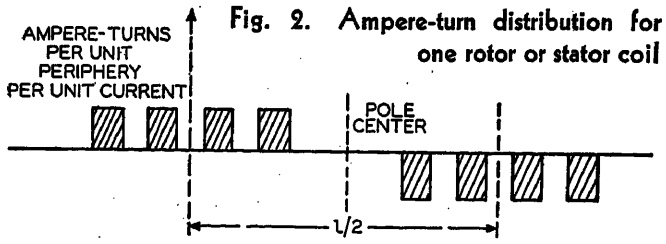

**Fig. 2. Ampere-turn distribution for one rotor or stator coil**

by a boundary condition specifying the discontinuity in the normal derivative of $E$. Thus if along a surface ($y$ = constant) there is a current sheet in the $z$-direction of linear intensity $I$, then:

$$\Delta H_x = -0.4\pi I \tag{6a}$$

where $\Delta H_x$ is the increment or discontinuity in $H_x$.

From equations 6$a$ and 2

$$\frac{\partial}{\partial t}(\Delta H_x) = \Delta \frac{\partial}{\partial t} H_x = -10^8 \Delta \left(\frac{1}{\mu}\frac{\partial E}{\partial y}\right) = -0.4\pi \frac{\partial}{\partial t} I \tag{6b}$$

For long rotors, neglecting end effects, the currents and induced voltages may be assumed to point in the $z$-direction (i.e., to be parallel to the rotor axis) and to be functions only of $x$, $y$; while the magnetic field is normal to the $z$ axis and also independent of $z$. Therefore, let

$$E_z = E = E(x, y)$$

and obtain from equation 2

$$\frac{\partial}{\partial t} H_x = -\frac{10^8}{\mu}\frac{\partial}{\partial y} E \qquad \frac{\partial}{\partial t} H_y = +\frac{10^8}{\mu}\frac{\partial E}{\partial x} \tag{7}$$

This shows that the magnetic field can be expressed in terms of a single (now scalar) function $E$ as far as its changes are concerned. However, this induced electric field $E$ is not invariant under motions relative to the axes employed. Therefore, to compute the proper induced voltages in coils in motion with respect to the field, as e.g., in the stator coils due to the motion of the rotor and to take account of static magnetic fields, we introduce a vector magnetic potential $\psi$ defined in the original system of co-ordinates by the relation

$$\psi = \int_{-\infty}^{t} E dt \tag{8}$$

whereupon equations 2, 3, and 5$a$ may be replaced by

$$H = -\frac{10^8}{\mu} \nabla \times \psi \tag{9}$$

$$\nabla \cdot \psi = 0 \tag{10}$$

$$\nabla^2 \psi = 4\pi\mu\, 10^{-9} i \tag{11}$$

and boundary condition of equation 6$b$ by

$$\Delta\left(\frac{1}{\mu}\frac{\partial \psi}{\partial y}\right) = 4\pi 10^{-9} I \tag{12}$$

The vector potential can be defined by this set of equations and since it points in the $z$-direction still offers the possibility of expressing the magnetic and electric fields in terms of a single scalar function. This function (or rather, $-10^8\ \psi$) may be interpreted as the total flux enclosed between the point in question and a reference point and is in fact perfectly analogous to the flux linkage of circuit theory.

## The Circuit Currents

As explained under the assumptions, it will be assumed throughout the following that a proper mean radius has been chosen both for rotor and stator and that smooth cylindrical surfaces of these mean radii actually replace the slotted rotor and stator surfaces. The armature and field windings are considered to be ribbon-like and to lie on these surfaces. Developing the rotor and stator surfaces along parallel plane surfaces in accordance with assumption 6, and replacing the rotor and stator by semi-

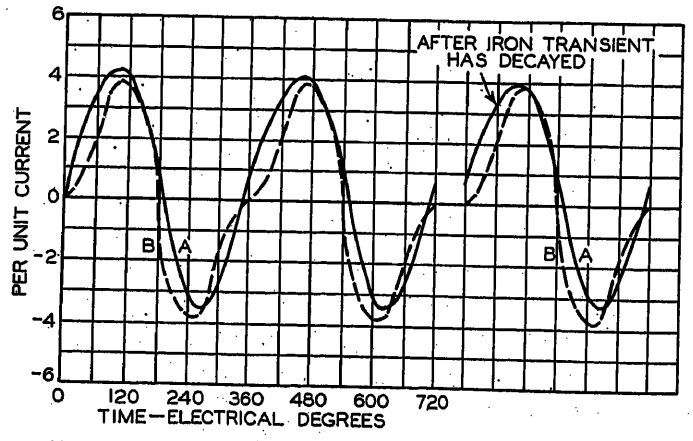

**Fig. 3. Short-circuit current of a turbine generator**
Phase-a switch closed at instant of minimum linkage

Case 1 — $l_s = 0.18$, $\mu = 100$
*A*—With solid rotor *B*—With laminated rotor

infinite blocks and the rotation $\omega'$ about the $z$-axis by an equivalent translation, we arrive at figure 1. Suppose the rotor is rotating with angular velocity $\omega'$. Since Maxwell's equations are for axes fixed in conducting materials, we take $x$, $y$, $z$ axes fixed in the rotor as shown and let $x_1$, $y$, $z$ be similar axes fixed relative to the stator. Thus

$$x_1 = x - r\int \omega' dt \tag{13}$$

Consider one rotor coil with current $I_r$, and several stator coils with currents $I_a$, $I_b$, . . . . The actual ampere-turn distribution due to these currents may be as shown

in figure 2. The rectangular blocks correspond in position to the slots. (It should, of course, be understood that figure 2 is only representative and the number, height, and spacing of the ampere-turn blocks depend on the machine being analyzed.) If the equation of this curve is $a(x)$, then the ampere turns due to rotor current $I_r$ is $I_r a(x)$. The function $a(x)$ is periodic of period $l$, and is odd about the pole center and even about a line midway between adjacent poles.

Hence

$$a(x) = \sum_{n=1,3,5,\ldots} A_n \cos nax, \quad a = \frac{2\pi}{l} \tag{14}$$

Similar ampere turn curves apply to each stator coil. For one of these coils, e.g., we have:

Ampere turns $= I_a\, b\,(x_1)$

where $b$ is again odd and even as above, and

$$b(x_1) = \sum_{n=1,3,\ldots} B_n \cos nax_1 \tag{15}$$

If there are 3 stator coils with similar winding distributions, obtained from that of coil $a$ by translating through 120 and 240 electrical degrees, the total stator ampere turns are

$$I_s(x_1) = I_a b(x_1) + I_b\left(x_1 + \frac{l}{3}\right) + I_c b\left(x_1 - \frac{2l}{3}\right) \tag{16}$$

To find the field, we express the stator ampere turns also in terms of $x$, i.e., in terms of co-ordinates fixed with respect to the rotor and then solve the equations

$$\nabla^2\psi = 0 \tag{17}$$

in the gap, and

$$[\nabla^2 - \beta^2 p]\psi = 0 \tag{18}$$

in the rotor for the vector potential $\psi$, picking the solution which: ($a$) is zero for $y = -\infty$; ($b$) is continuous at the rotor (and stator) surface; and ($c$) is such that at the rotor and stator surfaces $y = 0$, $y = g$, $-\Delta H_x = 0.4\pi$ times the surface current density.

By equation 12 these conditions are:

$$\frac{\partial}{\partial y}\psi\Big|_{y=0+} - \frac{1}{\mu}\frac{\partial}{\partial y}\psi\Big|_{y=0-} = 4\pi 10^{-9} I_r(x) \tag{19}$$

$$-\frac{\partial}{\partial y}\psi\Big|_{y=g-} = 4\pi 10^{-9} I_s(x) \tag{20}$$

The induced electric field $E$ can now be found from the relation

$$E = \frac{\partial}{\partial t}\psi \tag{21}$$

## Coil Voltage Equations

With $E$ known, the voltage equations for the coils may be obtained by adding to the applied voltage the integral of the induced voltage $E$ over the length of the coil. For the rotor coil:

$$RI_r = e_r + Zk\int_0^l a(x)E(x)dx \tag{22}$$

To treat the stator coils which are now moving relative to the $x$, $y$, $z$ system, recall that the function $-10^8\,\psi$ is a measure of the instantaneous flux linking any point.

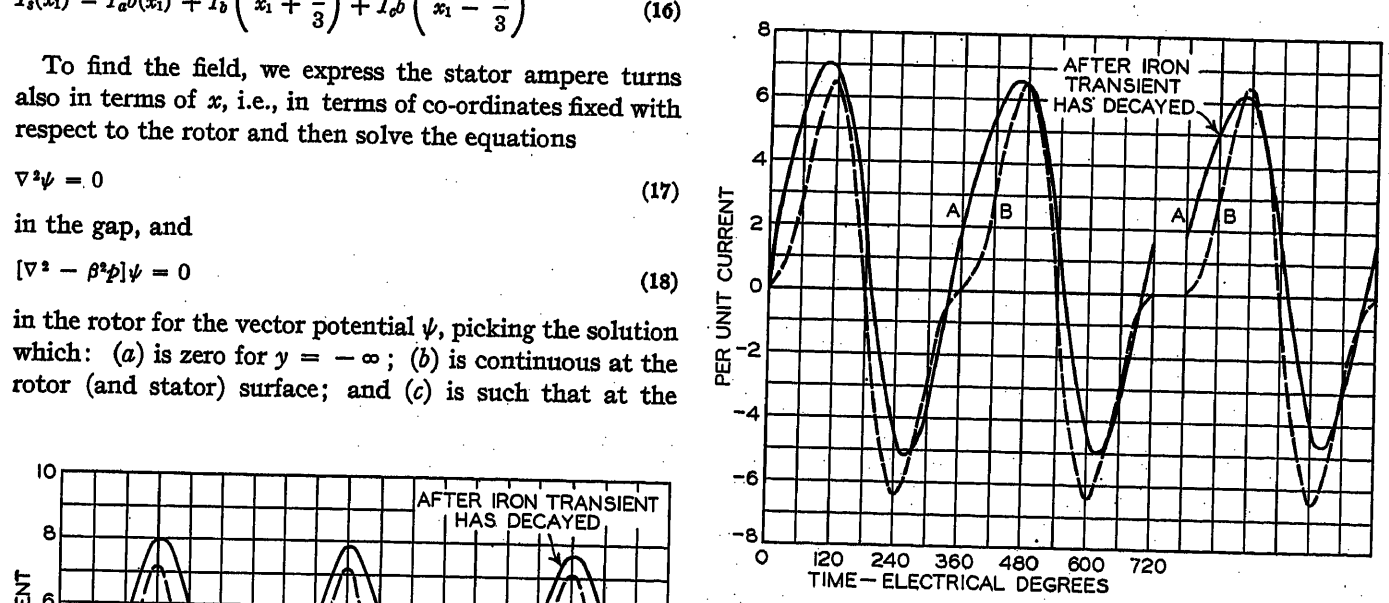

**Fig. 4. Short-circuit current of a turbine generator**

Phase-$a$ switch closed at instant of maximum linkage; other conditions same as for figure 3

**Fig. 5. Short-circuit current of a turbine generator**

Phase-$a$ switch closed at instant of minimum linkage
Case 2—$l_s = 0.09$, $\mu = 100$
$A$ and $B$—Same as for figure 3

Thus to find the induced electromotive force in a coil in motion relative to the $x$, $y$, $z$ system, e.g., a stator coil fixed in the $x_1$, $y$, $z$ axes of the stator, we need only express $\psi$ in terms of $x_1$, $y$, $z$ and then use an equation similar to equation 21:

$$E(x_1) = \frac{\partial}{\partial t}\psi\,(x_1, y, t) \tag{23}$$

For stator coil $a$ the electromotive force equation is

$$r_s I_a = e_a + Zk\int_0^l b(x_1)E(x_1)dx_1 \tag{24}$$

Similar equations hold for the other 2 stator coils.

## Current With Constant Speed

We now assume constant rotor speed. Then from equation 13,

$$\begin{aligned} x_1 &= x - r(\omega' t + \gamma/k) \\ &= x - (\omega t + \gamma)r/k \end{aligned} \tag{25}$$

or

$$ax_1 = ax - \omega t - \gamma.$$

To simplify the solution we represent the applied voltages by the relations

$$\left.\begin{aligned} e_a &= C\,e^{j\omega t} + C'\,e^{-j\omega t} + e_0 \\ e_b &= C\,\alpha^2 e^{j\omega t} + C'\,\alpha\,e^{-j\omega t} + e_0 \\ e_c &= C\,\alpha\,e^{j\omega t} + C'\,\alpha^2\,e^{-j\omega t} + e_0 \end{aligned}\right\} \tag{26}$$

where $\alpha = e^{j2\pi/3} = -1/2 + j\sqrt{3}/2$ is the primitive cube root of unity. In the case of balanced 3-phase sinusoidal voltages, $C$, $C'$ might be chosen so as to yield real voltages $e$ or else $C'$ might be made to vanish and the real parts of the resulting complex voltages and currents identified with the physical voltages and currents.

The stator currents may be expressed in similar form as

$$\left.\begin{aligned} I_a &= D\,e^{j\omega t} + D'\,e^{-j\omega t} + i_0 \\ I_b &= \alpha^2 D\,e^{j\omega t} + \alpha D'\,e^{-j\omega t} + i_0 \\ I_c &= \alpha D\,e^{j\omega t} + \alpha^2 D'\,e^{-j\omega t} + i_0 \end{aligned}\right\} \tag{27}$$

where $D$, $D'$, and $i_0$ are yet to be determined. Then from equation 16 the total stator ampere-turns are:

$$\begin{aligned} I_s(x_1) = De^{j\omega t}&\left[b(x_1) + ab\left(x_1 + \frac{l}{3}\right) + \alpha^2 b\left(x_1 + \frac{2l}{3}\right)\right] + \\ D'e^{-j\omega t}&\left[b(x_1) + \alpha b\left(x_1 + \frac{l}{3}\right) + \alpha^2 b\left(x_1 + \frac{2l}{3}\right)\right] + \\ i_0&\left[b(x_1) + b\left(x_1 + \frac{l}{3}\right) + b\left(x_1 + \frac{2l}{3}\right)\right] \end{aligned} \tag{28}$$

or, after some algebraic reduction utilizing the relation $1 + \alpha^n + \alpha^{2n} = 3$ or 0 according as $n$ is or is not divisible by 3,

$$\begin{aligned} I_s(x) = \frac{3}{2}\sum_{n=0,\,\pm 6,\ldots} B_{|n+1|}\,[De^{j(n+1)(ax-\gamma)-jn\omega t} + \\ D'e^{-j(n+1)(ax-\gamma)+jn\omega t}] + i_0\frac{3}{2}\sum_{n=\pm 1,\,\pm 3,\ldots} B_{|3n|}\,[e^{j3n(ax-\omega t-\gamma)} + \\ e^{-j3n(ax-\omega t-\gamma)}] \end{aligned} \tag{29a}$$

In terms of $x_1$, or referred to the stator,

$$\begin{aligned} I_s(x_1) = \frac{3}{2}\sum_{n=0,\,\pm 6,\ldots} B_{|n+1|}\,[De^{j\omega t+j(n+1)ax_1} + D'e^{-j\omega t-j(n+1)ax_1}] + \\ \frac{3}{2}\sum_{n=\pm 1,\,\pm 3,\ldots} B_{|3n|}\,[e^{j3nax_1} + e^{-j3nax_1}] \end{aligned} \tag{29b}$$

From equation 29 it is seen that if $i_0 = 0$ and $D$ and $D'$ are constants, $I_s$ may be described either as a sinusoidal wave $e^{\pm j(ax-\gamma)}$ stationary relative to the rotor but modulated by a function fixed relative to the stator or as a sinusoidal wave stationary relative to the rotor plus harmonic waves which travel along the rotor with speeds only slightly less than that of the rotor.

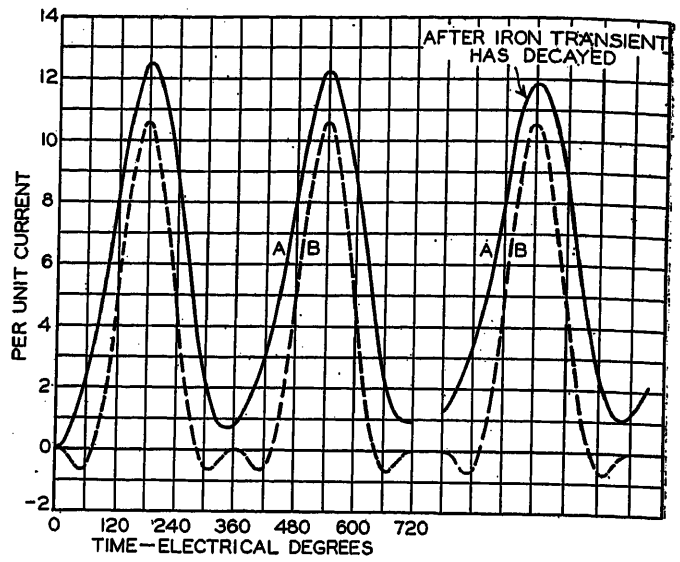

**Fig. 6. Short-circuit current of a turbine generator**

Phase-a switch closed at instant of maximum linkage, other conditions same as for figure 5

Now suppose the $I_r$, $D$, $D'$ vary as $e^{pt}$, i.e., substitute $I_r e^{pt}$ for $I_r$, etc., where the new $I_r$, $D$, $D'$, and $i_0$ are constants, and solve the field equations 17, 18, subject to the boundary conditions expressed by equations 19 and 20, and with the current distributions expressed by equations 14 and 29$a$ simultaneously present. From the resulting $\psi$ find $E$ by means of equations 21 and 23, then substitute in equations 22 and 24 to obtain the circuit voltage equations (see appendix II). Considering only the fundamental components, there result the following 4 linear equations in $I_r$, $D$, $D'$, and $i_0$,

$$\left[(R + Lp) + \frac{KA_1^2}{aQ}\,p\cosh ag\right]I_r + \frac{3KA_1B_1p}{2aQ}\,(De^{-j\gamma} + D'e^{j\gamma}) = e_r \tag{30a}$$

$$\left[\frac{KA_1B_1e^{j\gamma}}{2aQ}\,(p + j\omega)\right]I_r + \left[r_s + \frac{(uq + v)}{Q}\,(p + j\omega)\right]D = C \tag{30b}$$

$$\left[\frac{KA_1B_1e^{-j\gamma}}{2aQ}\,(p - j\omega)\right]I_r + \left[r_s + \frac{(uq + v)}{Q}\,(p - j\omega)\right]D' = C' \tag{30c}$$

$$[r_s + l_0 p]i_0 = e_0 \tag{30d}$$

where

$$K = 2\pi 10^{-8} Z l k$$

$$Q = q\cosh ag + \sinh ag$$

$$q = \frac{\beta}{\mu a}\left[p + \left(\frac{a}{\beta}\right)^2\right]^{\frac{1}{2}}$$

$$u = l_s\cosh ag + \frac{3KB_1^2}{2a}\sinh ag$$

$$v = l_s\sinh ag + \frac{3KB_1^2}{2a}\cosh ag$$

In these equations there have been included field and armature leakage inductances which were omitted from the previous steps of the development in order to avoid undue complication. Solving equations 30 for the currents $I_r$, $D$, $D'$ in terms of the applied voltages, we find

$$\Delta I_r = a^2\{(p^2+\omega^2)(uq+v)^2 + r_s Q\,[r_s Q + 2p(uq+v)]\}e_r - \frac{3}{2}KA_1B_1ap\{r_sQ(Ce^{-j\gamma} + C'e^{j\gamma}) + (uq+v)\,[(p-j\omega)Ce^{-j\gamma} + (p+j\omega)C'e^{j\gamma}]\} \quad (31a)$$

$$\Delta D = -\frac{1}{2}KA_1B_1ae^{j\gamma}[(p^2+\omega^2)(uq+v) + r_s(p+j\omega)Q]e_r + \left[(R+Lp)a^2Q\{(p-j\omega)(uq+v) + r_sQ\} + KA_1^2ap\left\{\frac{1}{2}(p-j\omega)[uQ+\cosh ag(uq+v)] + r_sQ\cosh ag\right\}\right]C + KA_1^2ap\,\frac{3KB_1^2}{4a}(p+j\omega)e^{2j\gamma}C' \quad (31b)$$

$$\Delta D' = -\frac{1}{2}KA_1B_1ae^{-j\gamma}[(p^2+\omega^2)(uq+v) + r_s(p-j\omega)Q]e_r + \left[(R+Lp)a^2Q\{(p+j\omega)(uq+v) + r_sQ\} + KA_1^2ap\left\{\frac{1}{2}(p+j\omega)[uQ+\cosh ag(uq+v)] + r_sQ\cosh ag\right\}\right]C' + KA_1^2ap\,\frac{3KB_1^2}{4a}(p-j\omega)e^{-2j\gamma}C \quad (31c)$$

where

$$\Delta = (R+Lp)a^2\{(p^2+\omega^2)(uq+v)^2 + r_sQ[r_sQ+2p(uq+v)]\} + KA_1^2ap\{(p^2+\omega^2)u(uq+v) + r_s[Q(r_s\cosh ag + up) + \cosh ag\,(uq+v)p]\} \quad (31d)$$

### Electrical Torque

The torque may best be computed by considering the interaction of the stator current with the normal component of flux at the stator surface. We then have in cgs units (ergs),

$$\text{Torque} = -0.1\,rZk\int_0^l I_s(x_1)\,[H_y(x_1)]_{y=g}dx_1 \quad (32)$$

Considering only the fundamental component, we have

$$I_s(x_1) = \frac{3}{2}B_1[De^{j(\omega t+ax_1)} + D'e^{-j(\omega t+ax_1)}] \quad (33)$$

$$[H_y(x_1)]_{y=g} = \frac{0.4\pi A_1}{Q}I_r\sin(ax_1+\omega t+\gamma) + \frac{1.2\pi B_1(\cosh ag + q\sinh ag)}{2jQ}[De^{j(ax_1+\omega t)} - D'e^{-j(ax_1+\omega t)}] \quad (34)$$

If $I_s$ and $H_y$ are real, the expressions above will give the instantaneous torque correctly; however, if they are complex we must either take the real parts before substituting in equation 32 or else add to equation 32 a similar expression obtained by replacing either the field or the current by its conjugate imaginary and take the real part of half the sum.

### The Operational Solution and Its Evaluation

In the above solution time entered as $e^{pt}$ (or $e^{pt\pm j\omega t}$) where $p$ was a constant. The solution can be adapted, however, to the study of arbitrary applied voltages and in particular to various transient problems by regarding them as operational expressions. Thus if the expressions for $I_r$, $D$, $D'$ in equation 31 be considered to operate on the unit function, the result represents the currents obtained when, in the applied voltages, $e_r$, $C$, $C'$ are replaced by $e_r\mathbf{1}$, $C\mathbf{1}$, $C'\mathbf{1}$. According to the modern interpretation of operational calculus the operational solution is obtained merely by superposing the solutions for various values of $p$. More exactly the operational expressions just described are to be viewed as the coefficients of $e^{pt}/p$ in the Bromwich integral.

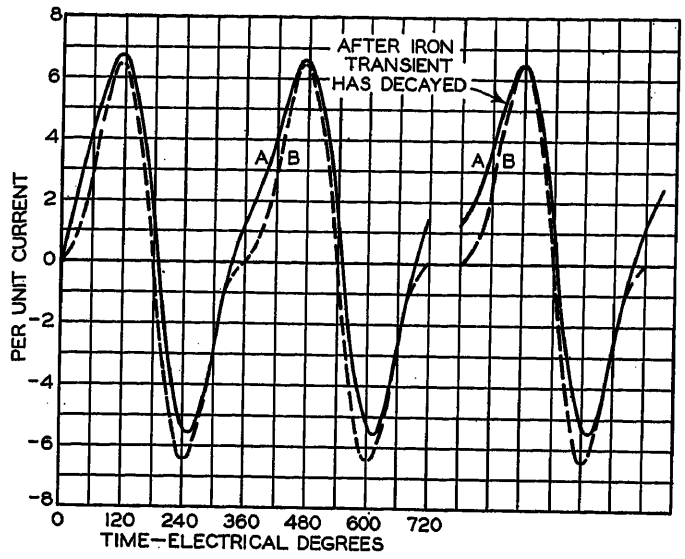

**Fig. 7. Short-circuit current of a turbine generator**

Phase-a switch closed at instant of minimum linkage
Case 3 — $l_s = 0.09$, $\mu = 1{,}000$
*A* and *B*—Same as for figure 3

The equivalent time functions cannot be directly found in tables. To evaluate the operational expressions, note that they are rational fractions in $p$ and $q$, $q$ being the square root of a factor linear in $p$. They may be converted to rational fractional functions of $q$ by expressing $p$ in terms of $q$, as

$$p = \left(\frac{a}{\beta}\right)^2[(\mu q)^2 - 1] \quad (35)$$

If the resulting functions of $q$ are now expanded in partial fractions the result is of the form

$$\sum_n \frac{a_n}{q-q_n}$$

where $q_n$ are the $q$ roots of the denominator $\Delta$ expressed in terms of $q$. Replacing $q$ by its equivalent in $p$, there is obtained

$$f(p) = \sum_n \frac{b_n}{\left[p+\left(\frac{a}{\beta}\right)^2\right]^{\frac{1}{2}} - c_n} \quad (36)$$

In this form $f(p)\mathbf{1}$ may be evaluated (it will be noted that the operational expressions in $p$ correspond to the

integrand of the Fourier rather than the Bromwich integral, and thus operate on $p1$, that is on the unit impulse, rather than on 1) by the formula[1]

$$\frac{1}{(p+\rho)^{\frac{1}{2}}+c}\,1 = \frac{1}{c^2-\rho}\left[c - \rho^{\frac{1}{2}}\,erf(\rho t)^{\frac{1}{2}} - ce^{(c^2-\rho)t}\,erfc(ct^{\frac{1}{2}})\right] \quad (37)$$

where $erf(x)$ is the error function, defined by the equation

$$erf(x) = \frac{2}{\sqrt{\pi}}\int_0^x e^{-x^2}dx$$

and $erfc(x)$ is the complementary error function

$$erfc(x) = 1 - erf(x)$$

As $\Delta$ is a polynomial of the eighth degree in $q$ there will be 8 terms like equation 37 in the final expression for current. Actually it is found that the $q$ roots of $\Delta$ are in general complex so that the value of the error function of $(ct^{\frac{1}{2}})$ cannot be found in tables but must be computed by expansion in series.

It is of interest to indicate the degree of complexity of the result and its simplification as affected by further assumptions:

1. In general an eighth degree equation in $q$ must be solved.
2. If the field resistance $R$ is zero, the degree reduces to 6.
3. If the armature resistance $r$ is zero, only a cubic need be solved.
4. If both field and armature resistance are zero, the denominator is reduced to linear factors.
5. If the $(p\psi)$ terms of the stator induced voltage are neglected in comparison to the $(\omega\psi)$ or "generated" voltage terms, a fourth degree equation must be solved.
6. If in addition to assumption 5 the field resistance is neglected, only a quadratic equation need be solved.

## Applications to 3-Phase Short Circuits

As an example of the application of equations 31 the 3-phase short circuit current of a turbine-generator from no load has been computed. In order to simplify the work the armature and field circuit resistances have been neglected. This should not affect the result very much within the first few cycles.

For this condition the armature current equations may be reduced to:

$$\Delta D = \left[-(p-j\omega)\left\{\left(LaQ + \frac{1}{2}KA_1^2\cosh ag\right)(uq+v) + \frac{1}{2}KA_1^2uQ\right\} + (p+j\omega)\frac{1}{2}KA_1^2\frac{3}{2}\frac{KB_1^2}{a}\right]jVe^{j\gamma} \quad (38a)$$

$$D' = \text{conjugate of } D \quad (38b)$$

where

$$\Delta = (p^2+\omega^2)[La(uq+v) + KA_1^2u](uq+v) \quad (38c)$$

$D$ may be at once evaluated by formula 37 since the 6 $q$-roots of $\Delta$ are evident by inspection.

The current for a solid-rotor machine has been compared directly with that for a similar machine with laminated rotor in order to show clearly the effect of the solid iron.

### Case 1

Figures 3 and 4 show the results for a turbine-generator of normal design. Figure 3 is for short circuit at the instant of zero flux linkage in phase $a$ ($\gamma = 90°$), while figure 4 is for short circuit at the instant of maximum flux linkage in phase $a$ ($\gamma = 0$). The principal constants of this machine are:

Number of poles = 4
Speed = 1,800 rpm
$\pi Z/2l$ = 1.91 = ratio of length to diameter
$2g/l$ = 0.0425 = ratio of air gap to pole pitch
Rotor $\lambda$ = 57,200 (ohms per centimeter cube)$^{-1}$
$L$ = 0.05 per unit (corresponding to field leakage $= \frac{3}{2}\left(\frac{B_1}{A_1}\right)^2 0.05 =$ 0.09 per unit)
$l_s$ = 0.18 per unit
Rotor $\mu$ = 100

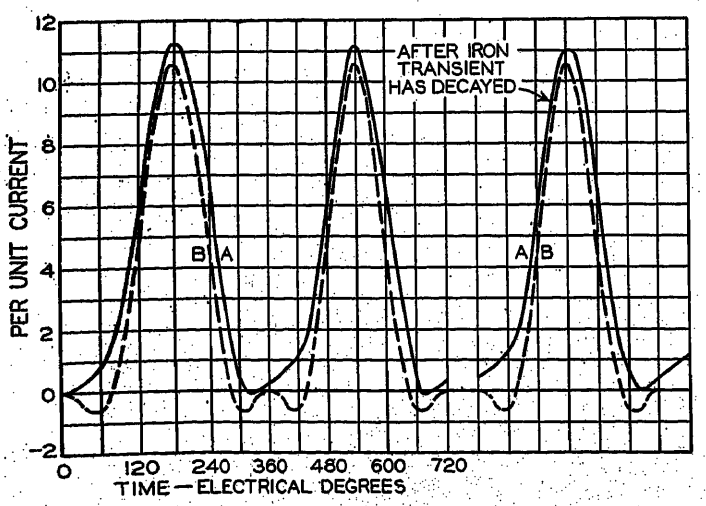

**Fig. 8. Short-circuit current of a turbine generator**

Phase-$a$ switch closed at instant of maximum linkage, other conditions same as for figure 7

### Case 2

Figures 5 and 6 show the effect of reducing the armature leakage $l_s$ to half its previous value, or to 0.09 per unit, all other constants remaining unchanged.

### Case 3

Figures 7 and 8 show the effect of a higher permeability. For this case,

$l_s$ = 0.09 per unit
$\mu$ = 1,000

The expressions for current in the 3 cases given are, with normal full-load current as the unit,

*Case 1.* $l_s = 0.18$, $\mu = 100$

$$i_a = (4.24 - 1.75F_c + 1.02F_s)\cos\gamma - (3.58 + 0.20e^{949t}\,erfc(30.8t^{\frac{1}{2}}))\times \cos(\omega t+\gamma) + (-0.46 + 1.29F_c + 0.12F_s)\cos(2\omega t+\gamma) + (-0.84 + 1.02F_c + 1.75F_s)\sin\gamma + 1.18e^{114.5t}\,erfc(10.7t)^{\frac{1}{2}}\sin(\omega t+\gamma) - (0.33 + 0.12F_c - 1.29F_s)\sin(2\omega t+\gamma) \quad (39a)$$

*Case 2.* $l_s = 0.09$, $\mu = 100$

$$i_a = (5.60 - 3.51F_c + 4.09F_s)\cos\gamma - (5.30 + 0.25e^{1461t}erfc(38.2t^{\frac{1}{2}}))\times \cos(\omega t + \gamma) + (-0.05 + 2.80F_c - 1.41F_s)\cos(2\omega t + \gamma) + (-2.58 + 4.09F_c + 3.51F_s)\sin\gamma + 4.15e^{329t}erfc(18.1t^{\frac{1}{2}})\sin(\omega t + \gamma) - (1.60 - 1.41F_c - 2.80F_s)\sin(2\omega t + \gamma) \quad (39b)$$

*Case 3.* $l_s = 0.09$, $\mu = 1{,}000$

$$i_a = (3.14 - 0.24F_c + 2.43F_s)\cos\gamma - 5.29\cos(\omega t + \gamma) + (2.15 + 0.19F_c - 1.53F_s)\cos(2\omega t + \gamma) + (-0.52 + 2.43F_c + 0.24F_s)\sin\gamma + 0.95e^{3290t}erfc(57.4t^{\frac{1}{2}})\sin(\omega t + \gamma) - (0.42 - 1.53F_c - 0.19F_s)\sin(2\omega t + \gamma) \quad (39c)$$

where $F_c$, $F_s$ are the Fresnel integrals defined by the equations

$$F_c = \int_0^{\omega t} \frac{\cos x\,dx}{(2\pi x)^{\frac{1}{2}}}, \quad F_s = \int_0^{\omega t} \frac{\sin x\,dx}{(2\pi x)^{\frac{1}{2}}} \quad (40)$$

The Fresnel integrals, rather than error functions as might be expected from formula 37, are present since with reasonable values of $\mu$ the significant $q$ roots have very nearly equal real and imaginary components and

$$erf(xe^{\pm j\pi/4}) = \sqrt{2}e^{\pm j\pi/4}\,[F_c(x^2) \mp j\,F_s(x^2)]$$

This relation may be shown as follows:

Let

$$y^2 = \pm jz$$

then at

$$y = xe^{\pm j\pi/4}$$

and

$$z = x^2$$

$$erf(xe^{\pm j\pi/4}) = \frac{2}{\sqrt{\pi}}\int_0^{xe^{\pm j\pi/4}} e^{-y^2}dy = e\sqrt{2}^{\mp j/4}\int_0^{x^2}\frac{e^{\mp jz}dz}{\sqrt{2\pi z}}$$

$$= \sqrt{2}\,e^{\pm j\pi/4}\int_0^{x^2}\frac{(\cos z \mp j\sin 2)dz}{\sqrt{2\pi z}} = \sqrt{2}e^{\pm j\pi/4}[F_c(x^2) \mp jF_s(x^2)]$$

Tables of both the error function and the Fresnel integral are given in reference 7.

The coefficients of the trigonometric functions in equations 39 have been plotted in Figs. 9, 10, 11 so that they may be compared directly to the corresponding coefficients for the laminated-rotor machine without the necessity of considering the instant of short circuit.

For a laminated rotor ($\lambda = 0$) the short-circuit current equations reduce to

CASE 1

$$i_a = 2.23\cos\gamma - 3.59\cos(\omega t + \gamma) + 1.36\cos(2\omega t + \gamma) \quad (41a)$$

CASE 2

$$i_a = 3.11\cos\gamma - 5.28\cos(\omega t + \gamma) + 2.17\cos(2\omega t + \gamma) \quad (41b)$$

CASE 3

$$i_a = 3.08\cos\gamma - 5.27\cos(\omega t + \gamma) + 2.19\cos(2\omega t + \gamma) \quad (41c)$$

These last equations are in the same form as that given by Doherty and Nickle in a previous paper.[2]

Inspection of figures 9, 10, 11 shows the expected reduction in second-harmonic current; a slight reduction

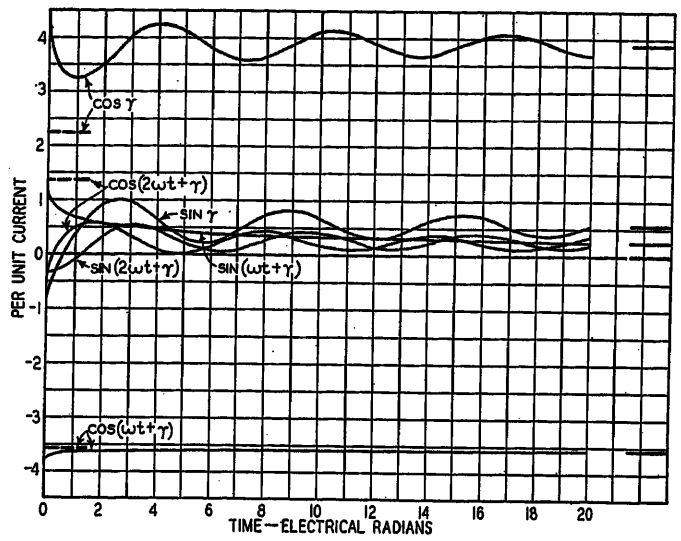

**Fig. 9. Coefficients of trigonometric functions in expression for short-circuit current of solid-rotor turbine generator, case 1**

Dashed lines are for machine with laminated rotor

for the unsaturated case ($\mu = 1{,}000$) and a great reduction for $\mu = 100$, which corresponds roughly to a small degree of saturation. It is interesting to note that the "fundamental" component of current is practically unaffected by the rotor eddy currents and is a function principally of the assumed values of field and armature-leakage reactance. The constant values approached by the coefficients are indicated on the figures and are very closely realized after a few cycles. We observe that although the expressions for current are somewhat complicated the general effect of the rotor eddy currents is simply to produce a more nearly sinusoidal wave shape of current and an effective phase shift. This phase shift is indicated by the presence of sine terms in the current equations 39 in addition to the cosine terms of the laminated rotor case (equations 41). Therefore according to equations 39 there is no switching angle which will completely eliminate the d-c component and result in a perfectly symmetric current.

The results further show that in the laminated-rotor machine the current is not affected appreciably by changes in rotor permeability in the range $\mu > 100$, while even for $\mu = 10$ the change is not great. For example, for $l_s = 0.18$,

$$\mu = \infty,\ i = 2.18\cos\gamma - 3.55\cos(\omega t + \gamma) + 1.37\cos(2\omega t + \gamma) \quad (42a)$$

$$\mu = 10,\ i = 2.46\cos\gamma - 3.64\cos(\omega t + \gamma) + 1.18\cos(2\omega t + \gamma) \quad (42b)$$

for $l_s = 0.09$,

$$\mu = \infty,\ i = 3.07\cos\gamma - 5.26\cos(\omega t + \gamma) + 2.19\cos(2\omega t + \gamma) \quad (43a)$$

$$\mu = 10,\ i = 3.42\cos\gamma - 5.40\cos(\omega t + \gamma) + 1.98\cos(2\omega t + \gamma) \quad (43b)$$

These currents indicate a 2.5 per cent decrease in transient reactance and a 38 per cent decrease (these changes are in

per cent of the unsaturated values; that is, $x_d'$ (sat.)/$x_d'$ (unsat.) = 0.975; $x_d$ (sat.)/$x_d$ (unsat.) = 0.62) in synchronous reactance when compared with the formula of reference 2. Saturation in the main flux path thus has little effect on short-circuit current. This justifies the assumption of infinite stator permeability and shows that in order to account for increased short-circuit current we must include the effect of saturation and eddy currents in the leakage paths. The magnitude of the short-circuit current shown by tests cannot be ascribed wholly to a "subtransient" reactance; it must be accounted for in part by a decrease in transient reactance (or field and armature leakage reactance) due to saturation.

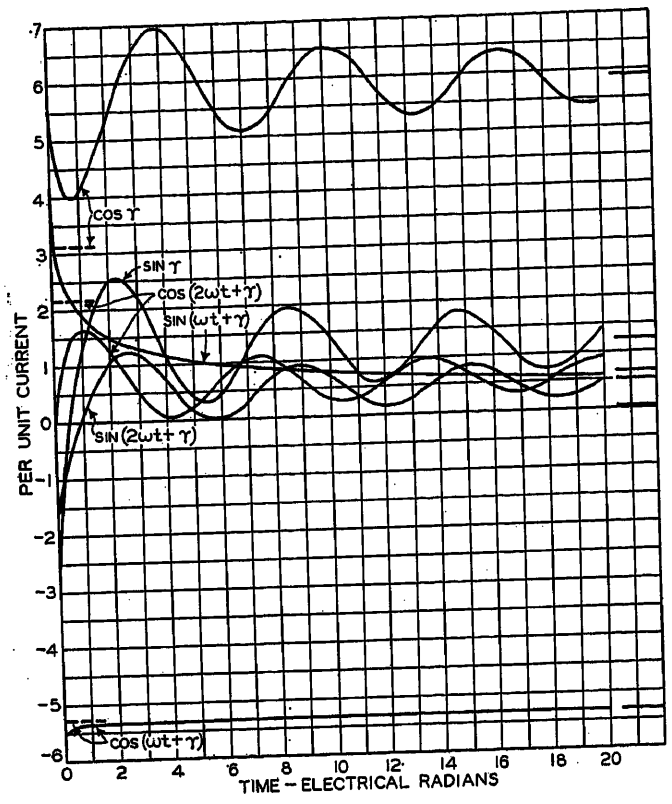

**Fig. 10. Coefficients of trigonometric functions in expression for short-circuit current of solid-rotor turbine generator, case 2**

Dashed lines are for machine with laminated rotor

The subtransient effect has been calculated from figures 9, 10, and 11 by comparing the magnitudes of the oscillatory component of current extrapolated to zero time with those after the iron transient has died out. The subtransient reactance computed on this basis is about 85 or 90 per cent of the transient reactance for $\mu = 100$ and about 97 per cent for $\mu = 1{,}000$. This indicates the importance of taking account of saturation and eddy currents in the leakage paths. In the present work field and armature leakage reactances have been assumed as constant quantities unaffected by the eddy currents, but the effect of eddy currents on the leakage reactances will be shown later.

## Field Current Build-Up

As a second application of the general equations developed in this paper, the field current on sudden application of field voltage (with open-circuited armature) has been determined. The operational expression for field current is:

$$I_f = \frac{Qe_f}{QR + p\left(QL + \frac{KA_1^2}{a}\cosh ag\right)} \tag{44}$$

Taking $\mu = 100$ and solving equation 44, we obtain, for a solid rotor,

$$I_f = 1 + 0.0054\, e^{476t}\, erfc\,(21.8t^{\frac{1}{2}}) - 0.507\,[e^{(-0.214+j0.053i)-j0.130}\, erfc\,(0.452\, e^{j1.44t^{\frac{1}{2}}}) + e^{(-0.214-j0.053i)+j0.130} erfc\,(0.452\, e^{-j1.44t^{\frac{1}{2}}})] \tag{45a}$$

and for a laminated rotor,

$$I_f = 1 - e^{-t/4.24} \tag{45b}$$

Figure 12 shows the computed currents for both a laminated and solid rotor. The curve for the solid rotor case may be approximately represented by an equation of the form

$$I_f = 1 - 0.89e^{-t/4.25} - 0.11\, e^{-t/0.39} \tag{45c}$$

showing that a representation of the solid rotor by an equivalent short-circuited winding is in this case satis-

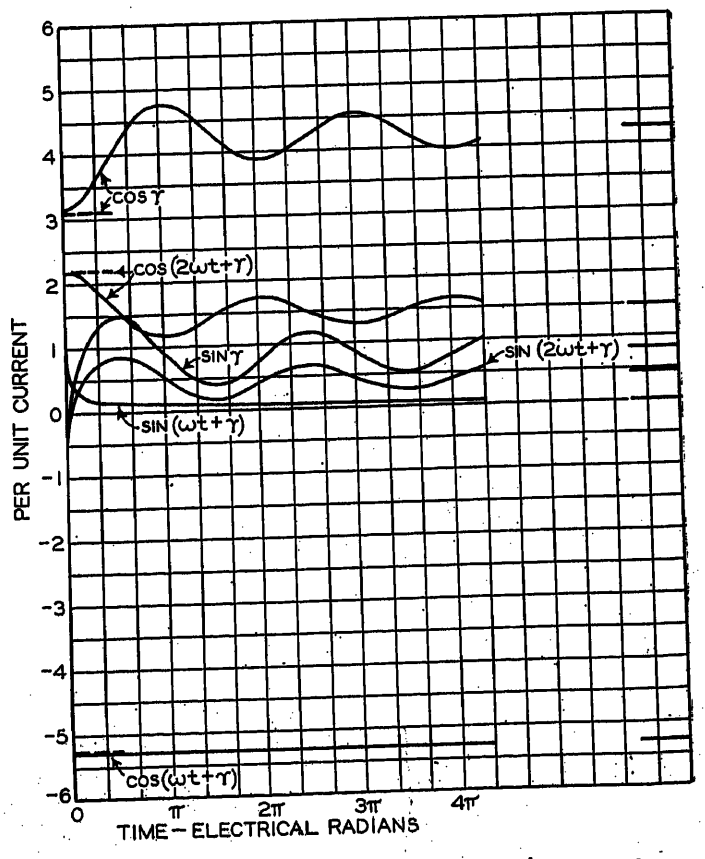

**Fig. 11. Coefficients of trigonometric functions in expression for short-circuit current of solid-rotor turbine generator, case 3**

Dashed lines are for machine with laminated rotor

factory. If the curve of figure 12 is regarded as a single exponential function, the time constant (determined as the time required to reach $(1 - e^{-1})$ of its final value) is 11 per cent less than that for a laminated rotor.

The transient problem of a stationary magnetic circuit linked with a single coil has been presented in a somewhat more simplified form by at least 2 previous writers.[3,4] Here we have taken account of the actual flux distribution in the iron and gap and of the distribution of the field winding, but since the whole effect of rotor eddy currents is seen from figure 12 to be rather small (at least for $\mu > 100$), the results in the case of field build-up show no great discrepancies from their work.

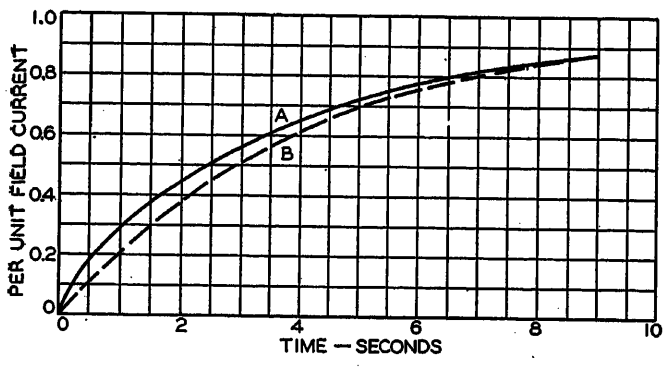

**Fig. 12. Field current of a turbine generator with solid rotor, upon sudden application of field voltage**

*A*—With solid rotor *B*—With laminated rotor

## Flux Decay

A third application of the theory has been to the determination of the rate at which the flux changes following a sudden change in stator current. In the example given here we consider the field to be open-circuited and compute the flux decay following opening of the stator circuit. This will correspond to the decay of the quadrature axis component of flux.

From equation 49 it follows that for sudden changes in stator current there is the operational expression:

$$\psi \text{ is proportional to } \frac{\cosh ag + q \sinh ag}{q \cosh ag + \sinh ag} \qquad (46)$$

Here we are not concerned with the absolute magnitude but only with the shape of the flux-time curve. For a machine for which $2g/l = 0.051$ and $l_s = 0$, we obtain the equations of flux decay (per unit initial value): for $\mu = 1{,}000$,

$$\psi = 0.985\, e^{2.8t}\, erfc\,(4.67t^{\frac{1}{2}}) - 0.007\, erfc\,(0.032t^{\frac{1}{2}}) \qquad (47a)$$

for $\mu = 100$,

$$\psi = 1.048\, e^{2.18t}\, erfc\,(1.48t^{\frac{1}{2}}) - 0.071\, erfc\,(0.10t^{\frac{1}{2}}) \qquad (47b)$$

Note that the flux drops immediately to 98 per cent of its initial value, the drop representing that portion of the quadrature axis flux which did not link the rotor but was only in the air gap. Although the expressions appear rather complicated it becomes evident by inspection that, with less than about 5 per cent error, a very simple relation exists between the flux at any time and the assumed permeability. That is, we may assume the flux to be a function of the product of permeability and time (see figure 13), so that the time constant is inversely proportional to the permeability.

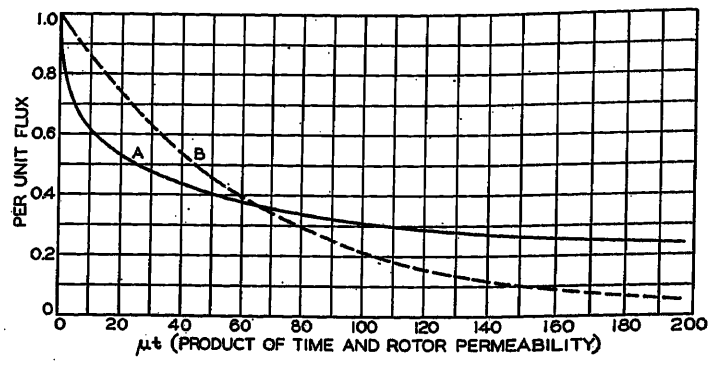

**Fig. 13. Flux decay in a turbine generator, upon sudden removal of armature current**

*A*—Quadrature-axis flux
*B*—Exponential through value $1/e$

## Steady State Impedances

In order to show the relation between the design factors used in the present theory and the circuit constants of ideal synchronous machine theory,[5] we shall find the expression for synchronous impedance. From either equation 30*b* with $p = 0$ and $I_r = 0$, or equation 31*b* with $p = 0$ and $e_r = 0$,

$$\frac{C}{D} = r_s + j\omega\left[l_s + \frac{3KB_1^2}{2a}\left(\frac{\cosh ag + \mu^{-1}\sinh ag}{\mu^{-1}\cosh ag + \sinh ag}\right)\right]$$

Thus

$$\text{Synchronous Reactance} = \omega\left[l_s + \frac{3KB_1^2}{2a}\left(\frac{1 + \mu^{-1}\tanh ag}{\mu^{-1} + \tanh ag}\right)\right]$$

Similarly, from equations 53 the field self-inductance[6] may be recognized as

$$L + \frac{KA_1^2}{a}(\mu^{-1} + \tanh ag)^{-1}$$

## Conclusions

In order to account completely for the observed phenomena of turbine-alternator transient performance and to compute correctly the behavior under specified terminal conditions it may be necessary to include the effects of the slots, of harmonics, of saturation, of hysteresis, of eddy currents, of the rotor surface curvature and of their influence not only on the main flux path but also on the leakage flux paths. For this reason the present paper should be regarded as presenting merely a first step in the complete solution of the general problem. Also, the

final equations of this paper have been established only for the symmetric 3-phase case. This was done because the 3-phase case is susceptible to simple solution by the operational method. However, many problems in addition to those used as examples can be solved by the methods of this paper despite this limitation. For example:

1. Short circuit from any symmetric load condition
2. Sudden (or any) change in field excitation with any symmetric armature load
3. Calculation of flux change, in addition to current and voltage change, for any of the other cases solved
4. Sudden change of load impedance (switching)
5. Prescribed change of terminal voltage.
6. Transient torque and forces for any of the conditions listed above
7. Negative-sequence reactance
8. Current for continuous load pulsation
9. Speed-torque relation for a solid rotor machine running as an induction motor
10. Eddy current losses

From the results of the calculations the following specific conclusions may be drawn:

1. Saturation in the main flux path does not affect appreciably the magnitude of the short-circuit current.
2. Eddy currents in the main body of the solid rotor may account for a 10 to 15 per cent reduction in subtransient reactance below transient reactance.
3. The larger difference between transient and subtransient reactance shown by tests must be due to (*a*) retaining ring saturation and eddy currents; (*b*) tooth tip saturation (and eddy currents in case of the rotor teeth).
4. Eddy currents in the solid rotor may account for about a 10 per cent decrease in the apparent field open circuit time constant.
5. The effective time constant of the quadrature axis flux varies inversely as the rotor permeability (at least in the range of permeability greater than 100).

## Appendix I—Symbols and Nomenclature

$H$ = magnetic intensity vector
$i$ = current-density vector
$E$ = electric-intensity (voltage-gradient) vector
$B$ = magnetic flux-density vector
$t$ = time
$\lambda$ = specific conductivity
$\mu$ = permeability
$\beta^2 p = \beta^2 \frac{\partial}{\partial t} = 4\pi\lambda\mu 10^{-9} \frac{\partial}{\partial t}$
$x, x_1, y, z$ are co-ordinate directions as shown in figure 1; $x$ and $x_1$ tangential, $y$ radial, and $z$ axial; $x$, $y$, $z$ are fixed in the rotor while $x_1$ is fixed in the stator
$\psi$ = vector magnetic potential
$\omega'$ = angular velocity of rotor (see figure 1)
$r$ = radius of rotor
$I$ = coil currents; $I_r$ rotor coil current; $I_a$, $I_b$, . . . stator coil currents; $I_s$ resultant of all stator ampere-turns
$l$ = length along rotor surface of $2\pi$ electrical radians or twice pole pitch
$a = 2\pi/l$
$A_n$, $B_n$ are coefficients of Fourier series for the ampere turn distributions
$R$ = rotor-coil resistance
$L$ = rotor coil leakage inductance
$r_s$ = stator coil resistance
$l_s$ = stator coil leakage inductance in the direct (or quadrature) axis
$l_0$ = zero phase sequence stator coil leakage inductance
$e$ = applied voltage; $e_a$ = voltage applied to coil $a$; $e_r$ = voltage applied to rotor coil, etc.
$k$ = number of pairs of poles
$\omega$ = electrical angular velocity = $k\omega'$
$\gamma$ = angle by which the rotor "leads" the stator
$C, C', e_0$ = coefficients of complex components of stator terminal voltage
$D, D', i_0$ = coefficients of complex components of stator current
$g$ = air-gap length
$Z$ = machine axial length
$K = 2\pi 10^{-9} Z l k$
$q = \frac{\beta}{\mu a}\left[p + \left(\frac{a}{\beta}\right)^2\right]^{\frac{1}{2}}$
$Q = q \cosh ag + \sinh ag$
$u = l_s \cosh ag + \frac{3KB_1^2}{2a} \sinh ag$
$v = l_s \sinh ag + \frac{3KB_1^2}{2a} \cosh ag$
$2V$ = magnitude of open-circuit armature phase voltage

## Appendix II

The solutions of the field equations 17 and 18, subject to the boundary conditions expressed by equations 19 and 20, and considering only the fundamental components, yield:
At the rotor surface, $y = 0$,

$$\psi = \frac{-4\pi 10^{-9} e^{pt}}{\left[\frac{\sqrt{\beta^2 p + a^2}}{\mu a} + \tanh ag\right] a \cosh ag} \times \left[I_r A_1 \cos ax \cosh ag + \frac{3}{2} B_1 (De^{j(ax-\gamma)} + D'e^{-j(ax-\gamma)})\right] \quad (48)$$

At the stator surface, $y = g$,

$$\psi = \frac{-4\pi 10^{-9} e^{pt}}{\left[\frac{\sqrt{\beta^2 p + a^2}}{\mu a} + \tanh ag\right] a \cosh ag} \times \left\{I_r A_1 \cos(ax_1 + \omega t + \gamma) + \frac{3}{2} B_1 \left[\cosh ag + \frac{\sqrt{\beta^2 p + a^2}}{\mu a} \sinh ag\right] \times [De^{j(ax_1+\omega t)} + D'e^{-j(ax_1+\omega t)}]\right\} \quad (49)$$

From equation 48 the electric intensity at the rotor surface is simply

$$E_r(x) = \frac{\partial}{\partial t}\psi = p\psi \quad (50)$$

while, from equations 49 and 23, at the stator surface

$$E_s(x_1) = \frac{\partial}{\partial t}\psi(x_1) = \frac{-4\pi 10^{-9} e^{pt}}{\left[\frac{\sqrt{\beta^2 p + a^2}}{\mu a} + \tanh ag\right] a \cosh ag} \times \left\{\frac{I_r A_1}{2}[(p + j\omega)e^{j(ax_1+\omega t+\gamma)} + (p - j\omega)e^{-j(ax_1+\omega t+\gamma)}] + \frac{3}{2} B_1 \left[\cosh ag + \frac{\sqrt{\beta^2 p + a^2}}{\mu a} \sinh ag\right] \times \left[D(p + j\omega)e^{j(ax_1+\omega t)} + D'(p - j\omega)e^{-j(ax_1+\omega t)}\right]\right\} \quad (51)$$

# Electrical Characteristics of Suspension-Insulator Units

By C. L. DAWES
FELLOW AIEE

REUBEN REITER
ASSOCIATE AIEE

**Effects of humidity, corona, and mechanical stress on the electrical characteristics of porcelain and glass suspension-insulator units are shown in this paper. Moisture, alone and combined with corona, is found to produce surface deposits which cause hysteresis effects in the power, power factor, and capacitive characteristics, and mechanical stress is found to reduce the power, power factor, and capacitance. The effect of stress is reduced where soft metal is used in place of cement in assembling the unit.**

ALTHOUGH for a number of years the flashover and puncture characteristics of suspension-insulator units have been investigated extensively, very little study has been made of their power-loss, power-factor, and capacitance characteristics. The only published work of any importance is that of Draeger.[1] The extent and value of his measurements were limited, however, by the bridge facilities available to him at the time (1925). Moreover, he did not take into consideration the effect of humidity on the characteristics, which has been found by the authors to be the factor which, with corona, has the greatest effect on the electrical characteristics of the insulators. Furthermore, the authors have been able to carry the investigation much further than Draeger and to relate "corona hysteresis" to the combined effects of humidity, corona, and a microscopic surface deposit produced by corona.

The insulators tested were 10-inch porcelain disk-type suspension insulators supplied by the Locke Insulator Corporation, and a Pyrex 776, 10-inch glass disk-type suspension insulator supplied by the Corning Glass Works.

## Summary

1. The electric and dielectric circuits of a suspension-disk insulator consist of the porcelain and cement between cap and pin which is practically invariable, and the capacitance between the surfaces of the shell in series combinations with the surface resistance. This circuit is highly variable due to changes in surface resistance.

2. The surface resistance is a function of adsorbed moisture and decreases with increase in absolute humidity and increases with decrease in absolute humidity. The surface resistance also decreases with corona formation.

3. At any fixed voltage the electrical characteristics of the insulator vary with time. This is due to the change in surface resistance caused by Joule heating and to "island formation." The resistance may increase with time or it may decrease, depending on the part of the test cycle at which it is operating.

4. The electric and dielectric characteristics of the insulator are functions of the absolute humidity or of the absolute amount of moisture in the atmosphere.

5. Corona forms at lower voltage with increasing values of absolute humidity.

6. The power factor is practically a linear function of the absolute humidity.

7. Corona reacting with oxygen, nitrogen, and moisture of the atmosphere forms acidic compounds which deposit on the insulator surface, causing change in the surface resistance.

8. The combined action of the corona, acidic compounds, and the sputtering of the metal of the cap and pin form semipermanent conducting microscopic "island" deposits which cause a decrease in surface resistance. Such island deposits can be removed only by vigorous rubbing.

9. The moisture film on the insulator surface together with the island deposits causes a hysteresis effect in the electrical characteristics of the insulator.

10. The changes in surface resistance also vary the amount of shell capacitance connected between cap and pin. Hence the total insulator capacitance increases with decrease in surface resistance and *vice versa*.

11. The electric and dielectric characteristics of the insulator are not greatly affected directly by temperature, but are affected indirectly in that absolute humidity of air is a function of temperature.

12. Mechanical stress for the most part causes a decrease in the power factor and capacitance due to the compression of the cementing material. After such material has a permanent "set" further change is slight and with glass insulators the characteristics remain independent of further stress.

## Method of Measurement

The electrical characteristics were measured by means of the mutual-inductance type of high-voltage bridge developed and used in the high-voltage laboratories at Harvard University. The simplified diagram of connections of the bridge and the test insulator is shown in figure 1.

In order to facilitate the connection of the high-voltage lead and the low-voltage shielding, the insulator was tested in an inverted position. No differences in effects between this position and the upright one were noted.

The details of the bridge connections have already been published.[2] The shielding $S_2$ surrounding the low-voltage lead *ab* to the specimen is balanced to the

A paper recommended for publication by the AIEE committee on power transmission and distribution. Manuscript submitted August 17, 1936; released for publication November 10, 1936.

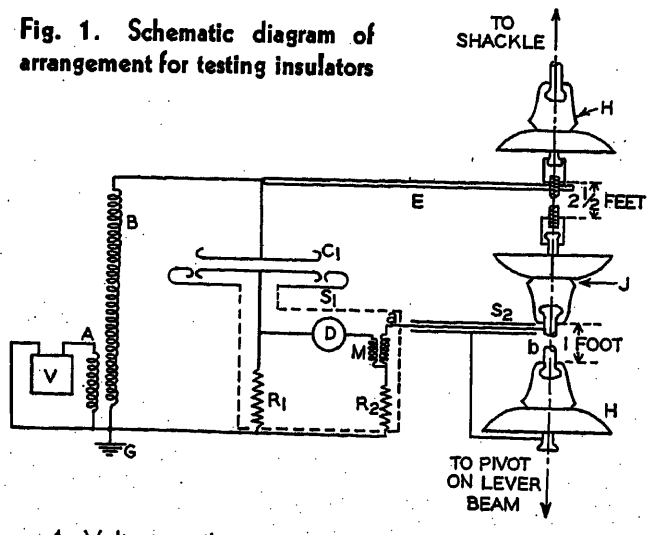
The authors wish to express their thanks to K. A. Hawley, formerly of the Locke Insulator Corporation, Davidge H. Rowland, and C. W. Roberts, both of the Locke company, and Dr. J. T. Littleton of the Corning Glass Works for their co-operation in the conduct of this research. The authors also are indebted to Dean Harry E. Clifford of the graduate school of engineering, Harvard University, for his assistance and to Victor G. Mooradian and Dr. Carl Shapiro of the metallurgical department for their assistance in the microphotography.



same potential as the lead *ab* so that capacitive effects between them are eliminated. The bridge is provided with an amplifier to give it the necessary sensitivity, and filters to eliminate harmonics from the circuit.[3]

## Equivalent Circuits of Disk Insulators

In figure 2*a* is shown the cross section of a typical insulator unit and the approximate electrical circuits. There is a capacitance $C$ of approximately 30 micro-microfarads between the cap and the pin. The dielectric is the porcelain, and the cement used to fasten the cap and pin in place. Such dielectrics obviously involve dielectric loss so that in the equivalent circuits of figures 4*b* and 4*c*, the capacitance $C$ is shown shunted by a resistance $R$ to simulate this loss. The dielectric characteristics of the porcelain and the cement remain practically constant under all conditions, although a slight increase in power factor with increase in voltage may be attributed to the ionization of occluded gases. The values of $C$ and $R$ may be changed slightly by mechanical stress.

The glazed porcelain shell may be considered as consisting of a number of capacitances $C'$ between the upper and lower surfaces. If the surface resistance were infinite, the capacitances $C'$ would have very little effect on the total insulator characteristics. These capacitances are, however, connected in the insulator circuit by the surface resistance $R'$ which is caused by moisture and other conducting deposits on the surface, as well as by corona which is also conducting. As will be shown later, the surface resistance $R'$ depends on the humidity and the voltage, and it has a very large effect on the insulator characteristics. Hence the effects of the shell capacitance depend on the surface resistance and they will vary with changes in the surface resistance.

**Fig. 1. Schematic diagram of arrangement for testing insulators**

T-circuits and this combination is connected in parallel with $C$ and $R$ to give the equivalent circuit of the entire insulator. The entire diagram of figure 2*b* may be simplified to that of *c* in which the over-all effect of the capacitances $C'$ and the surface resistance $R'$ for any one set of conditions are replaced by the capacitance $C_1$ and the resistance $R_1$. The variation of the surface resistance $R'$ with humidity, corona, and elapsed time of test for the most part accounts for the changes in the characteristics of the insulator.

## Time Lag

In making the measurements of power, power factor, and capacitance, it was found that very much higher values for these factors were obtained with decreasing values of voltage than with increasing values, thus giving a hysteresis effect. This effect is illustrated in figure 3 as well as in figures 4, 5, 6, and 7. It was also found that the hysteresis effect increased with absolute humidity, as is shown in figure 5.

Moreover, in making the measurements, it was found that the values of power, power factor, and capacitance for any definite voltage were not fixed, but varied with time. At low humidity and with increasing values of voltage, these factors increased with time. At high humidity and with increasing values of voltage, at low voltage, they decreased with time, but after corona formed they increased with time due to the surface deposits to be described later. These effects are illustrated in figures 3 and 4.

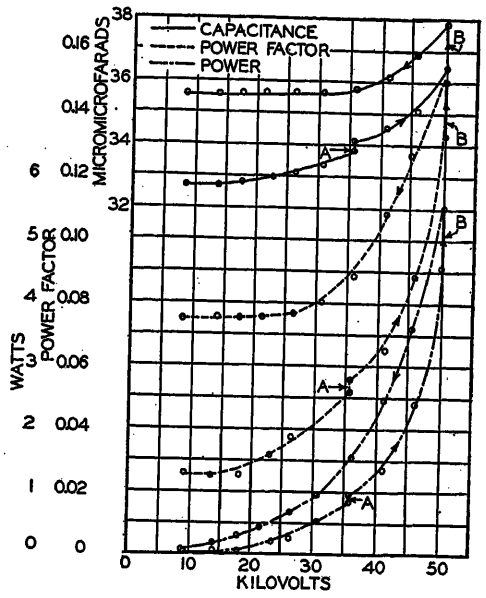

**Fig. 3. Characteristics of porcelain insulator, showing time lag and hysteresis effects at 60 cycles and 20 degrees centigrade**

*A*—Lapse of time of 10 minutes

*B*—Lapse of time of 2 hours

In figure 3 the increases in power, power factor, and capacitance for an interval of 10 minutes at 35 kv are shown. Also, the same effects are shown for a 2-hour interval at 50 kv, but the increases are much greater.

Careful study of this phenomenon showed that the values of power, power factor, and capacitance varied almost as does a direct current in an inductive circuit with resistance in series when a continuous voltage is suddenly switched across it, or when such a circuit is short-circuited. The change is at first rapid but the rate of change diminishes with time. It seemed that theoretically steady conditions would be reached only after infinite time. To reach the steady condition for each bridge balance would therefore require a prohibitively long time. Moreover, in order to interpret the phenomena, it is not necessary that the exact values corresponding to the ultimate steady state be obtained. Hence, in making the measurement it was decided to choose such values of time as would give from 85 to 90 per cent of the difference between the ultimate and initial readings.

The relationships among the characteristics obtained at the different values of time are shown in figure 4, *A* and *B* giving those for increasing values of voltage, and *C* and *D* giving those for decreasing values of voltage. In all the figures the characteristics *aa'* give the values of power factor which would be obtained if the measurement were made instantaneously. The characteristics *bb'* give the values of power factor which would be obtained if the measurement were made at infinite time. The characteristics *cc'* are those actually obtained and they lie at approximately 85 to 90 per cent of the distance from *aa'* to *bb'*. As will be shown later, these time-lag effects are due to the humidity of the atmosphere and to the accumulation of a deposit on the insulator surface.

It was found that the value of the time necessary to obtain curves *cc'* was not constant but varied with the voltage, the humidity, and the amount of corona formation. In a large measure, the time was determined by experience combined with watching the rate at which the bridge balance changed. The approximate values of time are as follows:

| Kilovolts Across Insulator | Elapsed Time Before Taking Reading, Minutes |
|---|---|
| 2 | 5 to 20 |
| 10 | 5 to 20 |
| 20 | 10 to 25 |
| 30 | 15 to 45 |
| 40 | 25 to 80 |
| 50 | 30 to 120 |

## Electrical Characteristics and Absolute Humidity

Early in the research it was found that the electrical characteristics of the insulators were, in a large measure, functions of the humidity. First it was attempted to relate the characteristics to the relative humidity, but there seemed to be no remote relationship, even, between them. Further investigations showed that the characteristics were closely related to both specific humidity and to absolute humidity. (Specific humidity is the actual amount of moisture per unit weight of dry air.) In this paper absolute humidity in grains of moisture per cubic foot of air is used (7,000 grains of moisture equal one pound).

In the authors' experimental work there were little means for controlling the humidity so that usually it was necessary to await natural changes in the laboratory. As a rule, high values of humidity occurred in summer and low values on cold winter days.

In figure 5 are shown the power-factor characteristics for a porcelain insulator with increasing and decreasing values of voltage for 3 different values of absolute humidity, $s = 2.6$, $s = 4.48$, and $s = 7.56$.

The very low value (2.6) was obtained on a cold,

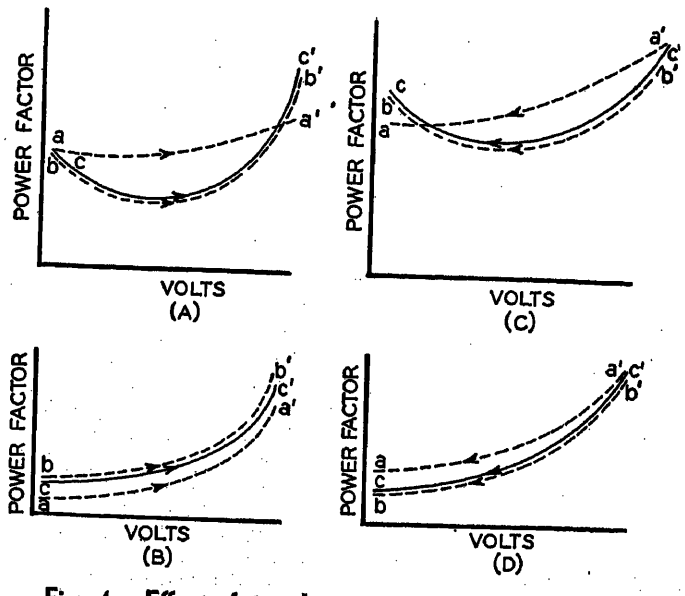

**Fig. 4. Effect of time lag on insulator characteristics**

*A*—High humidity, increasing voltage
*B*—Low humidity, increasing voltage
*C*—High humidity, decreasing voltage
*D*—Low humidity, decreasing voltage

dry winter day; the intermediate value (4.48) was obtained on a cool, autumn day, and the high value (7.56) was obtained during a hot, muggy day in July. Similarly, in figure 6 are shown the capacitance characteristics for the same insulator at these same 3 values of absolute humidity. In figure 7 is shown the power-factor characteristic of a glass insulator obtained at an absolute humidity of 4.7. It may be noted that with all the characteristics of figures 5, 6, and 7, the values for decreasing voltage are greater than for increasing voltage.

It will also be noted in figure 5 that with the low value of absolute humidity, $s = 2.6$, the power factor increases continuously with increase in voltage and decreases continuously with decrease in voltage. With the intermediate value of absolute humidity, $s = 4.48$, the power factor remains constant until 35 kv and then increases. This increase in power factor is caused by the corona which forms at approximately 35 kv. With the high value of absolute humidity, $s = 7.56$, the power factor first decreases rapidly with increase in voltage, reaches a minimum at approximately 25 kv, and then increases due to corona formation. The characteristic for descending values of voltage is similar, except that it lies above the first characteristic.

These characteristics are typical. With low values of absolute humidity, the power factor always increases with voltage, rising more rapidly after corona formation. With larger values of absolute humidity, the power factor at first decreases with increase in voltage until corona forms, when it increases. It is also found that with large values of absolute humidity the difference between the ascending and the descending characteristic increases (see figure 5). Corona forms at lower values of voltage with increasing values of absolute humidity. For example, in figure 5 corona formation begins at 34 kv when $s = 4.48$, and at 26 kv when $s = 7.56$ (also see figure 12).

## "Island" Deposits on Surface

It is well known that corona activates the air and causes the oxygen, nitrogen, and water vapor to combine and form weak nitric acid. This acid deposits on the insulator surface near the cap and pin to form initially conducting spots or small islands. The voltage gradient over the surface causes arcs to snap from island to island, vaporizing the deposits and scattering them over a wider area. At high voltages these arcs become longer and brighter and more explosive scattering of the vapors occurs. In the authors' opinion it is these arcs which in large measure cause radio interference.

These acidic islands are more or less conducting and it is in part due to their formation that the power factors, etc., increase with time.

Several factors led to the belief that, in addition to the acidic spots, a more or less permanent deposit must form on the insulator surface, but it was some time before this fact could be substantiated. After the voltage had initially been increased to its maximum value and then lowered, the power, power factor, and capacitance were greater than with increasing values of voltage, as is shown by the descending voltage characteristics, figures 5, 6, and 7. In subsequent tests these quantities always remained above their initial values, and, in fact, they increased continuously with continued application of voltage, particularly if the absolute humidity were large. However, if the surface were cleaned, vigorous wiping

being necessary, the characteristics returned to the initial values.

Carefully polished surfaces of metals were then subjected to a corona discharge with moisture present and island formations could be readily seen under the microscope. (One of the authors has found that corona makes a very effective etching agent in micro-

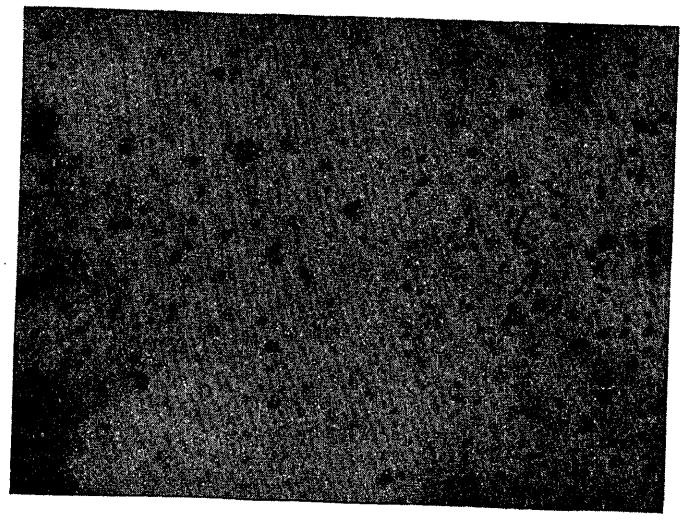

**Fig. 8. Microphotograph of deposit near pin on porcelain insulator caused by corona and moisture**

Magnification 120 diameters

photography.) Later, by means of a dark-field type of microscope, it became possible to detect the island deposits on porcelain, and a microphotograph taken near the pin is shown in figure 8. The examination of the surface is made difficult by the fact that microscopes are not adapted to bring to the objective the portions of the porcelain surface near the cap and pin, and thecurved surfaces make microphotography very difficult. Hence, it is necessary to break the porcelain without disturbing the deposits, and to select suitable pieces for examination. It is the island deposits such as are shown in figure 8 that cause the permanent changes in the insulator characteristics to which reference has already been made.

The authors have made several attempts to learn more about the nature of the deposit. It can be removed by wiping the surface vigorously and, as has already been stated, the characteristics of the insulator return to their initial values. The deposit is a very thin film consisting of microscopic islands, some of which are crystalline in form. The film is so thin and so difficult to remove that, so far, a chemical analysis has not been possible. The authors believe, however, that it consists of the nitric-acid deposit already discussed in combination with the metal of the cap or pin which has been deposited by the sputtering effect of the corona. This is substantiated by some experiments made on pieces of porcelain placed within a corona field, with moisture present. If a sheet of glass was interposed between the high-voltage electrode and the porcelain, no deposit occurred. If, however, moist air is interposed between the high-voltage metal electrode and the sur-

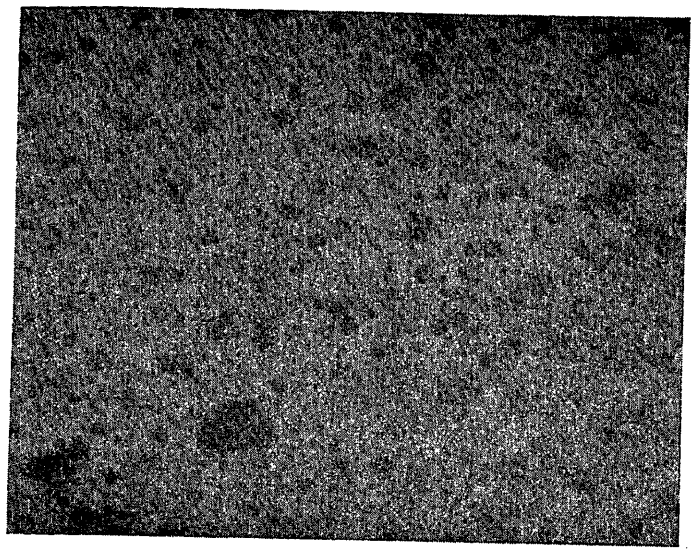

**Fig. 9. Microphotograph of deposit on glazed porcelain formed artificially by simulating natural conditions in the presence of corona and moisture**

Magnification 300 diameters

face of the porcelain, a deposit almost identical with that shown in figure 8 results. A microphotograph of this deposit is shown in figure 9. This seems to show that the deposit involves the metal of the electrodes. Further study of these deposits, with chemical, X-ray, and microscopic aid, is now in progress.

## Hysteresis in Power Factor Curves

With the preceding discussions of humidity, corona, and the surface deposits on the insulator surface, it now becomes possible to analyze the corona hysteresis characteristics.

Consider, for example, the characteristic for $s = 7.56$ in figure 5. With increasing values of voltage the power factor decreases. Due to the humidity an adsorbed film of moisture has accumulated on the surface of the insulator, accounting for the resistance $R'$ in figures 2*a* and 2*b*. At the lower values of voltage, if the voltage is brought to any particular value and held constant, the power factor will diminish, that is, the characteristic tends to go from $aa'$ to $bb'$ in figure 4*A*. This is due to the joulean heating effect ($I^2R'$) on the insulator surface which vaporizes some of the moisture and hence increases $R'$ (figure 2, *a* and *b*). This will continue until a steady state is reached, that is, until a balance is reached between the moisture removed by heat and that which is steadily being deposited from the humid atmosphere. With increasing voltage, the surface heating effect is increased, and more moisture is driven from the insulator surface. This increases the value of $R'$ (figure 2*b*) and the power factor again diminishes with time. This effect continues until corona forms.

Corona itself is an energy loss and will accordingly of itself increase the power factor. Moreover, it is conducting in character and causes the surface resistance $R'$ to decrease (figure 2, *a* and *b*). Up to a certain point a decrease in $R'$ increases the power fac-

Numbers on curves are absolute humidities in grains of moisture per cubic foot

**Fig. 11 (right). Power factor of porcelain insulator as a linear function of absolute humidity at constant voltage; data from increasing voltage**

Numbers on curves are potentials in kilovolts

tor. Corona thus accounts for the increase in power factor which occurs at the higher values of voltage.

With low values of absolute humidity, the adsorbed surface moisture is so small that it has very little and at times negligible effect on the power and power factor. As the voltage is raised with very low absolute humidities, a slight increase in power factor occurs as is shown by the characteristic, $s = 2.6$, in figure 5. This undoubtedly is due to corona formation occurring in the pores of the porcelain and cement and in any small voids that may exist between cap and pin. With a higher value of absolute humidity, $s = 4.48$ (figure 5), the value of power factor remains substantially constant until corona forms. This undoubtedly occurs because the effects of humidity, which cause a decrease in power factor, are being balanced with the corona formation in the voids, which causes an increase in power factor.

With decreasing voltage the power-factor characteristics lie above those for increasing voltage as has already been stated. This is due primarily to the conducting surface deposits resulting from the combined action of corona and moisture. As the voltage decreases, the corona formation itself decreases and the resulting power factor decreases. A point will, however, be reached when corona ceases and the characteristic will reach a minimum (see characteristic $s = 7.56$, figure 5). With further decrease in voltage, and hence in surface heating, moisture will again deposit on the insulator surface and the power factor will now increase. As the voltage becomes less, less heat is evolved on the insulator surface, more moisture deposits, and the power factor continues to increase with diminishing values of voltage.

With low values of humidity the effect of surface loss is negligible so that the rise in power factor with diminishing voltage does not occur as is shown by the characteristics for $s = 4.48$ and $s = 2.6$ in figure 5.

## Capacitance Characteristics

A study of $a$ and $b$ in figure 2 shows that the total capacitance of the insulator consists of the sum of the capacitance $C$ of the head of the insulator and the capacitances $C'$ between the conducting surfaces of the shell. The effectiveness of the capacitances $C'$, however, depends on the value of the surface resistance $R'$. With $R'$ infinite, the capacitances $C'$ have negligible effect on the total capacitance of the insulator. The effect of $C'$ increases as $R'$ diminishes and the maximum effect of $C'$ occurs when $R'$ is zero. Hence the value of the total capacitance $C$ of the insulator depends on the conductance of the film of surface moisture.

With low values of absolute humidity, the capacitance changes little with voltage. There is a steady rise in capacitance with voltage, as is shown by the 2 characteristics at $s = 2.6$ and $s = 4.48$ in figure 6. This rise is undoubtedly due to corona formation in the voids in the porcelain and cement between cap and pin. There is but slight rise in capacitance after corona formation at the edges of the cap and the pin. This is because the corona probably does not extend sufficiently far out from the cap and the pin to include much of the capacitance $C'$ of the shell.

The effect of the adsorbed surface moisture is well illustrated by the characteristic for $s = 7.56$. At first the capacitance dimin-

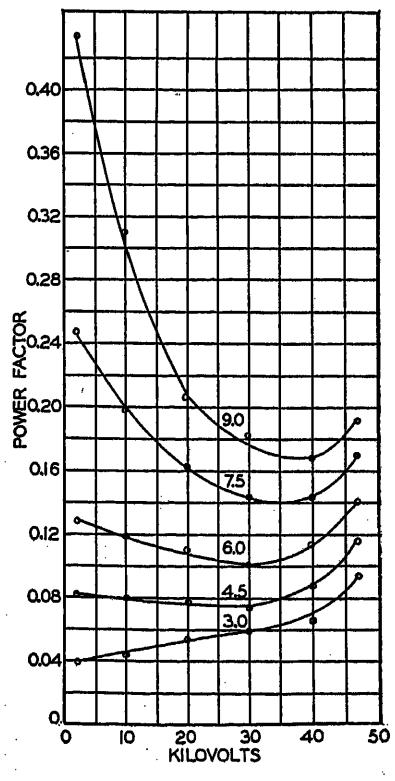

**Fig. 12. Power factor of porcelain insulator as a function of voltage at different absolute humidities; interpolated data from increasing voltage**

Numbers on curves are absolute humidities in grains of moisture per cubic foot of air

ishes with increasing voltage due to the increasing surface resistance $R'$. When corona forms the capacitance increases slightly due to reduction in surface resistance by corona and island deposits. With diminishing voltage the capacitance increases due to the combined effect of returning adsorbed surface moisture and the permanent island deposits. Hence the total capacitance of a disk insulator is a function of the deposit and the adsorbed moisture on the surface, and of the corona.

In figure 10 is shown a complete family of capacitance-kilovolt characteristics with increasing values of voltage for 5 different values of absolute humidity. These characteristics further illustrate the analysis of the relationship of capacitance to absolute humidity. That is, at low values of absolute humidity, the changes in capacitance are small; at large values, they are considerable.

## Power Factor and Absolute Humidity

It is found that if the values of power factor for constant voltage be plotted as functions of absolute humidity, the best representative characteristics are

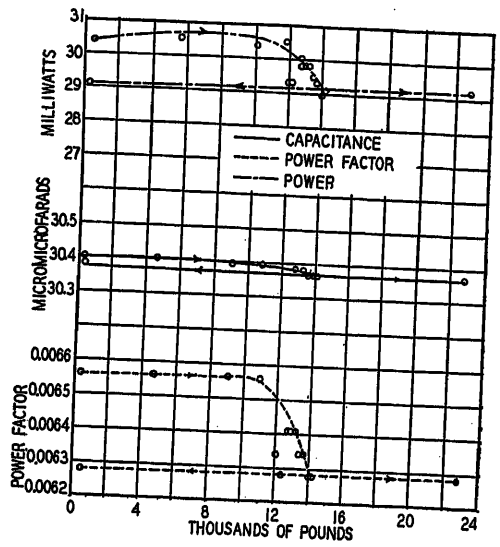

**Fig. 13. Electrical characteristics of glass insulator as functions of mechanical stress at 60 cycles, 21.5 degrees centigrade, and 30 kv**

linear. Three such characteristics for 10, 30, and 46.7 kv are shown in figure 11. For the sake of clearness, similar characteristics for other values of voltage are omitted.

If the data for the characteristics of power factor versus absolute humidity such as are given in figure 11 are replotted, with power factors as functions of kilovolts at constant values of absolute humidity, characteristics similar to those of figure 12 are obtained. These characteristics are similar to those of figures 3 and 5 except that they include more values of absolute humidity. A study of these curves shows that with increasing voltage the rise due to corona formation at the edges of cap and pin begins at lower values of voltage with increasing values of absolute humidity. With decreasing voltage the reverse is true.

In the foregoing relationships, the effect of temperature has not been mentioned. The authors' studies showed no explicit relationship of any of the characteristics to temperature over the annual range of atmospheric temperature variation. Over extreme ranges of temperature Draeger[1] shows a relationship. However, it must be remembered that absolute humidity is a function of the temperature. Hence indirectly, temperature does affect the electrical characteristics of suspension disks.

## Electrical-Mechanical Characteristics[1]

In order to study the effects of mechanical stress on the electrical characteristics, the suspension disk was so mounted that mechanical stress could be applied and measured simultaneously with the high-voltage electrical measurements. It was anticipated that any dislocation of the cap or pin by mechanical stress would affect the electrical characteristics of the insulator. The stress was applied by means of a large automobile jack acting through a lever with a 5 to 1 ratio. With this arrangement, stresses as high as 40,000 pounds could be applied.

The stress was measured by means of an extensometer. A steel rod $1\frac{1}{4}$ inches in diameter for 10-inch length was connected in series with the insulator. It was necessary to choose a diameter which would give an elongation sufficiently great for measurement and yet permit the steel to retain perfect elasticity and not be stressed beyond the yield point.[5] The ends of the rod were reduced to $\frac{3}{4}$ inch diameter to adapt them to the special fittings. The elongation of only

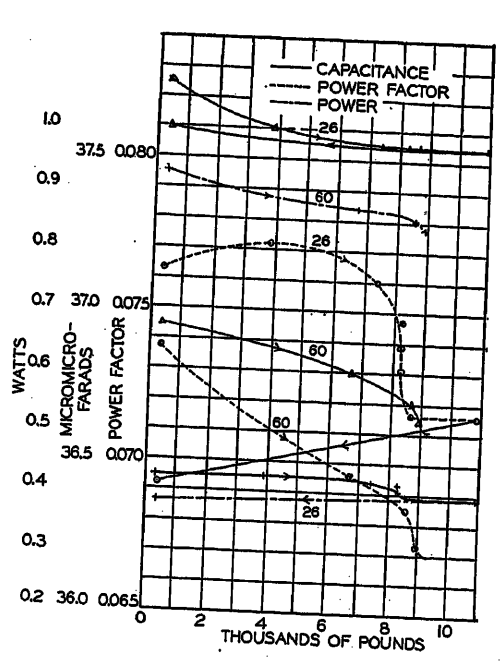

**Fig. 14. Electrical characteristics of porcelain insulator as functions of mechanical stress at constant frequencies of 26 and 60 cycles, 19 degrees centigrade, 30 kv, and 4.3 absolute humidity**

Numbers on curves are frequencies in cycles per second

3 inches of the rod at the center was measured. The extra length of 10 inches is necessary in order to insure stress equalization over the cross sections near the center. The elongation was measured by means of a combination of mirrors, knife edges, and telescopes. The elongation of the rod was magnified $10^6$ times.

The effects of mechanical stress on power, power factor, and capacitance for the glass insulator are shown in figure 13. For an applied potential of 30 kv until a stress of 12,000 pounds is reached, little or

no effect on the characteristics occurs. Then all 3 quantities show a small decrease. (The quantities in figure 13 are plotted to a large scale.) The change in the power and the power factor is approximately 4 or 5 per cent and the change in the capacitance is extremely small. The stress is then carried to 23,000 pounds. All these quantities remain constant up to this value of stress. They also remain constant as the stress is carried back to zero.

Similarly, in figure 14 are shown the effects of stress on the porcelain insulator. The characteristics are obtained at 30 kv and at the 2 frequencies, 26 and 60 cycles. The stress at 60 cycles was not carried back to zero because of the insulator's failure. It may be noted that although the effects of stress are in general similar to those for glass, yet the characteristics are not so simple. They tend to have a steady drop before the critical stress of 8,500 pounds is reached, when they drop rapidly. Moreover, after the application of the critical stress, the quantities, except the power at 26 cycles, do not remain constant as with glass. This would be expected. With glass the pin is held by a soft metal. With application of stress the metal would be pressed more firmly against the glass and little change in conductive relationships of this metal to the glass would be expected. On the contrary, with the porcelain insulator the cement used to fasten the cap and pin is an imperfect dielectric probably containing moisture. Under mechanical stress its dielectric properties would be expected to change considerably. The effect of stress appears to diminish the power, power factor, and capacitance, undoubtedly because of changes in the geometrical relationships between cap and pin.

The authors feel that the results of this research may assist in the obtaining of a better understanding of insulator performance and design, as well as of radio interference resulting from surface discharge.

## Sealed-Off Ignitrons for Welding Control

(*Continued from page 40*)

The welding of large pieces, particularly when done rapidly with automatic machinery, usually requires the use of water-cooled tubes. There are few resistance-welding machines in use today requiring currents higher than these tubes are able to control.

## Advantages of Sealed-Off Ignitrons

The sealed-off ignitron tube provides the following attractive features for welding control. No other device offers all of these advantages:

1. Tubes have no moving parts and so require little or no attention throughout their normal life. They are designed for long life. As compared with mechanical devices for rapidly opening and closing high current circuits, maintenance expense is low.

2. Tubes provide flexibility, short timing, and accuracy of control otherwise unobtainable. This reduces surface heating, thus minimizing deformation and oxidation of work and lengthening electrode life. They permit welding of metals or alloys which were previously difficult if not impossible to weld.

3. Ignitron tubes, because of their ability to pass very high peak currents, are connected directly in the primary circuit of the welding transformer.

4. Ignitron tubes, particularly the metal models, are not fragile and so do not require extreme care in handling. They may be safely installed by unskilled workmen.

5. Sealed-off ignitrons are replaceable units. Tube failure results in only the few minutes shutdown necessary to accomplish replacement. When welding equipment is one link in a continuous production line, the avoidance of long forced shutdowns may result in sizeable savings.

6. Sealed-off ignitrons are small in size, comparatively, and, with the small amount of auxiliary apparatus they require, save valuable space in high production shops.

At higher currents the longer total life of the more completely demountable and repairable continuously pumped tanks weigh in their favor. The capacity above which tanks might be preferred is dependent upon the ultimate life of the sealed-off tubes, the cost of development of larger sealed-off sizes, and the manufacturing cost of those developed. When higher power is needed it may be desirable as an alternative to develop ignitrons of approximately present current ratings but capable of operating at higher voltages.

Two or three years ago these ignitron tubes were in the developmental stage and were used in a few commercial applications.[8] Today there are many equipments located in key positions of large volume production lines producing more consistent welds at higher speed than is practical with other types of control.

# Short-Time Spark-Over of Gaps

By J. H. HAGENGUTH
ASSOCIATE AIEE

**In this paper data are presented on spark-over values of rod gaps, insulators, bushings, sphere gaps, and solid insulation for a range of spark-over times of approximately from 0.2 to 4 microseconds. The problems of accurate measurement that are involved are also discussed, and a shielded resistance voltage divider is described.**

DURING the last few years considerable progress has been made in impulse testing technique.[1,2] The results obtained in different laboratories on the spark-over of sphere and rod gaps with the standard 1.5 x 40 wave where spark-over occurs after the crest of the wave agree well and have permitted standardization of such spark-over curves.

There has been little data published on spark-over values of gaps and insulation at very short time lags (less than 2 microseconds).[3,4] These data become important when insulation co-ordination is considered. A given gap might protect a piece of insulation when a 1.5x40 wave of low amplitude is applied to the combination, such that spark-over takes place after the crest of the wave, but the insulation might fail if a wave of much higher voltage or steeper front is applied. Therefore, to enable satisfactory co-ordination of various insulating structures it is important to know the behavior of gaps and insulation for the steepest waves expected on transmission lines.

The greatest rate of voltage rise of traveling waves due to lightning is not definitely known. However, from some oscillograms obtained in field investigations it is quite safe to assume that 1,000 kv per microseconds or more is a rate of voltage rise, which can occur quite frequently at least at the point where lightning strikes a line. If a rate of 1,000 kv per microseconds is assumed, this means, for instance, a spark-over at 300 kv at 0.3 microseconds.

The problems concerning the accuracy of the impulse measurements when high spark-over voltage and short spark-over time are involved are discussed in part I of the paper. Definitions of rate of voltage rise and of time to spark-over are discussed since they are important for comparison of results obtained in different laboratories. In part II of the paper, results of tests on rod gaps, insulators, bushings, sphere gaps, and solid insulation covering a range of spark-over time of approximately 0.2 to 4 microseconds, are presented.

## I. Impulse Testing Technique

### The Voltage Divider

The resistance type of divider has been found to be an ideal tool for the reduction of high impulse voltages to true images of low enough amplitudes, which permit recording with a cathode ray oscillograph, when tests are made to determine the minimum spark-over of gaps with the standard 1.5x40 wave. The resistance can be measured conveniently and the true ratio between oscillograms and actual spark-over voltage can be established with certainty.

For the standard wave the distributed constants of the divider such as its inductance, capacitances to ground, and capacitance between successive turns of the non-inductively wound cards, are of negligible importance. However, the presence of the distributed constants changes the apparent ratio of the divider when high potentials with spark-over occurring at short times are to be measured. For instance, a 10,000-ohm divider, which is used in the range between 200 kv and 1,000 kv slants a rectangular front to about a 0.4-microsecond front and a $^1/_2$-microsecond front to about $^3/_4$-microsecond front in certain positions of the divider with respect to a ground plane. Consequently the breakdown voltage of a sphere gap might be recorded much too low as shown on figure 1*a*, which was taken with a $6^1/_4$-centimeter gap illuminated both by a mercury quartz lamp and a spark from a gap. Although the gap did not spark every time (see full wave on same figure), the amplitude of the recorded spark-over voltage was only $^1/_2$ the amplitude of the full wave. When the waves of figure 1*b* are considered, however, it is evident that the spark-over actually occurred after the crest is reached and the disturbing result in figure 1*a* is due only to the distortion caused by the divider. In the appendix equations are given showing the distortion caused by the different distributed constants of the divider and also some curves pertaining to some particular case illustrating their separate effect.

When examining the effect of the various distributed constants on the distortion, it was found, that the main offender was the capacitance to ground which together with the resistance of the divider slants the wave front. Therefore for equal capacitance to ground the distortion will be greater as the resistance of the divider increases. In the above test, this capacitance had been equally distributed by placing the divider about 6 feet above and parallel with the ground plane. In usual practice such a divider will be moved around in the laboratory, to place it in the optimum position with respect to the test

A paper recommended for publication by the AIEE committee on instruments and measurements. Manuscript submitted October [illegible] publication December 1, 1936.

piece and the effect of the capacitance to ground will be greater or smaller depending on any particular case.

Another source of error obtained with any divider at tion rapid changes of voltage is the presence of the rapidly againanging fields produced from the impulse generator proper, from the connecting lines, sphere gaps, etc., each changing at a somewhat different rate but all contributing a part to the distortion of the field around the divider.

Therefore, 3 conditions are imposed in eliminating the distortion:

1. The effect of the capacitance to ground must be compensated.
2. A change in position of the divider must not change the compensation.
3. The influence of external fields should be kept as small as possible.

To eliminate the effect of the capacitance to ground a method similar to that used in shielded winding transformers[5] has been employed. This method is shown diagrammatically in figure 2. The shield is shaped in such a manner, that by means of capacitance $C_s$ it supplies just the right amount of current through capacitance $C_g$ to ground, which is required to maintain the voltage $e$ at an amplitude equal to the ratio of resistances at that point. Such a divider also will meet condition 2 by fixing the ground plane permanently to the divider. However, condition 3 cannot be met very readily without going to a very large grounded shield above the divider, which the available space in the laboratory usually would not permit.

To meet all 3 of the conditions a different type of divider was developed which is shown in figure 3. In this divider a center cylindrical electrode serves as the line shield. The tank serves as the ground plane as well as the shield against external fields. The resistor is placed in the field between the line and ground shield in such a way that equal parts of resistances are placed on equipotential lines of correct potential differences. The divider as shown can be used up to 700 kv for minimum breakdown voltage tests on a 1.5x40 wave and up to 2,000 kv on front of the wave tests. In addition to the shielding, the distortion effect has been minimized by keeping the di resistance low—7,000 ohms. The tank is filled wit to avoid forming of corona. The minimum ratio of divider is 100 to 1, since the surge impedance of the de cable of 100-ft. length, which is used to transmit the sur to the oscillograph plates, equals 70 ohms. This ratio can be increased to approximately 1,400 to 1 by placing a required low resistance parallel to the cable at the divider end of the cable.

## The Impulse Circuit

For testing with high rates of voltage rise, it is very important, that the divider is connected as closely to the test piece as possible, to avoid reflections of connecting lines and also to avoid measuring the inductive drop on long connecting lines from the steep wave fronts. One factor which produces distortion on the front as well as on the tail of chopped waves is the position of the test piece in the generator discharge circuit, figure 4*a*. The inherent inductance of the circuit is divided into 3 parts; the inductance of the impulse generator proper $L_t$, the inductance of the line to the test piece $L_L$, and the inductance of the ground return $L_g$. The effect of these inductances is twofold:

1. On the front of the waves, the rate of rise is influenced by the apparent addition of a superimposed oscillation. This is due to the fact, that at the initial moment, when the impulse generator discharges, the voltages in the circuit distribute according to the inductances. Depending then on the ratio of $L_g$ to the total inductance in the circuit $L_t + L_L + L_g$ the amplitude of this initial inductive kick will be large or small. This inductive effect will have largely disappeared at the time the gap breaks down, provided

the breakdown occurs between 50 per cent and 100 per cent of the wave crest.

2. After spark-over of the test piece the load capacitance is short circuited by the low resistance of the arc and the discharge circuit changes practically into a $L$, $R$, $C$ circuit with an oscillatory discharge with a time constant approximately proportional to $LC$. In the extreme case then the breakdown voltage would be of sinusoidal form of long time constant (8 to 10 microseconds) while the true time constant of the gap breakdown is of the order of a fraction of a microsecond.

To avoid the above discrepancies it is desirable to keep $L_g$ as small as possible by connecting the grounded end of the test piece to the generator through short leads,

figure 4*b*. The actual position of true ground with respect to the generator is then not so important as long as discharge currents do not flow through the ground straps. It can be seen from figure 4*a*, that traveling waves of considerable amplitude would be set up in the divider cable sheath, if the cable sheath were connected to the grounded side of the test piece, while in case of figure 4*b*, the cable can be connected at that point without complications.

## Effect of Circuit Constants on the Spark-Over on the Front of Waves

The control of wave fronts depends on the inductance and resistance in series with the discharge circuit, on the generator stray capacitance to ground and the capacitance of the test piece or any additional load capacitance. Usually the inductance inherent to the circuit is fixed and it is more convenient to control fronts by choosing the proper values of load capacitances and series resistances. For tests on minimum spark-over especially of air gaps, it is quite immaterial whether a relatively large resistance or a large load capacitance is chosen except that the resistance must be large enough to prevent superimposed oscillation. For breakdown on the front of waves, somewhat different results are obtained using the same time constant $RC$ but using either high $R$ or high $C$.

Figure 5 shows a typical wave front, with breakdown at $t_1$ and $t_1'$. Breakdown at $t_1'$ would occur with large resistance, (for instance, 2,000 ohms) and at $t_1$ with the small resistance, (for instance 400 ohms). The difference between the 2 waves is due to the voltage drop caused across the resistance by the relatively large charging and especially streamer currents[6] through the gap shortly before breakdown. Naturally the larger the resistance the greater will be the drop and the more will the voltage wave depart from that natural to the circuit. It is evident that the spark-over voltages would be quite different in the 2 tests although the rate of voltage rise as determined by conventional methods, is practically the same for the 2 waves. Therefore if plotted on a curve showing rate of rise against breakdown voltage, a considerable spread of test points would be observed. The importance of this phenomenon with respect to evaluation of results will be discussed later.

With respect to the maximum rate of rise and maximum voltage, that can be obtained from an impulse generator, curves of figure 6 are prepared. The generator has a rating of 2,500 kv at a discharge capacitance of 0.011 microfarads and an inherent inductance of 120 microhenries including leads.

It was desired to determine whether the generator was of sufficient size to test transformers with steep fronts of

2. 7/3.7 = 1.9 units
2′. 7/2.3 = 3 units

**Fig. 7. Comparison of definitions of rate of voltage rise**

the order of 1,000 kv per microsecond. A transformer can be represented by a capacitance equal to its impulse capacitance when chopped waves of short duration are applied. The impulse capacitance of transformers ranges from approximately 300 to 2,500 micromicrofarads.

Tests were made with the electrical transient analyzer.[7] The analyzer represents an ideal tool for such purposes and eliminates a large amount of routine labor in evaluating the equations. In the curves of figure 6 the rate of rise is calculated by using the crest voltage as measured with the analyzer and dividing it by the time interval from zero to crest. The maximum rate of rise obtainable is therefore greater than indicated on the curves of figure 6. It can be seen from figure 6, that in the range of load capacitances from 300 to 2,000 micromicrofarads, rates of rise between 1,000 and 2,800 kv per microsecond can be obtained with maximum voltages of approximately 2,000 kv. These values are sufficiently high to permit spark-over of test gaps parallel to transformers with spacings up to 70 inches at 1,000 kv per microsecond voltage rise. For tests on transformers of higher voltage ratings, a larger impulse generator is available. It should of course, be realized, that the constants to be chosen for the wave front test would not at all be suitable for testing on the tail of the wave. For instance, when using $R_2 = 50$, $C_2 = 5{,}000$, a high-frequency oscillation results which is superimposed on the wave front. However, it is just this superimposed oscillation which produces the wave front of 1,200 kv per microsecond rise. Since the test is required to be made on the front of the wave, only the first rise of the wave will be applied to the gap. It is, therefore, immaterial whether a 1.5x40 wave is used for testing a gap with steep wave fronts as long as the rate of voltage rise follows the specification. The use of 1.5x40 waves for tests on the front of the wave would limit the spark-over tests to relatively small gap spacings or else would require an impulse generator of uneconomical proportions.

## Definition of Breakdown Voltage, Time to Breakdown, and Rate of Voltage Rise

If impulse generators contained resistances and capacitances only, it would be an easy matter strictly to define terms determining the time to breakdown, and the rate of voltage rise on wave fronts, However, throughout the impulse discharge circuit, especially of the high-voltage impulse generators, inductance of sometimes considerable value is distributed. These inductances, together with the generator capacitance and capacitances to ground, such as stray capacitances and load capacitance, produce oscillations on the wave front and the waves do not have strictly exponential characteristics. While these phenomena are not disturbing when testing with 1.5x40 waves for minimum spark-over of gaps, they tend to magnify the difficulties of exact definition, and comparison of results of different investigators is difficult unless the same procedure is used for evaluating the oscillograms.

Two main groups of definitions are used at present, both of which practically ignore the time to breakdown but rather use the rate of voltage rise to record results of tests of spark-over voltages of a gap. The rate of voltage rise is defined as:

(*A*) A line drawn through 2 points with an amplitude of 10 per cent and 90 per cent of the crest voltage intersects the zero line and a line through the maximum voltage parallel to the zero axis.

(*B*) A tangent drawn to the steepest part of the front intersects the zero line and a line through the maximum voltage parallel to the zero axis.

In both cases division of the maximum voltage by the time interval between the 2 intersection points gives the rate of voltage rise.

Method *A* has the advantage of a clearer definition since in most cases, it is quite a simple problem to define the 10 per cent and 90 per cent point and the 2 intersection points, while it is generally extremely difficult to determine a tangent. Both methods however, have slight inconsistencies as follows:

Figure 7*a* shows a wave front without superimposed oscillations. The relative rate of rise is indicated for 4 conditions:

1. Spark-over at 10 units of voltage, method *A*, 2.6 units of rate of voltage rise.
2. Spark-over at 7 units of voltage, method *A*, 2.2 units of rate of voltage rise.
3. Spark-over at 10 units of voltage, method *B*, 5.3 units of rate of voltage rise.
4. Spark-over at 7 units of voltage, method *B*, 5.0 units of rate of voltage rise.

The resulting rates of rise show considerable difference although for about 50 per cent the rate of rise of the 2 waves is identical. The relative rate of rise for the wave breaking down at 7 units of voltage is even less than that for the 10 unit breakdown when obtained with method *A*.

The method of $B$ would indicate a rate of rise twice as large as that of $A$. Further actual wave fronts are often of a form as shown on figure 7*b*, because optimum test conditions cannot be obtained. The method $A$ would practically give the same rates of rise as that in figure 7*a*, while it would be very difficult to use method $B$. From the above discussion it appears that the use of the rate of voltage rise to determine spark-over voltages is at least confusing if used with any of the above definitions.

From comparative tests such as mentioned in connection with figure 5, it appears that the maximum rate of rise as defined above is relatively unimportant, while the crest voltage and the time to spark-over seem to be quite definitely related. For instance, spark-over voltages obtained with the same time constant $RC$ but large and small series resistance $R$ lie on a smooth curve when plotted against time to spark-over but when plotted against rate of voltage rise (by standard definition) a considerable spread is observed.

From these considerations, it was found to be an advantage to use the average rate of rise as the factor which determines the breakdown. Average rate of rise is obtained by dividing crest voltage by the time to spark-over. The wave zero under this definition would be defined as the point of intersection with the zero axis of a line drawn through the 10 per cent and 90 per cent points of crest voltage.

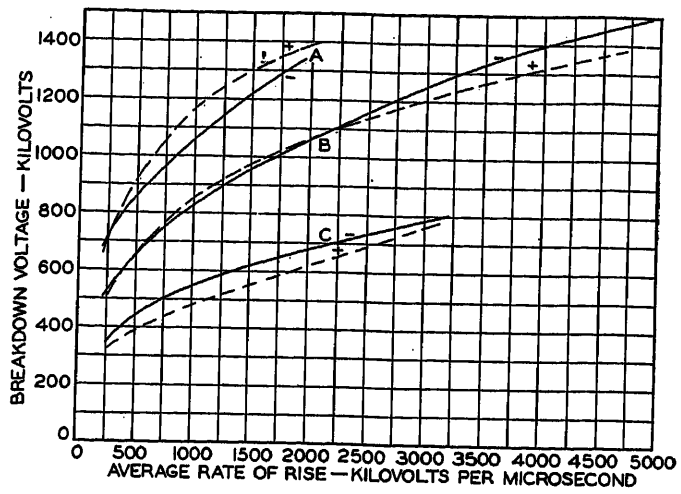

**Fig. 9. Variation of spark-over voltage with steepness of applied wave corrected for standard conditions**

Solid curves negative polarity, dashed curves positive polarity

· 2,000 ohms series resistance
+ 1,500 ohms series resistance
× 0 ohms series resistance
1.5x40-microsecond wave for tests with 2,000 ohms series resistance, positive polarity

Necessary discrimination has to be used when due to enforced testing conditions the front of a wave is not smooth but has for instance the shape of figure 7*b*. At the spark-over at 7 voltage units, the 10 per cent point should not be chosen at the first rise in voltage, but on the zero extension of the following voltage rise as shown by line 2′.

## II. Results of Breakdown Tests

### Accuracy of Test Results

Tests of breakdown on the front of waves are conducted in the following manner. Beginning at minimum spark-over of the gap for a 1.5x40 wave the charging voltage of the impulse generator is raised in 10 per cent steps. For each charging voltage usually 3 arc-overs are recorded by oscillograms. As the voltage is raised higher the losses in the series resistance due to streamer currents become greater than the increase in voltage. At this point the series resistance is lowered or removed completely which changes the wave front accordingly. The oscillograms are then analyzed for spark-over voltage and the time to spark-over. Figure 8 is included to show what accuracy can be expected from a single random calibration point. It is evident that down to 0.4 microsecond the spread of values is of the order of 10 per cent and usually less. This spread is partly due to variations in gap spark-over, partly to errors in scaling of oscillograms, partly to the error inherent to the divider and oscillograph. For breakdown times of less than 0.4 microsecond the error becomes greater. Here the greatest error is due to the scaling of the oscillograms. Usually the time to spark-over is the greater source of error, although for these fast times the sweep is chosen such that 1 microsecond represents 40 to 60 millimeters on the time axis of the oscillogram. Even

at these fast sweeps an error in displacing the line for 10/90 per cent by 2 millimeters at both ends amounts in an error in time to breakdown of about 0.1 microsecond.

The errors, real and apparent, due to variations in gap spark-over and the scaling of oscillograms can be practically eliminated by comparing a large number of oscillograms, and curves such as shown on figure 8 can be drawn with a fair degree of accuracy even to such short times as 0.2 microsecond.

It should be noted that portions of this curve were obtained with different values of series resistance which partly overlap. The continuity of the curve is not disturbed, although the relative slope of wave fronts for different values of resistance is quite different.

## Spark-Over Curves of Gaps

The results of tests on 10, 20, and 30-inch rod gaps are shown on figure 9 for positive and negative polarity. These curves were drawn by using the average curves obtained as outlined above. The kilovolts per microsecond values were calculated by using crest voltage and time to breakdown as explained earlier in the paper. The curves level somewhat at the high rates of rise and appear to approach some straight line characteristic. The left-hand portion of figure 8 seems to substantiate this. Here the voltage rises almost abruptly while the time to breakdown hardly changes. A difference of about 10 per cent is indicated between positive and negative breakdown voltages.

To compare gaps of different size and different character it is an advantage to use some common basis for comparison. As a characteristic curve the overvoltage-time to spark-over curve is considered. Overvoltage is defined as the voltage required to spark over a gap in excess of the minimum impulse spark-over voltage, for instance due to a 1.5x40 wave, at a spark-over time less than the minimum impulse spark-over time. Such curves

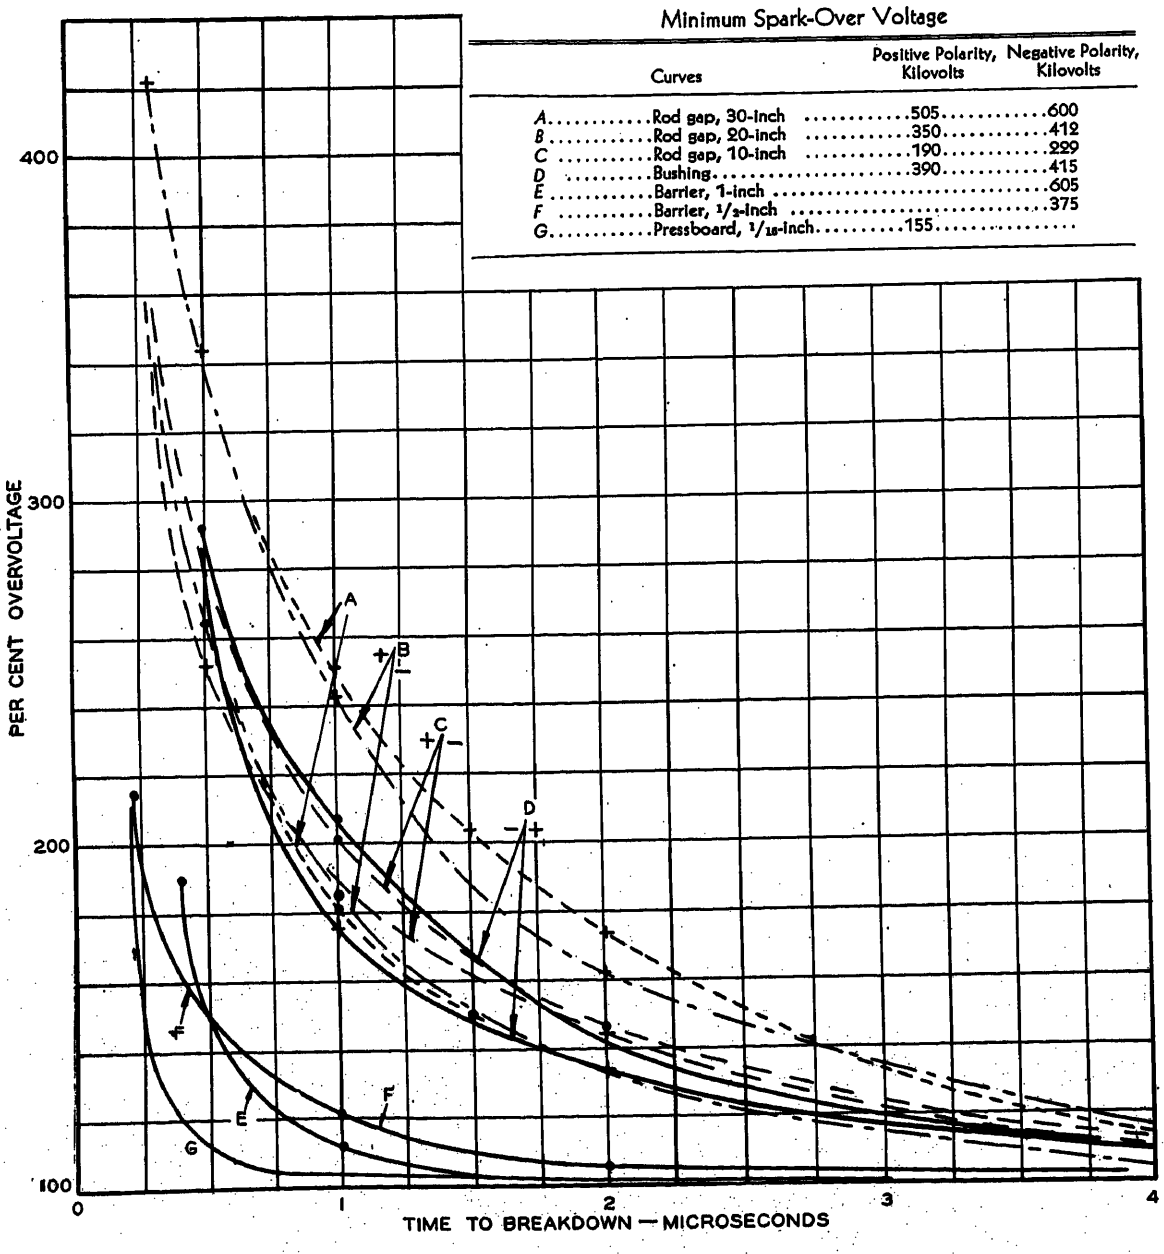

**Fig. 10. Overvoltage curves of rod gaps, bushings, and barriers**

Test electrodes of barriers are 4-inch round disks with square edges. Barriers consist of 3 oil ducts of 1/4 of total spacing each and 2 pressboard sheets 1/8 of total spacing each

10-inch and 20-inch gap. The insulator curves represent the average values for 1, 2, and 3 units of suspension insulators and the breakdown values for the $^1/_2$-inch and 1-inch barrier are averaged. The circles indicate the overvoltage values of a 50-centimeter sphere gap at 34.25-centimeter (68 per cent) spacing at negative polarity.

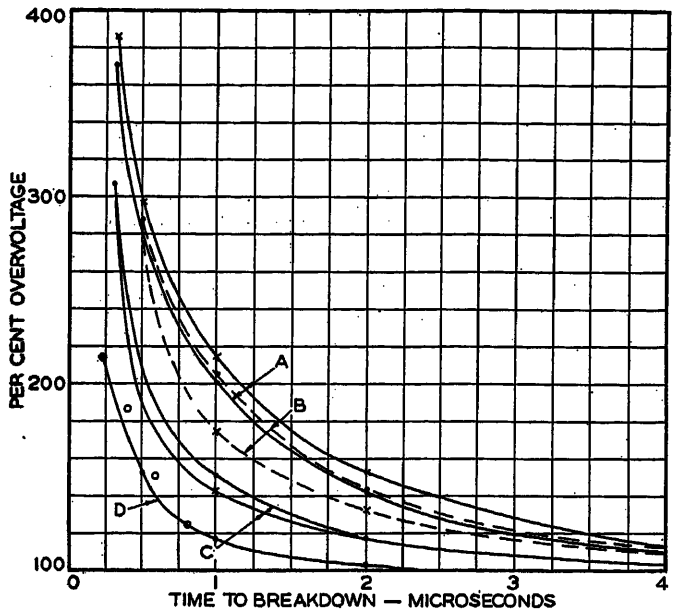

**Fig. 13. Comparison of overvoltage characteristics of different types of gaps**

*A*—Rod gap, average values of 10-inch and 20-inch gaps

*C*—Insulator, average values of 1, 2, and 3 suspension insulators
*D*—Solid and oil, average of $^1/_2$-inch and 1-inch barriers
Circles show voltage of a 50-centimeter diameter sphere gap spaced 34.25 centimeters
+ indicates positive polarity, • indicates negative polarity

Wherever possible the rod gap tests were made with the gap mounted according to standard specifications of the National Electrical Manufacturers Association, $H = (1.3\,S + 4'') \pm 10$ per cent where $H$ is the height of the gap above ground plane and $S$ is the spacing of the gap. However, the relative characteristics of pedestal insulators and rod gaps is such that the rod gap will not protect the pedestal at very short times to spark-over. In such cases the number of pedestal insulators was increased. Figure 14 has been prepared to show the breakdown characteristics for 2 pedestal insulators giving the specified height of the rod gap above the ground plane for a 20-inch rod gap. It shows that the curves for rod gap and pedestal insulators cross at 1 microsecond for the positive wave and approach at $^1/_2$ microsecond for a negative wave, which indicates that either may arc. It appears desirable to modify the NEMA rules for the condition of tests on the front of waves.

The above gaps with exception of the solid and barrier type represent strictly non-uniform fields. Contrary to this a sphere gap is considered to have a fairly uniform field. Figure 15 is included to show the spark-over characteristics of such a gap, when spark-over occurs at a short time. A 25-centimeter gap was chosen as representative for the larger gaps. It is evident that the sphere gap requires considerable overvoltage to spark-over at short time. The overvoltage values are shown in table I.

**Table I—Overvoltage Values of 25-Centimeter Sphere Gap, Positive Polarity**

| Time to Breakdown, Microseconds | Gap Spacing in Per Cent of Sphere Diameter | | |
|---|---|---|---|
| | 16 | 32 | 76 |
| 1 | 113 | 115 | 109 |
| 0.5 | 154 | 140 | 137 |
| 0.2 | 191 | 155 | |

The table shows that overvoltage values decrease as the gap spacing is increased.

Incidentally the crosses on these curves indicate tests made with artificial irradiation from a mercury arc light spaced 18 inches from sphere center with 60 watts input.

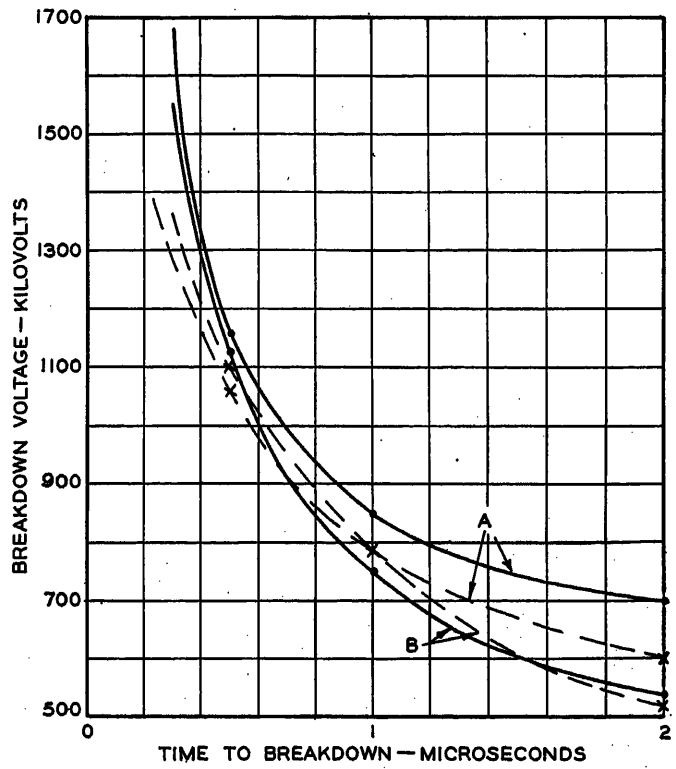

**Fig. 14. Volt-time characteristics of 2 pedestal insulators (A) and a 20-inch rod gap (B). The pedestal represents the standard mounting for this size gap**

+ indicates positive polarity, • indicates negative polarity

The effect of this ionization appears to be negligible for large gaps at relatively large spacings. From these curves it appears that for spark-over time of 1 microsecond or more the sphere gap indicates spark-over at the same voltage irrespective of voltage application.

For times shorter than 1 microsecond the established values of sphere gap spark-over do not apply. The over-voltage-time to spark-over characteristics for different spacings of the same gap are not the same. This requires a complete short time spark-over calibration for a number of spacings on each size sphere, if the sphere is to be used for measuring short time spark-over. Fortunately the oscillograph in connection with a proper divider has become a reliable instrument which can be used with confidence as a voltage measuring device when the sphere gap is not applicable. Figure 16 shows some representative oscillograms of spark-over of rod gaps

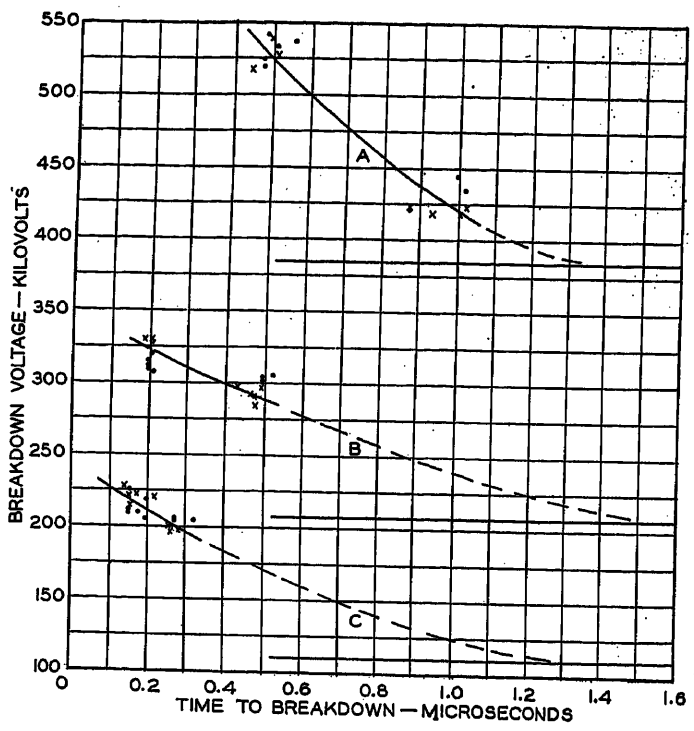

**Fig. 15. Spark-over voltage of a 25-centimeter sphere, at positive polarity**

Horizontal lines *M* are minimum breakdown voltages

*A*—19-centimeter spacing *B*—8-centimeter spacing

without and with transformer load and a sphere gap spark-over.

## Summary

1. A shielded resistance divider is described which incorporates the desirable features of the ordinary resistance divider and by means of shielding eliminates distortion inherent to such dividers on application of fast wave fronts.

2. The over-all accuracy of measurements of waves at short times is approximately 10 per cent or better for spark-over times of 0.4 microsecond or more, 15 per cent to 20 per cent for shorter times. This applies for individual test points. For a more accurate determination a series of 3 to 5 breakdowns can be used under identical condition of test circuits with a probable accuracy of better than 10 per cent.

3. The curves presented show that the relative short time spark-over voltages are highest for gaps with non-uniform field such as rod gaps, bushings, pedestal, and suspension insulators in the order named, figure 13. The gaps with more nearly uniform field such as

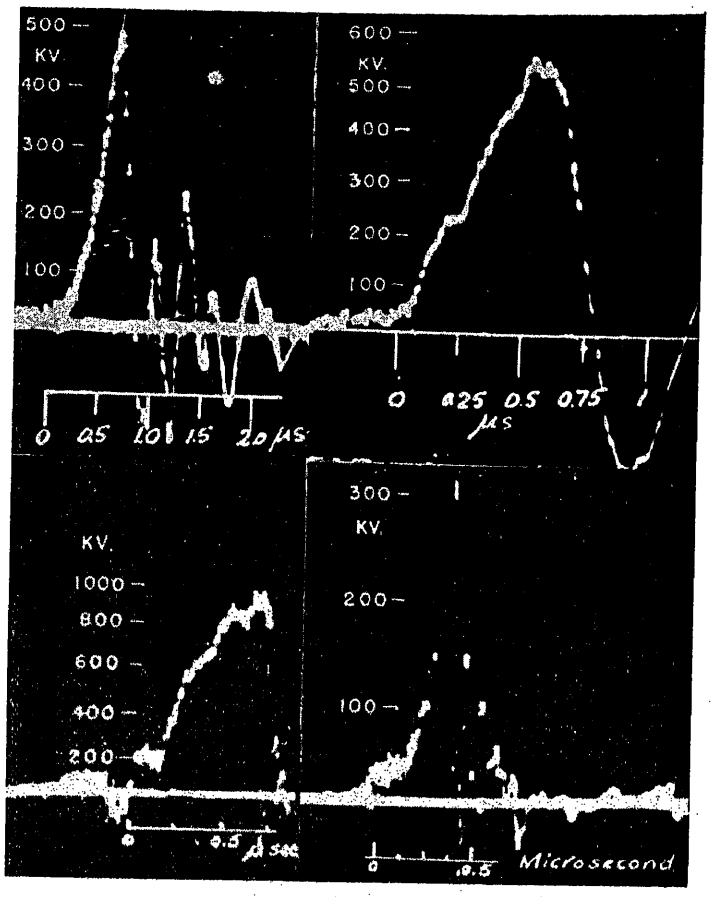

**Fig. 16. Oscillograms of front of wave spark-over**

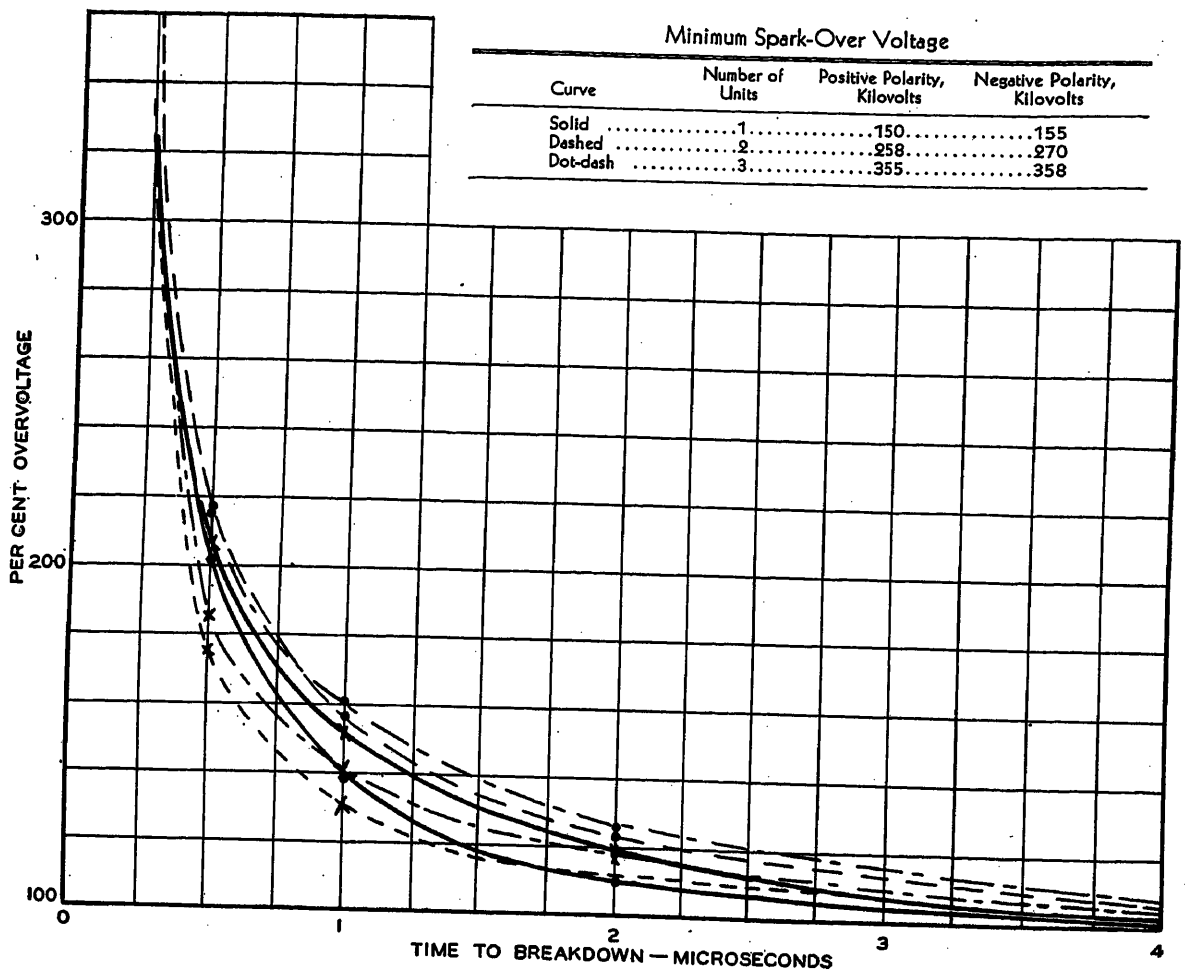
*A*—1/2-inch square rod gap, 10-inch spacing. Rate of rise 850 kv per microsecond; crest 475 kv; negative polarity

*B*—25-centimeter sphere gap, 19-centimeter spacing. Rate of rise 950 kv per microsecond; crest 551 kv; positive polarity



*C*—1/2-inch square rod gap, 20-inch spacing. Rate of rise 1,300 kv per microsecond; crest 913 kv; transformer load; negative polarity

*D*—1/2-inch square rod gap, 3-inch spacing. Rate of rise 1,330 kv per microsecond; crest 300 kv; transformer load, negative polarity

sphere gaps and the 4-inch disks used in tests with solid insulation show relatively high overvoltages but they occur at considerably shorter times than those of gaps with non-uniform fields.

4. Although a large number of volt-time curves has been made, a considerable amount of additional tests are required to complete the experiments, on which co-ordination can be perfected for the fastest rates of rise of natural lightning waves. Experience in the latter field is very restricted. However, rates of rise of 1,000 kv per microsecond and higher can be expected at least at the point of lightning contact. Further data are needed to enable a better understanding of requirements.

5. Impulse breakdown tests on front of waves can be made with similar ease as those on the tail of waves. The limits of accuracy, however, should be more liberal to allow for the greater spread in breakdown voltages of gaps when subjected to high rates of voltage rise.

Minimum Spark-Over Voltage

show at a glance the relative time to breakdown characteristics of the different types of gaps.

To increase the usefulness of overvoltage-time to spark-over curves the minimum spark-over voltage is noted below the figures. To obtain kilovolt values from the curves, it is necessary only to multiply the minimum spark-over voltage times the per cent overvoltage and to divide by 100.

The curves of figure 10 show the overvoltage-time to spark-over characteristics for rod gaps, bushings, solid insulation, and combinations of solid and oil insulation. It should be noted that the electrodes used for tests on solid insulation are 4-inch round disks with square edges, which produce a somewhat uniform field. It is evident that the overvoltage values of rods and bushings are considerably higher than those of the solid insulation. Part of this difference can be attributed to the difference in electrostatic field.

In figure 11 the curves for suspension insulators are shown. It is surprising that the overvoltage curves have such a small spread and an increase of overvoltage with increase in string length is hardly indicated. On the contrary the curves for pedestal insulators, figure 12, show larger differences in characteristic shape and a high increase in overvoltage as the number of insulators is increased, especially for positive polarity.

Figure 13 shows a summary of the previous curves. The curves for rod gaps correspond to the average of the

For conditions *A* and *C*; *K'* has been added externally to the divider

Inherent constants—$R = 10{,}200$ ohms; $C = 81 \times 10^{-12}F$; $L = 34 \times 10^{-6}h$; $K = 3 \times 10^{-12}F$

## Appendix

To study the behavior of a resistance divider, the divider was placed horizontally 6 feet above ground. Under this condition an extremely steep wave was applied to the divider and the response was measured at the grounded end. Since the effect of the series capacitance $K$ is beneficial, such series capacitance was externally applied to the divider (condition *A* and *C*, figure 17). However, it was found that the amount of series capacitance which could reasonably be connected to the divider was not nearly sufficient to benefit the transmission of the wave.

The equations for the 4 possible combinations of divider constants were solved and the results plotted together with the test results. From a comparison of tested and calculated waves, it appears that the calculations ignoring the inductive component of the divider (conditions *C* and *D*, figure 17) show as good agreement between test and calculation as those with the inductance included. It appears therefore that for simplicity of calculations the circuit *D* of figure 17 can be considered as being representative of the resistance divider circuit.

The equations for the voltage $e$ at a point $x$ to ground of the divider for the 4 conditions are:

A. $$\frac{e_x}{E} = x + \epsilon^{-at}\sum_1^\infty \frac{2}{\pi s}\sin \pi s x \quad \cos \pi s \frac{\alpha^2}{\alpha^2 + \pi^2 s^2}\left(\cos b_s t + \frac{\alpha}{b_s}\sin b_s t\right)$$

when

$$\frac{\pi^2 s^2}{LK(\alpha^2+\pi^2 s^2)} > a^2$$

$$\frac{e_x}{E} = x + \sum_1^\infty \frac{\sin \pi s x}{s\pi} \cos \pi s \frac{\alpha^2}{\alpha^2+\pi^2 s^2}\left\{\left(1+\frac{a}{\omega_s}\right)\epsilon^{-(a-\omega_s)t} + \left(1-\frac{a}{\omega_s}\right)\epsilon^{-(a+\omega_s)t}\right\}$$

when

# A Single-Element Polyphase Directional Relay

By A. J. McCONNELL
ASSOCIATE AIEE

**Increased speed because of reduced inertia and greater torque is obtained from the polyphase directional relay described in this paper. A single cup-like moving element is used in place of multiple disks as used heretofore, the polyphase function being obtained by the use of multiple poles.**

THE IMPORTANCE of polyphase directional relays in relay protective arrangements is generally recognized today.

The first polyphase directional relays consisted of 2 or 3 single-phase elements connected to a common shaft. These single-phase elements were almost identical to existing forms of meters, namely, induction-disk watt-hour meters and indicating wattmeters. During the evolution of these devices, many improvements were made, some following the advances in meter design, and others being the result of problems met only in the protective relay field.

Notwithstanding these improvements, it became increasingly apparent that a relay with higher speed and greater torque was necessary for many applications. Furthermore, such a relay would be convenient even for those applications not requiring high speed, providing it involved no added expense.

## Improved Single-Phase Directional Relay

Improvements in the speed of single-phase and polyphase induction-disk relays have been limited by inherent high disk inertia and low torque efficiency. These limitations are largely overcome in the induction cylinder or cup relay recently developed. A single-phase power directional element of this design is shown in figure 1.

It consists of a stator with 8 laminated salients projecting inward and arranged symmetrically around a central magnetic core. The salients are fitted with alternate current and potential coils. In the annular air gap between the stator and central core is the cylindrical part of the cup-like induction rotor. The central core is fixed to the stator frame. The cup alone turns. The combination of the smaller rotor inertia and the greater efficiency of this design greatly increases the speed.

For some time, polyphase directional relays of this type of construction have been built using 3 elements having 3 rotors mounted on a single shaft.

## Single-Unit 3-Phase Directional Element

Engineers have long considered the economy of using one directional unit to perform the polyphase function. In fact, methods utilizing potential and current switching have been in use for some time, mainly in other countries. These, however, have the disadvantage of being complicated by auxiliary switching relays, in addition to the time lost in performing the switching function.

The multiple-pole induction-cylinder relay makes it possible, as will be shown, to combine the polyphase function of 3 elements in a single element without the use of auxiliary switching. This has resulted in a large reduction in size and weight, together with low inertia and high speed, as illustrated in table I.

The relay operating element is similar to the element shown in figure 1, but a magnetic return path is provided for each salient.

The production of torque is like that in the induction-disk directional relay and the unit may be considered to be a number of directional magnets acting upon the same rotor.

Referring to figure 2, each coil produces rotor currents which react with the flux of each other coil to produce torque. The torque of adjacent pairs of salients is large, relative to that of other pairs. For example, the torque produced by combination 1 and 3 is approximately 15 per cent of the torque produced by combination 1 and 2, while that produced by combination 1 and 4 is about 2 per cent, a negligible amount. The torques of alternate salients (*e. g.*, 1 and 3 or 2 and 4) being appreciable, the connections are so arranged that these torques balance out substantially to zero; an adjustment being provided in addition, for more accurate balance of the current torques.

**Table I—Comparison of Types of 3-Phase Relays**

| | Two-Disk Relay (Per Cent) | Three-Cup Relay (Per Cent) | One-Cup Relay (Per Cent) |
|---|---|---|---|
| Size | 100 | 100 | 50 |
| Weight | 100 | 100 | 50 |
| Torque per watt input | 100 | 190 | 156 |
| Inertia of moving element | 100 | 17 | 6.6 |
| Speed (equal input) | 100 | 330 | 480 |
| Speed (rated input) | 100 | 330 | 280 |

Thus, in analyzing the action of the relay, it is necessary to consider only the adjacent combinations.

Although the same performance characteristics of all the usual connections (quadrature, etc.) are possible, the connections shown in figure 2 appear to be the most suitable. Considering the interaction of adjacent combinations, $I_a$ acts with $E_B$ and with $E_A$. Since $E_B$ and $E_A$ are on opposite sides of $I_a$, combination 1–2 is of opposite sign to combination 2–3. Assuming the reaction of each

A paper recommended for publication by the AIEE committee on protective devices. Manuscript submitted October 31, 1936; released for publication November 27, 1936.

A. J. McCONNELL is design engineer, relay engineering department, General Electric Company, Philadelphia, Pa.

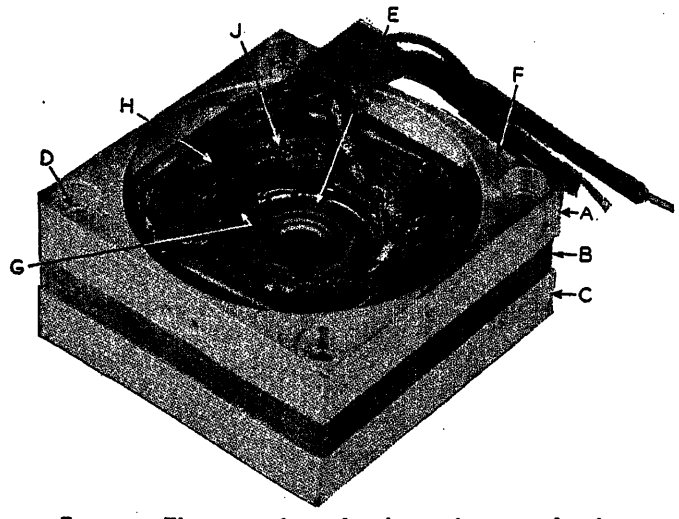

**Fig. 1. Element of single-phase directional relay**

*A*—Upper stator casting
*B*—Laminations
*C*—Lower stator casting
*D*—Rivets which fasten parts *A*, *B*, and *C* together
*E*—Central core (laminated iron) fixed to part *C*

*G*—Air gap in which rotor cup turns
*H*—Position for current coils
*J*—Position for potential coils

current coil with the counterclockwise potential coil as positive, and with the clockwise potential coil as negative, the total input (watts and reactive volt-amperes) to the relay will be[1]

$$P_R + jQ_R = (E_B - E_A)\bar{I}_a + (-E_A - E_B)\bar{I}_b + (E_A - E_C)\bar{I}_c + (E_A + E_C)\bar{I}_b$$

With the above power quantities supplied to the relay, it will have average torque proportional to

$$(|E_1|)(|I_1|)\cos(\phi_1 - 60 + \theta) + (|E_2|)(|I_2|)\cos(\phi_2 + 60 + \theta) \quad \text{(appendix I}A\text{)}$$

The corresponding equation for the torque of the standard quadrature connection of the usual type of induction-disk relay is

$$(|E_1|)(|I_1|)\cos(\phi_1 - 90 + \theta) + (|E_2|)(|I_2|)\cos(\phi_2 + 90 + \theta) \quad \text{(appendix II}A\text{)}$$

It may be seen that there is agreement between the 2 connections, except for 30 degrees in both the positive- and negative-phase-sequence terms.

With the connections of figure 2, there is a difference of 30 degrees in phase angle between a 3-phase fault and a dead phase-to-phase fault; maximum torque being at the more lagging angle in the phase-to-phase condition (appendix I*B*).

This characteristic is desirable because a 3-phase fault, from the relay point of view, is likely to be nearer unity power factor than is a phase-to-phase fault. This is because the phase angle at the relay during a 3-phase fault depends only on the impedance (line and arc) from the relay to the fault, whereas, during a phase-to-phase fault,

1. For numbered references see end of paper.

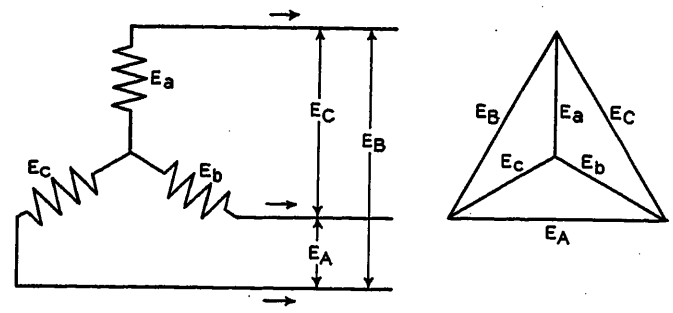

**Fig. 2a (right). Diagram illustrating relay connection**

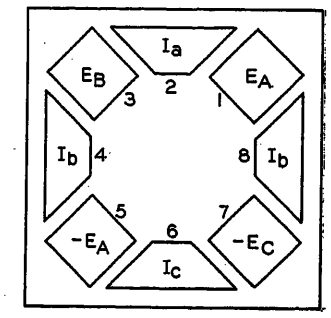

**Fig. 2b (above). Diagrams of current and voltage relations**

the phase angle depends on the impedance back to and including the generator as well as the impedance to the fault (appendix III). This inherent 30 degree shift is advantageous for another reason, namely, less resistance is required in the potential circuit than with the quadrature connection in order to obtain the same 3-phase phase-angle characteristics. The loss is therefore less.

## Quadrature and Other Connections

It is possible to obtain the performance characteristics of the well-known quadrature connection in several ways; 2 ways are illustrated in figure 3. Figure 3*a* utilizes phase-to-neutral voltages, the neutral being either ground or an artificial neutral formed by a common connection of the potential coils. Figure 3*b* uses a delta voltage on each potential coil. Appendix IV shows how each of these connections is equivalent to the quadrature connection.

It is also possible to obtain the equivalent of the adjacent connections by changing the cyclic order of either the voltages or currents of figure 3.

### Relays Using the 3-Phase Element in Combination With Other Elements

The element described in the preceding is, of course, a plain directional relay. On the same shaft have been added certain other elements of like construction in order to modify the characteristics. For example, it is often advantageous to prevent a directional relay from operating except during fault conditions. For this purpose, a voltage restraining element has been added. This type of relay is shown in figure 4.

Although a plain directional relay will often take care of ground faults as well as phase faults, it is necessary to add ground-fault protection when the torque caused by ground-fault voltage and current is less than that caused by load current, or when generation is present at one end only. To meet this requirement a strong ground-fault

element may be added to the 3-phase element, this combination being sufficient for almost any relay location.

The addition of a voltage-restraining element to the 3-phase directional and ground directional elements has resulted in an entirely new combination. A relay of this type is shown in figure 5.

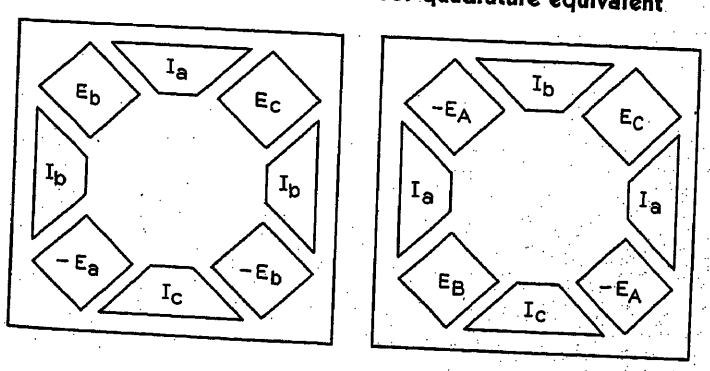
The successful use of the induction-cup element for the applications described above gives encouragement for the development of other forms of polyphase high-speed relays having a higher torque-to-input ratio and lower inertia of the moving parts.

## Nomenclature

$P_R$ = total power applied to relay
$Q_R$ = total reactive volt-amperes applied to relay
$I$ = current vector as a complex quantity (of the form $a + jb$)
$\bar{I}$ = conjugate of $I(a - jb)$
$|I|$ = absolute value of the vector $I(\sqrt{a^2 + b^2})$
$E$ = voltage vector as a complex quantity
$a$ = operator which rotates a vector 120 degrees in the counter-clockwise direction
$\alpha_1$ = angle by which the vector $E_1$ leads a reference line
$\beta_1$ = angle by which the vector $I_1$ leads a reference line
$\phi_1$ = $\alpha_1 - \beta_1$ = angle by which $I_1$ lags $E_1$
$\alpha_2$ = angle by which the vector $E_2$ leads a reference line
$\beta_2$ = angle by which the vector $I_2$ leads a reference line
$\phi_2$ = $\alpha_2 - \beta_2$ = angle by which $I_2$ lags $E_2$
$\theta$ = angle of lead (current leading voltage) at which maximum torque of a pair of adjacent salients occurs
$Z_1$ = positive-phase-sequence impedance of the generator
$Z_2$ = negative-phase-sequence impedance of the generator
$Z_L$ = positive- and negative-phase-sequence line impedance
$R$ = phase-to-neutral arc resistance
$K$ = relay torque constant per pair of adjacent salients

Subscripts $a$, $b$, $c$, $A$, $B$, $C$ are defined by figure 2$b$.
Subscripts 1, 2, and 0 denote positive, negative, and zero phase sequence, respectively.

## Appendix IA



Connections according to figure 2.
The total input to the relay is[1]

$$P_R + jQ_R = (E_B - E_A)\bar{I}_a + (\underline{-E_A} - E_B)\bar{I}_b + (-E_C + E_A)\bar{I}_c + \underline{(E_A + E_C)}\bar{I}_b$$

The underlined terms cancel, leaving

$$P_R + jQ_R = E_B\bar{I}_a - E_A\bar{I}_a + E_C\bar{I}_b - E_B\bar{I}_b + E_A\bar{I}_c - E_C\bar{I}_c$$

**Fig. 3. Relay connections for quadrature equivalent**

These power quantities can be expressed in terms of symmetrical components as follows:

$$E_B\bar{I}_a = (E_a - E_c)\bar{I}_a = E_0 + E_1 + E_2 - E_0 - aE_1 - a^2E_2)(\bar{I}_0 + \bar{I}_1 + \bar{I}_2)$$
$$= (1 - a)E_1\bar{I}_0 + (1 - a)E_1\bar{I}_1 + (1 - a)E_1\bar{I}_2 + (1 - a^2)E_2\bar{I}_0 + (1 - a^2)E_2\bar{I}_1 + (1 - a^2)E_2\bar{I}_2$$

The following table gives the coefficients of all of the sequence voltage-current products.

| Relay Quantities | $E_1\bar{I}_1$ | $E_1\bar{I}_2$ | $E_1\bar{I}_0$ | $E_2\bar{I}_1$ | $E_2\bar{I}_2$ | $E_2\bar{I}_0$ | $E_0\bar{I}_1$ | $E_0\bar{I}_2$ | $E_0\bar{I}_0$ |
|---|---|---|---|---|---|---|---|---|---|
| $E_B\bar{I}_a$ | $1 - a$ | $1 - a$ | $1 - a$ | $1 - a^2$ | $1 - a^2$ | $1 - a^2$ | 0 | 0 | 0 |
| $-E_A\bar{I}_a$ | $a^2 - a$ | $a^2 - a$ | $a - a^2$ | $a - a^2$ | $a - a^2$ | $a - a^2$ | 0 | 0 | 0 |
| $E_C\bar{I}_b$ | $1 - a$ | $a - a^2$ | $a^2 - 1$ | $a^2 - a$ | $1 - a^2$ | $a - 1$ | 0 | 0 | 0 |
| $-E_B\bar{I}_b$ | $a^2 - a$ | $1 - a^2$ | $a - 1$ | $1 - a$ | $a - a^2$ | $a^2 - 1$ | 0 | 0 | 0 |
| $E_A\bar{I}_c$ | $1 - a$ | $a^2 - 1$ | $a - a^2$ | $a - 1$ | $1 - a^2$ | $a^2 - a$ | 0 | 0 | 0 |
| $-E_C\bar{I}_c$ | $a^2 - a$ | $a - 1$ | $1 - a^2$ | $a^2 - 1$ | $a - a^2$ | $1 - a$ | 0 | 0 | 0 |
| Total | $3 - 6a + 3a^2$ | 0 | 0 | 0 | $3 + 3a - 6a^2$ | 0 | 0 | 0 | 0 |
| Total | $-9a$ | 0 | 0 | 0 | $-9a^2$ | 0 | 0 | 0 | 0 |

$$P_R + jQ_R = -9aE_1\bar{I}_1 - 9a^2E_2\bar{I}_2$$
but $a = \epsilon^{j120}$ $\quad a^2 = \epsilon^{j240}$
$E_1 = |E_1|\,\epsilon^{j\alpha_1}$ $\quad E_2 = |E_2|\,\epsilon^{j\alpha_2}$
$I_1 = |I_1|\,\epsilon^{-j\beta_1}$ $\quad \bar{I}_2 = |I_2|\,\epsilon^{-j\beta_2}$

(Note: Angles are in degrees.)

Therefore:

$$P_R + jQ_R = -9(|E_1|)(|I_1|)\epsilon^{j(\alpha_1 - \beta_1 + 120)} - 9(|E_2|)(|I_2|)\epsilon^{j(\alpha_2 - \beta_2 + 240)}$$
$$= 9(|E_1|)(|I_1|)\epsilon^{j(\alpha_1 - \beta_1 - 60)} + 9(|E_2|)(|I_2|)\epsilon^{j(\alpha_2 - \beta_2 + 60)}$$
$$P_R + jQ_R = 9(|E_1|)(|I_1|)[\cos(\alpha_1 - \beta_1 - 60) + j\sin(\alpha_1 - \beta_1 - 60)] + 9(|E_2|)(|I_2|)[\cos(\alpha_2 - \beta_2 + 60) + j\sin(\alpha_2 - \beta_2 + 60)]$$
$$= (|E_1|)(|I_1|)[\cos(\phi_1 - 60) + j\sin(\phi_1 - 60)] + 9(|E_2|)(|I_2|)[\cos(\phi_2 + 60) + j\sin(\phi_2 + 60)]$$

This is the total input to the relay in terms of symmetrical components. It is seen that the input consists of a positive-phase-sequence term with a voltage $E_1$, a current $I_1$, and an angle between $E_1$ and $I_1$ equal to $(\phi_1 - 60)$ and a similar negative-phase-sequence term with an angle $(\phi_2 + 60)$.

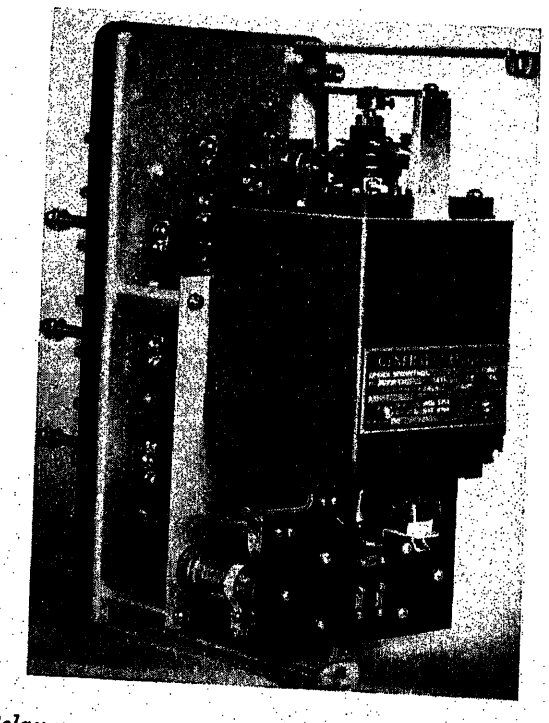


**Fig. 4. Three-phase directional relay with voltage restraint**

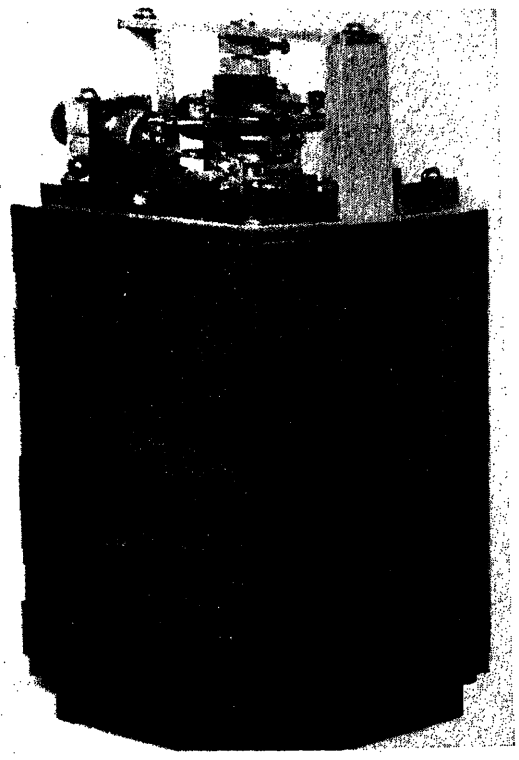

**Fig. 5. Three-phase and ground directional relay with voltage restraint**

On the basis of a pair of adjacent salients, the relay has average torque proportional to $(|E|)(|I|)\cos(\phi + \theta)$ where

$\phi$ = the angle by which the current lags the voltage
$\theta$ = the angle of lead (current leading voltage) at which maximum torque occurs

Thus, with the above input, the relay will have torque equal to

$$9K[(|E_1|)(|I_1|)\cos(\phi_1 - 60 + \theta) + (|E_2|)(|I_2|)\cos(\phi_2 + 60 + \theta)]$$

where $K$ is the relay torque constant per pair of adjacent salients.

## Appendix IB

Connections according to figure 2.

### Relay Torque During 3-Phase Fault

$$\text{Torque} = 9K(|E_1|)(|I_1|)\cos(\phi_1 - 60 + \theta)$$

Maximum torque is when $\phi_1 + \theta - 60 = 0$, that is, when $\phi_1 + \theta = 60$ (see figure 6)

### Relay Torque During Dead Phase-to-Phase Fault

Assuming $|E_1| = |E_2|$, $|I_1| = |I_2|$, and $\phi_2 = \phi_1 + 180$

$$\text{Torque} = 9K[(|E_1|)(|I_1|)\cos(\phi_1 - 60 + \theta) + (|E_1|)(|I_1|)\cos(\phi_1 + 180 + 60 + \theta)]$$

$$= 9K(|E_1|)(|I_1|)[\cos(\phi_1 - 60 + \theta) + \cos(\phi_1 + 240 + \theta)]$$

$$= 9\sqrt{3}K(|E_1|)(|I_1|)\cos(\phi_1 - 90 + \theta)$$

Maximum torque occurs when $\phi_1 - 90 + \theta = 0$
that is, when $\phi_1 + \theta = 90$ degrees (See figure 7)

## Appendix IIA

### Quadrature Connection

With the quadrature connection, $E_A$ operates with $-I_a$, $E_B$ with $-I_b$, and $E_C$ with $-I_c$.

The total input to the relay is

$$P_R + jQ_R = -E_A\bar{I}_a - E_B\bar{I}_b - E_C\bar{I}_c$$

| Relay Quantities | $E_1I_1$ | $E_1I_2$ | $E_1I_0$ | $E_2I_1$ | $E_2I_2$ | $E_2I_0$ | $E_0I_1$ | $E_0I_2$ | $E_0I_0$ |
|---|---|---|---|---|---|---|---|---|---|
| $-E_A\bar{I}_a$ | $a^2 - a$ | $a^2 - a$ | $a^2 - a$ | $a - a^2$ | $a - a^2$ | $a - a^2$ | 0 | 0 | 0 |
| $-E_B\bar{I}_b$ | $a^2 - a$ | $1 - a^2$ | $a - 1$ | $1 - a$ | $a - a^2$ | $a^2 - 1$ | 0 | 0 | 0 |
| $-E_C\bar{I}_c$ | $a^2 - a$ | $a - 1$ | $1 - a^2$ | $a^2 - 1$ | $a - a^2$ | $1 - a$ | 0 | 0 | 0 |
| Total | $3a^2 - 3a$ | 0 | 0 | 0 | $3a - 3a^2$ | 0 | 0 | 0 | 0 |

$$P_R + jQ_R = 3(a^2 - a)E_1\bar{I}_1 + 3(a - a^2)E_2\bar{I}_2$$
$$= -3\sqrt{3}\,jE_1\bar{I}_1 + 3\sqrt{3}\,jE_2\bar{I}_2$$
$$= 3\sqrt{3}(|E_1|)(|I_1|)e^{j(\alpha_1 - \beta_1 - 90)} + 3\sqrt{3}(|E_2|)(|I_2|)e^{j(\alpha_2 - \beta_2 + 90)}$$
$$= 3\sqrt{3}(|E_1|)(|I_1|)[\cos(\alpha_1 - \beta_1 - 90) + j\sin(\alpha_1 - \beta_1 - 90)] + 3\sqrt{3}(|E_2|)(|I_2|) \times [\cos(\alpha_2 - \beta_2 + 90) + j\sin(\alpha_2 - \beta_2 + 90)]$$

which is the total input to the relay in terms of symmetrical components and the relay torque is

$$3\sqrt{3}K[(|E_1|)(|I_1|)\cos(\phi_1 - 90 + \theta) + (|E_2|)(|I_2|)\cos(\phi_2 + 90 + \theta)]$$

## Appendix IIB

### Quadrature Connection

RELAY TORQUE DURING 3-PHASE FAULT

$$\text{Torque} = 3\sqrt{3}K(|E_1|)(|I_1|)\cos(\phi_1 - 90 + \theta)$$

Maximum torque is when $\phi_1 - 90 + \theta = 0$ that is, when $\phi_1 + \theta = 90$ (See figure 7)

RELAY TORQUE DURING DEAD PHASE-TO-PHASE FAULT

Assuming $|E_1| = |E_2|$, $|I_1| = |I_2|$, and $\phi_2 = \phi_1 + 180$

$$\text{Torque} = 3\sqrt{3}K[(|E_1|)(|I_1|)\cos(\phi_1 - 90 + \theta) + (|E_1|)(|I_1|)\cos(\phi_1 + 180 + 90 + \theta)]$$
$$= 6\sqrt{3}K(|E_1|)(|I_1|)\cos(\phi_1 - 90 + \theta)$$

Maximum torque is when $\phi_1 - 90 + \theta = 0$ that is, when $\phi_1 + \theta = 90$ (See figure 7)

# Ultrahigh-Speed Reclosing of High-Voltage Transmission Lines

By PHILIP SPORN
FELLOW AIEE

D. C. PRINCE
FELLOW AIEE

**Reclosure of circuit breakers following a fault on a high-voltage transmission line with a minimum of delay in order that synchronous load will not fall out of step is described in this paper. Apparatus that performs a complete operation in approximately 20 cycles on a 60-cycle system may be used to obtain a high degree of service continuity from a single-circuit transmission line.**

HIGH-SPEED reclosing of high-voltage transmission lines has been practiced for a number of years and has been described previously.[1] This method of reclosing has sometimes been termed "instantaneous reclosing." The term "instantaneous" obviously admits of no latitude. It has always, however, been broadly interpreted. As applied to reclosing of high-voltage circuits, as heretofore practiced, it is obviously a misnomer because the time involved has always been appreciable, running into a considerable fraction of a second. In this paper the authors have given the name of ultrahigh-speed reclosing to a reclosing operation at the maximum speed physical phenomena, particularly arc deionization, will permit. So far as is known, this is the first time that high-voltage transmission circuits have been set up to reclose on that basis.

## Background of the Problem

The experience back of high-speed reclosing and ultrahigh-speed reclosure is considerable. It has accumulated with the vast extension of transmission networks in the United States and with the experience in interruptions to service, particularly to industrial service, as a result of voltage surges or dips occurring on systems. The basic reason for these voltage dips was generally found to be the long time taken to clear faults occurring on the system. Going back 10 years, these times were frequently of the order of from 3 to 4 seconds. This long duration of reduced voltage, coupled with the fact that many of the industrial control systems were using extensively instantaneous undervoltage devices (instantaneous in this case involving times of from 5 to 10 cycles in the terms of a 60-cycle system) gave serious interruptions in section after section of the United States where transmission service was extensively substituted for rather short-feed localized generation service. The remedy adopted for these difficulties was two-fold. First, a reduction in time of relay action, and second, extensive work in the introduction of time delay undervoltage protection in connection with the control systems. The detailed methods for handling the problem in the latter fashion have again been described elsewhere.[2] All of these solutions, however, had definite limitations, first because many types of motor drives are fundamentally not susceptible to time-delay undervoltage protection as a cure and, second, there is always the problem of complete loss of service where a single line is utilized to take care of the supply into an area or station. One of these difficulties has lately been taken care of by extremely fast clearing of faults. Thus, in recent practice with the use of one-cycle carrier relaying it has been possible, even by using nothing more than a standard 8-cycle breaker, to get a maximum time clearing under all conditions of 0.15 second (9 cycles) and under these conditions the disturbance is not of sufficiently long duration to cause synchronous motor drives to drop out of step. However, there is still the problem of the single line which even with such rapid clearing of faults, of necessity, has to have a service interruption when the line is faulty. It is this particular problem that the authors and their associates had in mind and set themselves to solve in the development described herein.

In a measure this development is an outgrowth of the work done on high-speed breakers and high-speed relaying. Each of these particular developments has previously been described.[3,4,5,6] The problem posed was the attainment of a breaker reclosure so quickly that the net effect on load would be as if no interruption had taken place and no load would be lost. It is apparent that as regards lightning the same result could be obtained by the use of expulsion deionizing gaps. However, although considerable work in that direction has been carried out and some of it has been described,[7] it is a fact that the experience with gaps is still rather limited. Further, the gap has the disadvantage that it will not take care of anything but lightning difficulties and there are other difficulties besides lightning that may cause momentary flashovers which can be cleared and re-established by sufficiently fast reclosure. Besides, since there must be circuit breakers on the line in any event, if these circuit breakers by a special reclosing provision can approach the service standard of a line with both breakers and expulsion gaps, a considerable economic advantage is possible.

From all this it was apparent that a thorough exploration of the possibilities of ultrarapid reclosure by circuit breakers was in order. An examination of the problem

A paper recommended for publication by the AIEE committee on protective devices. Manuscript submitted October 31, 1936; released for publication November 21, 1936.

PHILIP SPORN is vice-president and chief engineer of the American Gas & Electric Company, New York, N. Y. D. C. PRINCE is chief engineer, Philadelphia (Pa.) works, General Electric Company.

1. For all numbered references see list at end of paper.

indicated that the following were essential parts of the solution to the problem:

1. Relaying must be provided which will locate the fault and communicate the trip impulse to all breakers involved in the shortest possible time and, if possible, in a time not exceeding one cycle.

2. Reclosing mechanisms must be provided which will open and reclose the breakers in a total time somewhere between 0.25 and 0.50 second, or a total time of somewhere between 15 and 30 cycles, with the chances very great of need in the direction of the smaller as against the larger of the 2 intervals.

3. The circuit breaker must extinguish the arc in the least possible time and in a period possibly not to exceed 5 or 6 cycles.

4. The actual arc causing the service interruption must not restrike when voltage is restored.

Some of these parts of the complete solution were already available or the facts with regard to the phenomena involved definitely known. Thus, it was definitely known that standard breakers could be obtained to operate in a period not to exceed 8 cycles, and special breakers in a period not over 3 cycles.[4] Again it was definitely known and experience had been previously obtained with a relay system functioning in a period not exceeding one cycle. However, the problem of getting a mechanism applicable to a standard breaker that would reclose in a period of from 7 to 8 cycles, or a total period from initiation of fault of 15 cycles, definitely had not been solved. Again, although the action of the arc upon re-establishment of potential had been previously explored[8] by others, insufficient and inconclusive data was available for complete guidance to a satisfactory solution of the problem presented. Nevertheless, it was decided that the period had arrived when it was necessary and desirable to attempt to bring to a solution this particular problem, taking advantage of what was available, and developing or exploring those parts that were unavailable from an equipment standpoint or unknown from a fundamental theoretical standpoint. This paper describes the developments thus made, the investigations both in the laboratory and in the field, and the performance of a system of rapid circuit interruption and ultrahigh-speed reclosing.

## Carrier Current Relaying System

Choice of relay equipment was determined by the desirability of high-speed operation combined with nearly simultaneous energization of the trip circuits of the breakers at each terminal. Carrier-current relaying is the only practical system which provides high-speed operation for any fault at any location on the circuit being protected.[9] When it came to a decision as to the type of carrier to be employed, one was confronted with the fact that as a matter of plain arithmetic a one-cycle system was almost essential. Thus, if 6 cycles is allowed for arcing and 8 cycles is permitted for reclosure after the arc has been extinguished, the total time available for relaying, if the total time of 15 cycles is to be adhered to, is only one cycle. It was obvious that if a larger amount of time was satisfactory for reclosure, some leeway was available in the relaying time but the one-cycle system, if practically available, was ideally suited for this problem.

The one-cycle relaying system utilized here has been previously described[5,6] as can be seen by reference to such previous data. The trip circuit is normally held open by the receiver relays and it is closed only by the dropping out of these relays when no carrier signal is received. Since the relays controlling the trip circuits at both ends are simultaneously de-energized by the stoppage of the carrier signal, the actual closing of the trip circuits will occur at nearly the same instant.

Because of the importance that the relaying plays in the entire scheme, it may be pertinent to review the salient parts of the relay scheme, their function and performance. Figure 1 shows the fundamental scheme and involves in essence the following equipment:

1. *Receiver Relay.* This is a polarized relay having a field winding and an operating winding arranged to be energized either from the local battery circuit or from the received carrier signal. The relay

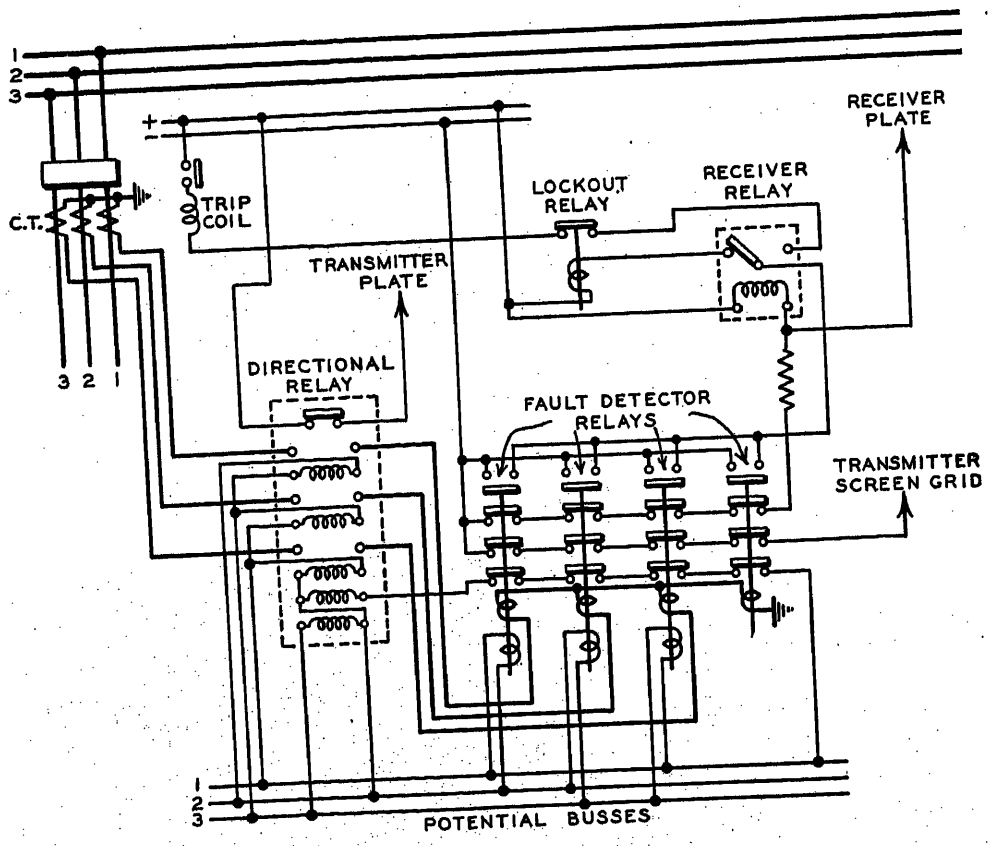

**Fig. 1. High-speed carrier-current relay circuit**

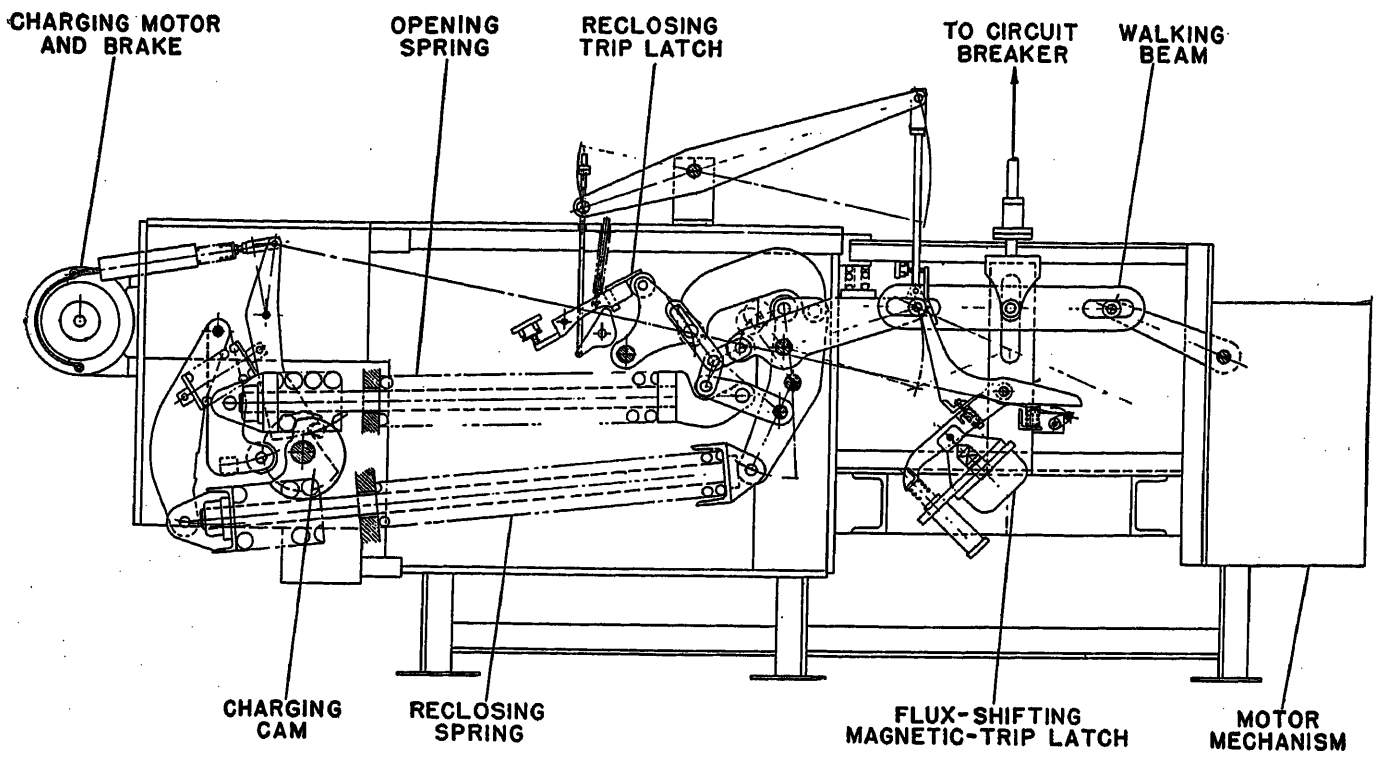

**Fig. 2. Schematic diagram of ultrahigh-speed reclosing mechanism for oil circuit breakers**

will close its tripping contacts when de-energized and hold the tripping contacts open normally when excited from the battery circuit and during fault conditions when excited from the received carrier signal. The relay will close its lockout contacts when energized and hold them closed normally when excited from the battery circuit and during fault conditions when excited from the received carrier signal.

2. *Fault Detecting Elements.* Three for phase faults, these being of the impedance type, that is, having a current operating winding and a voltage restraining winding, and one for ground faults having only a current winding. All of these fault detectors were equipped with 4 independent contacts for performing the following functions:

*a.* A circuit-opening contact for starting carrier by the removal of the grid bias.

*b.* A circuit-opening contact for disconnecting the receiver relay coil from the local battery supply.

*c.* A circuit-opening contact for removing voltage restraint from the directional relay.

*d.* A circuit-closing contact which is in series with the receiver relay contact and the tripping circuit.

3. *Directional Relay.* This is the polyphase type, having voltage restraint. This relay is of the new induction cup type, giving it greater speed than was obtainable with previous types of power directional relays.

4. *Lockout Relay.* This is a time-delay circuit-opening and circuit-closing auxiliary relay of the plunger bellows type which is adjusted to give a time delay of 5 cycles in opening or closing its contacts.

The sequence of operation is comparatively simple and may be described briefly as follows: Under normal conditions the directional-relay contacts are held closed by voltage restraint, applying plate voltage to the transmitter but the transmitter does not operate because of the normally closed contacts of the fault-detector relays which apply a negative bias to the screen grid of the transmitter. Further, the receiver-relay contacts are held open by the closed contacts of the fault-detector relays energizing the receiver-relay coil from the station battery. In case of an internal fault the directional relays will operate to stop the transmission of carrier at both ends of the line. When the carrier from both ends has been stopped then the receiver relays are de-energized and they both drop out, completing the trip circuits. The receiver relay operates in an average time of 0.35 cycle. The directional relay opens its contacts in an average time of 0.40 cycle so that the fundamental fastest time possible is approximately 0.75 cycle. Some variations on either side of that value are obviously possible. On an external fault one of the directional relays on the end where power is flowing from the line into the bus will permit the carrier signal to be maintained, thereby preventing tripping. The function of the lockout relay is to open the trip 5 cycles after the circuit-closing contacts of the fault detector have closed to prevent false tripping on a through fault as the result of sudden reversals of power flow and also to prevent tripping in case of system instability.

## Tripping and Reclosing Mechanisms and Circuit-Breaker Operation

Most standard mechanisms require about 0.5 second to close the circuit breaker. Reclosing mechanisms have been made providing an over-all time of this order by connecting 2 mechanisms together through a walking beam. One of the 2 mechanisms is at all times at rest with its latch reset. When tripped the circuit breaker opens until the energized mechanism builds up enough force to overcome the opening springs and momentum.

It was obviously necessary in this case to secure a much

higher speed than was obtainable in this way. Accordingly, a spring-charged mechanism was designed to take the place of one standard mechanism in the teamed arrangement. This mechanism is shown schematically in figure 2. A standard motor mechanism operates on one end of the main walking beam to the center of which the circuit-breaker linkage is attached. For ordinary switching operations and for the second opening should a flashover re-establish or repeat, this mechanism functions in a normal manner. The spring mechanism of the stored-energy type has 2 sets of springs; one set to reinforce the breaker opening springs, the other set to close. This mechanism when charged performs an opening and closing operation, its normal position being closed.

The spring mechanism has a high-speed latch of the flux-shifting type which operates with the opening springs to give a contact parting time of from 2.5 to 3.5 cycles. After the contacts have moved 8 inches a link attached to the opening mechanism trips the auxiliary opening springs and releases the closing springs. These then reclose the breaker. Figures 3 and 4 are views of the mechanism and an ultrahigh-speed breaker installation, respectively, which give an excellent idea of the size.

During the reclosing stroke the tripping circuit is transferred to the motor mechanism so that a permanent fault will be tripped off at once. As adjusted for test, one of these mechanisms gave an over-all time from initial trip impulse to contact make of 15 cycles. It proved rather difficult to hold this fine adjustment throughout so that the service record aimed at was much nearer 18 cycles. A typical calculated travel record is shown in figure 5. It may be noticed first that the total time from the instant of energization of the trip coil is 16 cycles: taking relay time at one cycle, this gives a total time from initiation of fault of 17 cycles. Second, the mechanism once started on a tripping cycle is definitely set for reclosure upon the completion of 8 inches of stroke without waiting for arc extinction. This definitely meant that the circuit breaker had to be reliable to the point where it would extinguish the arc on the completion of the allowed stroke, that is, 8 inches, with enough to spare for the tripping relays to reset. As will be brought out later, this was accomplished in general very successfully.

## Basic Ideas Underlying Ultrahigh-Speed Reclosing

As previously pointed out, one of the essential parts of the solution of the problem of ultrarapid reclosing was the necessity for the actual arc causing the service interruption not to restrike when voltage is restored. The usual fault against which protection is sought is a lightning stroke. The circuit in this case cannot be re-energized until the ionization produced by the stroke has been dissipated enough that the restored voltage may be withstood. This time was investigated in both field and laboratory tests. Griscom and Torok[8] have made a series of such tests, varying the current from 800 to 1,500 amperes and the voltage from 66 kv to 130 kv with the spacing of electrodes from 12 inches to 93 inches. They concluded that:

1. The restriking of arcs is a random phenomenon.

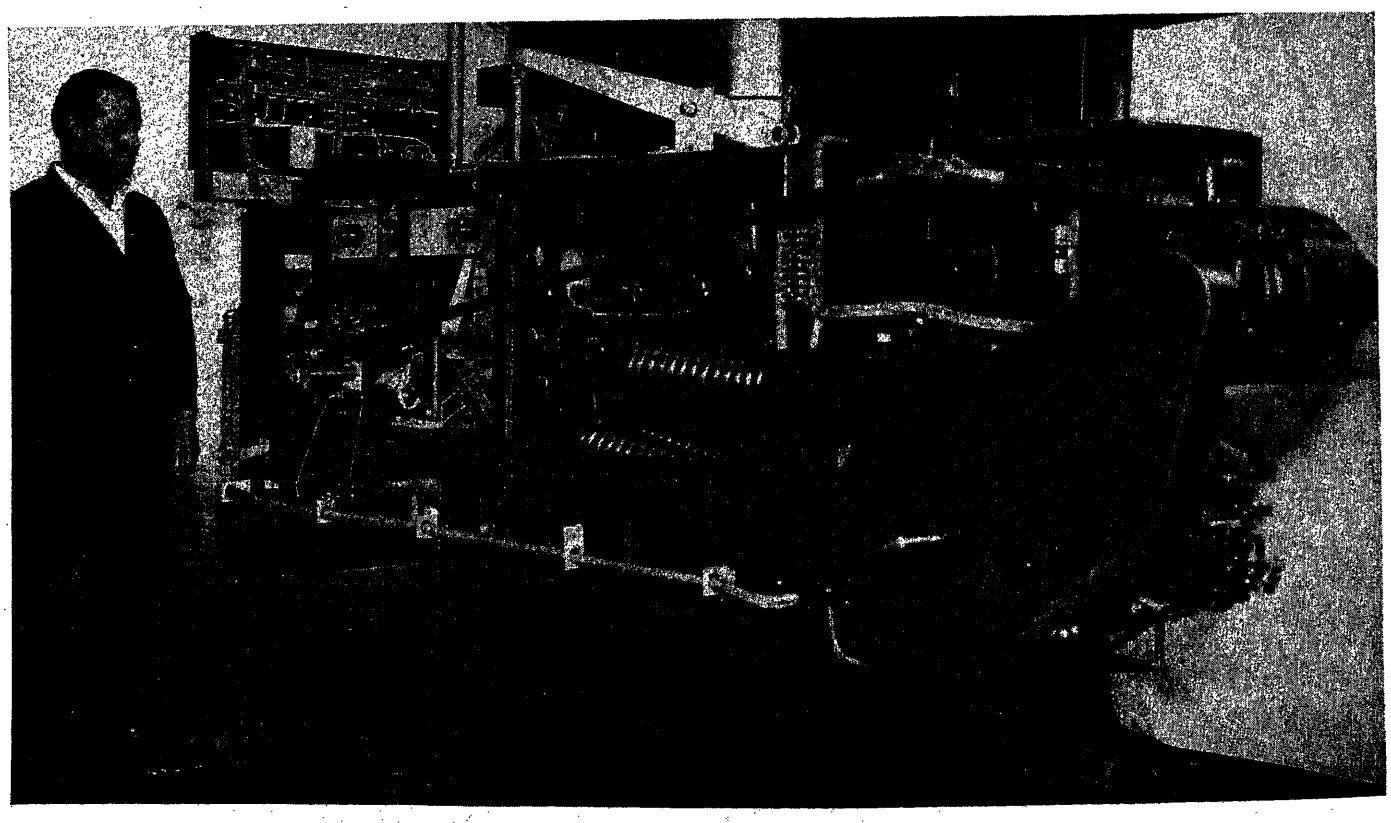

**Fig. 3. Ultrahigh-speed circuit-breaker reclosing mechanism**

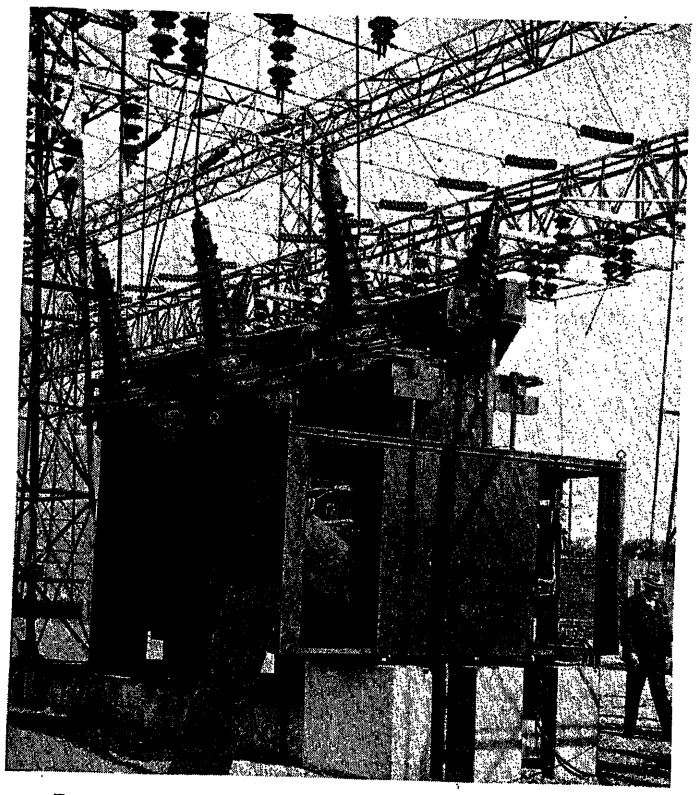

**Fig. 4. A 132-kv installation of the ultrahigh-speed reclosing breaker**

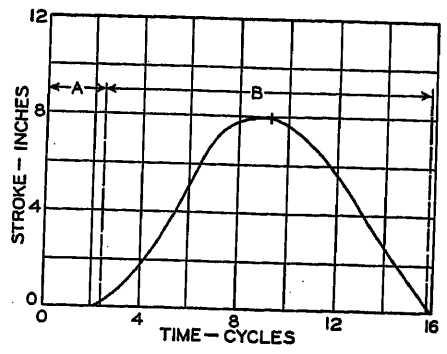

**Fig. 5. Travel record of ultra-high-speed mechanism**

*A*—Trip impulse of 2.4 cycles until contacts part

*B*—Contacts part to make 8-inch stroke during 13.4 cycles

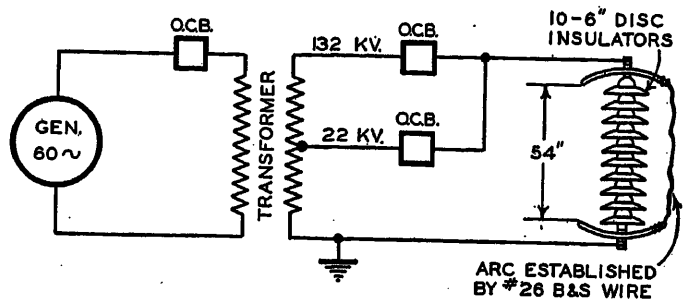

**Fig. 6. Circuit used for laboratory tests**

2. The probability of restrike increases with operating voltage for spacings ordinarily used.

3. The probability of restriking is only slightly affected by large variations in current.

4. For a given recovery voltage above a certain spacing, the probability of restriking is but slightly affected by the spacing of electrodes; below this value, spacing plays an important part.

The restriking times found by Griscom and Torok vary from about $1^1/_2$ cycles at 66 kv to a little over 3 cycles at 130 kv. The authors made some preliminary tests in 1935, under conditions similar to those used by Griscom and Torok but with currents of the order of 5,000 amperes, from which a probable restriking time of nearly 5 cycles resulted. These tests seemed to indicate that insufficient current range had been used in the earlier tests. Several other variables seemed to require attention, including velocity of wind, duration of arcing, and position of gap. In addition to these, the weatherman's part in the picture had to be determined. What would be the practical effect of multiple strokes of lightning? Would field experience show a larger or smaller proportion of successful reclosures than obtained in fair weather tests? It was decided to undertake additional tests along 3 lines:

1. Additional laboratory tests to further clarify the effects of voltage, current, distance between electrodes, wind, arc duration, etc.

2. Staged field tests to cross check against laboratory tests and determine the operation of high-speed reclosure under practical field conditions.

3. An extended field-operation test to determine from experience the service improvement possible with high-speed reclosure.

## Laboratory Tests

The method employed in the laboratory tests is indicated in figure 6. A fine-wire fuse is suspended between the ends of an insulator string, arcing horns, or other electrodes. The arc is drawn by closing a 20-kv circuit through this fuse. The fuse is quickly vaporized. The 20-kv circuit is then opened and after a time another circuit of higher voltage is closed. Some 300 tests have been made from which some conclusions seem justified, while others are in doubt. Figure 7 is a chart and table I is a summary of all the tests made. On the chart, crosses indicate a restrike and circles an absence of restrike. A line is drawn from the cross representing the longest restriking time to the circle representing the shortest non-restriking time. The center of this line should represent 50 per cent probability of restriking.

Any conclusions drawn are subject to modification as more experimental evidence becomes available.

In the meantime, the data on the chart and table may be examined to determine different tendencies. As a matter of probabilities, one may conclude that:

1. Restriking times are longer with a high-current arc.

2. Restriking times are longer the longer the arc is sustained.

3. Restriking times are longer in still air.

4. Moderate changes in electrode form, spacing, and location of arc are not important although a wider range might disclose differences as in 1, 2, and 3.

5. Restriking times vary from $2^1/_2$ to 12 cycles.

The line of development which would give a minimum

## Table I—Summary of Laboratory Tests on Effect of Various Changes on Restriking Time on String of Suspension Insulators

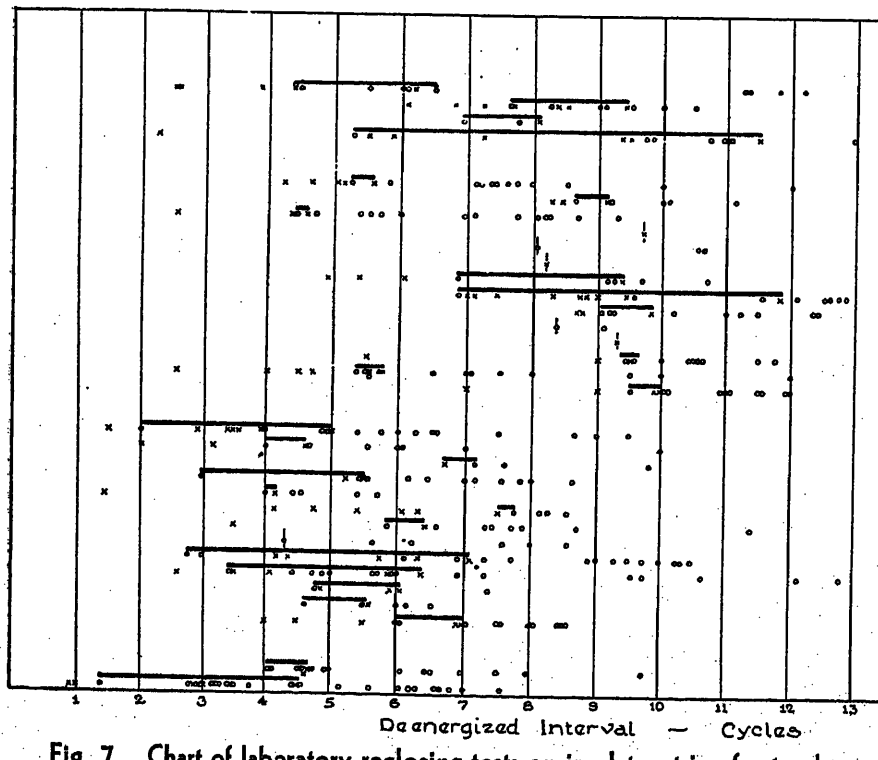
outage time should combine high-speed tripping to give short fault duration with high-speed reclosing.

If reclosing is to be at a long enough interval to give little probability of a restrike, voltage must not be applied to the line for about 12 cycles after the arc has been interrupted. With an 8 cycle breaker this gives 20 cycles for the over-all reclosure time. At the other extreme, reclosure after $2^1/_2$ cycles will be successful sometimes. If a flashover is caused by multiple lightning strokes, some reclosures longer than 20 cycles over-all may still be followed by restriking. For that reason, the final limits will not have been determined until after a considerable period of experience under actual service conditions.



## Field Tests

The actual installation of ultrahigh-speed reclosing breakers was made on the 59.2-mile 132-kv line between the Fort Wayne, Ind., station of the Indiana & Michigan Electric Company and the Deer Creek (Marion) station of the Indiana General Service Company. High-speed reclosing mechanisms of the type described herein were installed on the breakers at both stations. One-cycle carrier-current relaying was employed on the line for fast and simultaneous tripping of breakers at both ends of the line. Automatic high-speed oscillographs were installed at both stations to determine the performance of the breakers under actual operating conditions. As a preliminary to long-time test operation, a series of complete tests was made on May 17, 1936, and another on June 14, 1936, the object being not only to test thoroughly the performance of the assembled equipment but to ascertain, if possible, the likelihood of successful performance under actual operating conditions and the actual time to be used as the reclosure interval for such long time tests.

In all, 35 reclosure tests were made. A tabulated summation of 20 of these tests is indicated in table II.

Tests 1 to 4 illustrate the normal performance of the breakers and relays for an internal phase-to-ground fault. The carrier-current relays operated within from 0.70 to 1.00 cycle after the inception of the fault to energize the trip circuits of the circuit breakers. The line was completely de-energized from 5.3 to 7.2 cycles later and remained so for a period of from 10.7 to 12.0 cycles before being re-energized. The total time from the initiation of the fault until the reclosing of the last breaker was from 21.0 to 21.8 cycles. On all of these tests the line was re-energized without restriking of the arc.

Tests 5 to 7 show the performance for internal phase-to-phase faults not involving ground. Here it will be noted that in 2 of the tests the arc was restruck after the line was energized. The line was de-energized for periods of from 11.5 to 14.1 cycles, and the test where the line was de-energized for 14.1 cycles was the only case where the arc did not restrike after energization of the line.

In test 8 an internal phase-to-phase-to-ground fault was applied. Here the line was de-energized for 13.3 cycles and the line was re-energized without the arc restriking.

Tests 9 to 13 were made to determine the minimum time that the line could be de-energized on an internal phase-to-ground fault without the arc restriking upon energization of the line. This was accomplished by intentionally delaying the tripping time of the breaker at Deer Creek station by inserting a time-delay auxiliary relay in the trip circuit. It may be noted that the minimum time the line had to be de-energized averaged approximately 6.0 cycles in order to prevent the arc restriking. In test 13, voltage was reapplied a second time when the breaker at Deer Creek station finally reclosed. The dead time in the second interval was only 2.0 cycles.

Tests 14 to 20 were made to determine the performance of the reclosing equipments on a single tie line between 2 systems (not otherwise connected in parallel) with varying amounts of load transfer over the tie line. The system arrangement used on these tests represented a single 132-kv tie line approximately 340 miles long between the 2 generating stations.

With load transfers up to 28,000 kw over the tie line, the breakers and relays performed satisfactorily to hold the 2 systems in synchronism upon reclosure. With load transfer up to 40,000 kw over the tie line, the breakers reclosed satisfactorily at both terminals of the tie line but the operation of the relays retripped the breakers. Figure 6 shows 3 oscillograms taken at Fort Wayne station for tests 4, 7, and 15, respectively. The top oscillogram is for test 4 from which it will be noted that the directional relay contacts opened after 0.50 cycle, that blocking was removed in 0.60 cycle, and trip circuit energized in 1.0 cycle after the inception of the short circuit. Fault current was 300 amperes, primary current, and was interrupted in a total time of 6.3 cycles. The breaker contacts reclosed in 17 cycles, total time, or 16 cycles after the trip circuit was energized, as indicated by the oscillations in the current element. The point where the breaker contacts reclose can also be determined from the top oscillograph element which is attached to a travel recorder and gives the mechanical position of the breaker contacts throughout the operation.

The middle oscillogram is for test 7, which was a phase-to-phase short circuit in which the arc restruck. The relay operating time was somewhat faster in this case, the directional-relay contacts opening in 0.4 cycle, blocking being removed in 0.5 cycle, and the

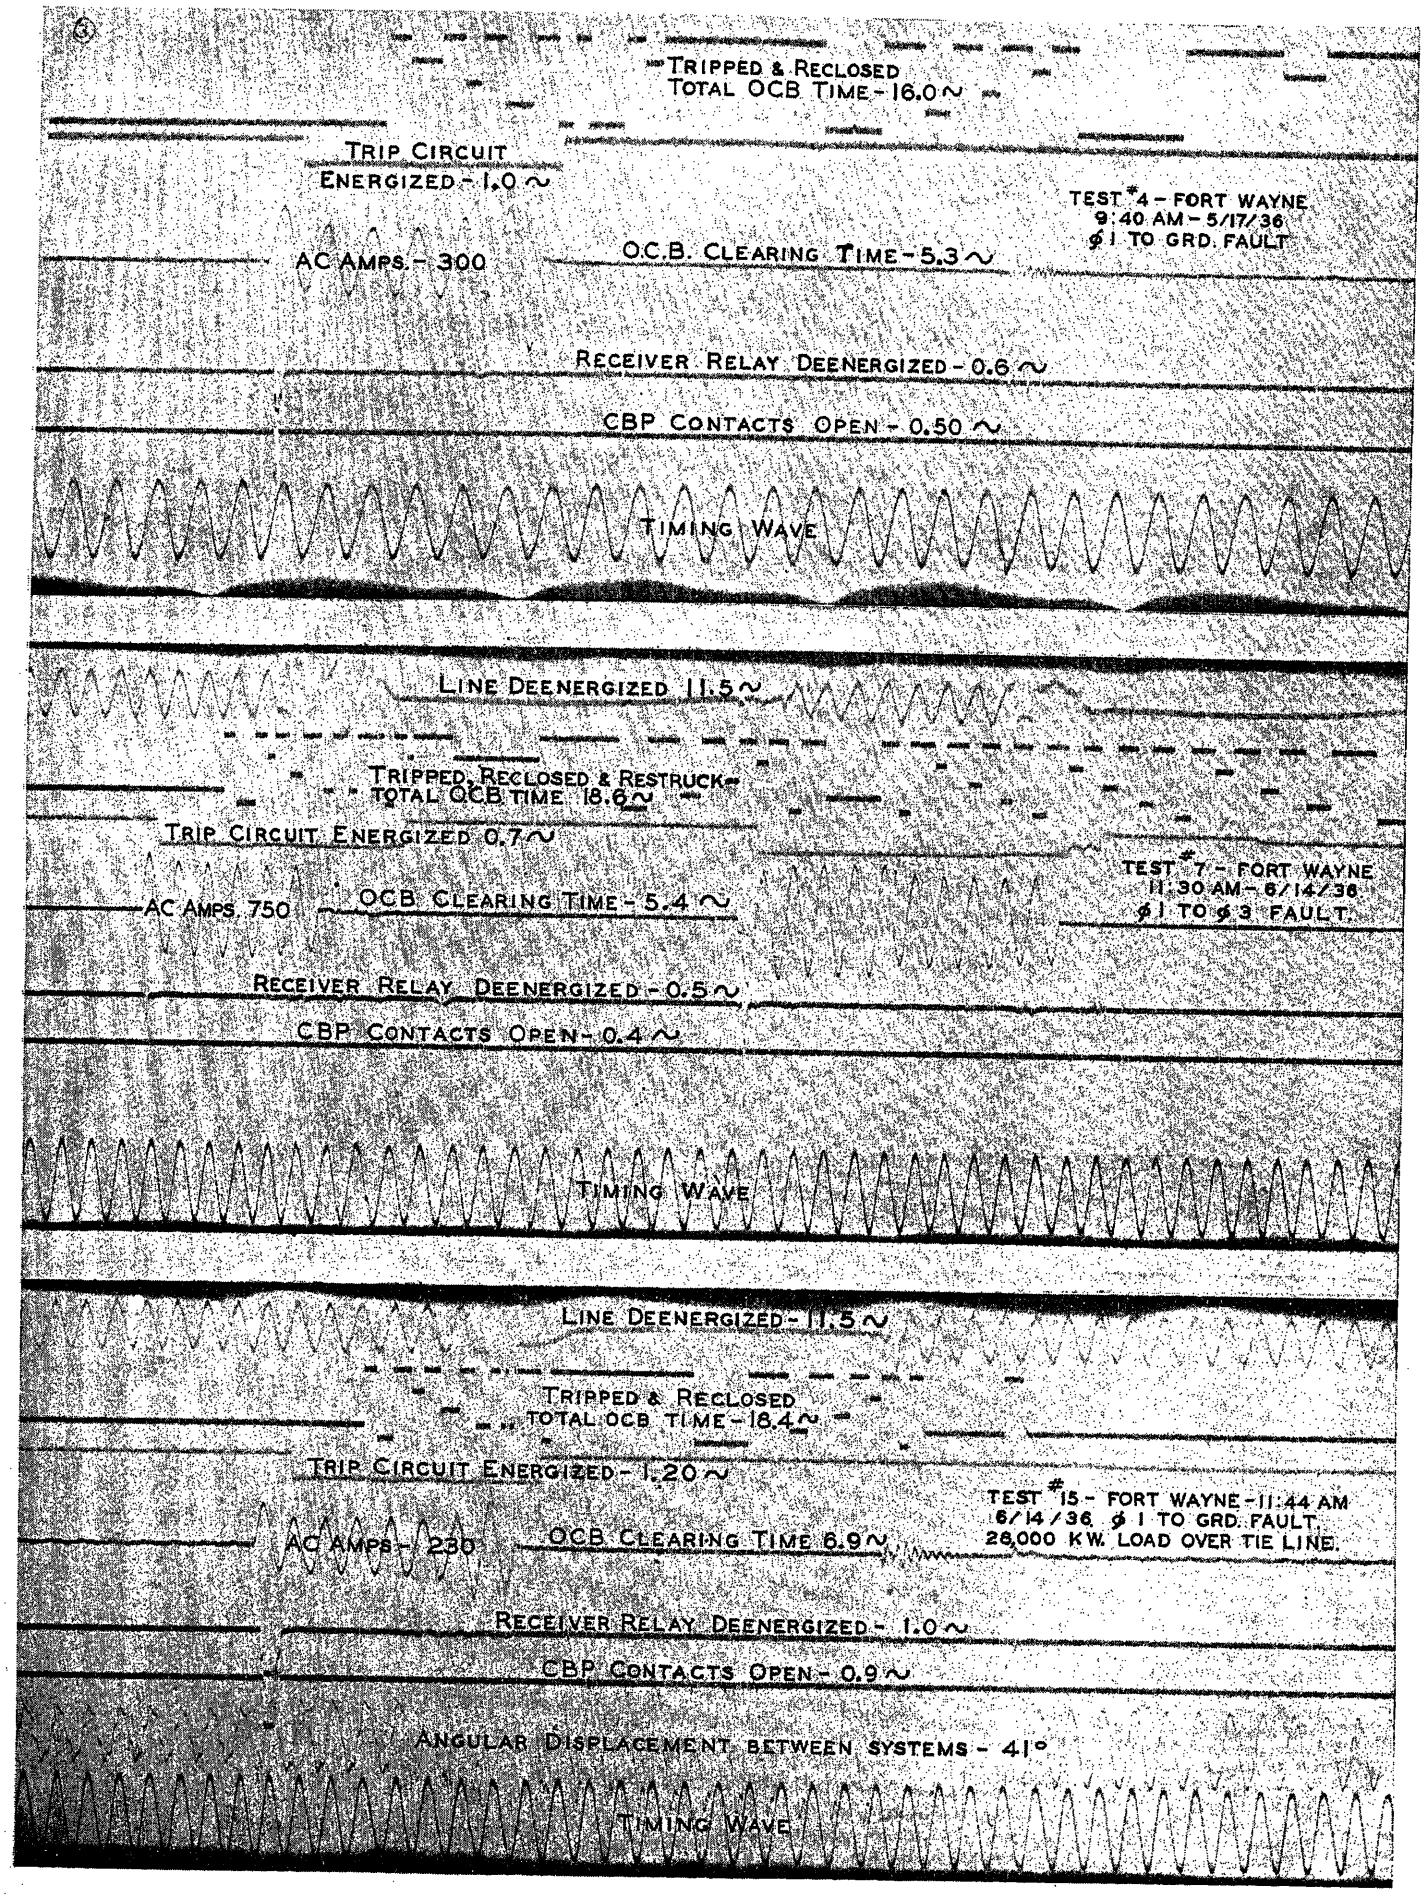

**Fig. 8. Oscillograms of field tests**

trip circuit energized in 0.7 cycle. Fault current was 750 primary amperes and was finally interrupted in a total time of 7.7 cycles. The breaker contacts reclosed in 19.3 cycles and this time the arc was re-established. In this case the top element of the oscillograph was connected to a potential transformer on the line and hence shows directly the total time the line was de-energized, which was 11.6 cycles.

The bottom oscillogram is for test 15. This was a single phase-to-ground fault with the systems out of parallel during the time the line was open. The relay operating time was 0.9 cycle for the directional relay contacts to open, 1.0 cycle for the blocking to cease, and 1.2 cycles before the trip circuit was finally energized. This slower relay time was probably due to the low fault current, which was only 230 primary amperes at the beginning of the fault. The fault current was interrupted in 8.1 cycles and the breaker reclosed 19.6 cycles after the fault began. The line was de-energized for 11.5 cycles. The angular displacement between the 2 systems was 41 degrees at the instant they reclosed. This was measured by connecting an element of the oscillograph so as to measure the vector difference between the voltages of phases one on the 2 systems. The oscillograph element measuring fault current measured ground current and hence does not show the original load current or the in-rush of current which occurred when the line was reclosed.

## Field Experience

Since the installation of the ultrahigh-speed reclosing equipments on the Fort Wayne-Deer Creek line in May 1936, there have been 4 lightning flashovers on this line. In all 4 cases, the flashover occurred between phase 3 and ground. The average time that the line was de-energized was 13.0 cycles. In 3 cases the breakers at both ends of the line tripped and reclosed within a total time of 22.0 cycles without the arc restriking. In one case, the breakers failed to stay in after reclosing because the arc restruck, which is believed to have been caused by a multiple lightning stroke. Figure 9 shows an oscillogram taken at Deer Creek station for a flashover from phase 3 to ground caused by lightning that occurred at 8:59 a.m. on August 28, 1936. The fault current was 1,165 amperes, primary current, and was interrupted in total time of 6.0 cycles. The breaker contacts reclosed in 22.5 cycles total time or 21.5 cycles after the trip circuit was energized. The line was de-energized for a period of 12.5 cycles. From the elements measuring the 3 phase-to-phase bus voltages, it may be seen that the fault was a flashover from phase 3 to ground.

## Future Possible Applications

It is, of course, extremely difficult, nor is it well within the province of a paper of this sort, to predict the course a development of this type will take. Even more difficult is the problem of indicating with so little experience available the possible immediate application. One thing, however, is certain, on lines forming part of extensive transmission networks and particularly where loads of appreciable magnitude are carried, if lightning is at all a factor it ought to be found economically extremely attractive to equip the 2 ends of any lines of that sort with mechanisms of the type described to make possible ultra-rapid reclosing on any lightning outage. As a matter of fact, on the power system with which one of the authors is associated, 2 such lines in addition to the one described are now being so equipped.

The application of ultrahigh-speed reclosing, the authors believe, may eventually make possible in some instances a reduction in the investment in transmission lines now required to give uninterrupted service to large industrial loads. That is, the duplicate line may, with the further development of this idea, give way to the single line with the possibility of giving as good service with the single line as can be given with the multiple feeds now used.

# Pole Flexibility as a Factor in Line Design

By HOWARD P. SEELYE
MEMBER AIEE

MYRON ZUCKER
MEMBER AIEE

**Poles are ordinarily considered as rigid struts in designing structures for supporting overhead lines, even in situations where they are not restrained by guys and it is known that movement takes place under variation in loading. This paper points out the importance of making allowance for this factor under certain conditions and gives the theory and practical methods for its solution.**

ALTHOUGH it is customary, in designing a structure for supporting overhead lines, to consider a pole as a rigid strut, there are situations where this assumption leads to considerable error. The processes whereby the flexibility of the supports can be taken into account are by no means obvious.

In certain cases, which are not at all infrequent in practice however, the neglect of this inherent characteristic of the materials will lead to unnecessary strength in some parts and insufficient strength in others. It is the purpose of this paper to point out some of these cases, to discuss methods by which this effect may be determined, and to indicate how these may be applied to the development of working rules and charts which can be applied to field problems with sufficient accuracy for practical purposes.

## Typical Cases in Which Flexibility Is of Importance

As a simple illustration of the effect of pole flexibility, consider a line dead-ended on a pole which, for some reason, cannot be guyed. A common practice in such a case would be to guy the next-to-last pole, either to an anchor or to the end pole itself, holding the greater part of the conductor tension on the guyed pole. The conductors in the end span are then slacked off to reduce the tension to an amount which will not exceed the allowable load on the unguyed pole under the heaviest condition of loading which is anticipated (see figure 1). If it is assumed that the total dead-end tension of the conductors must be held by the guy on pole $A$, that guy will be made unnecessarily strong, since part of this load is balanced by the tension of the conductors in the end span. If, on the contrary, the end pole $B$ is considered rigid, and full allowance is made for the guying effect of the conductors in the slack span on this basis, the load assigned to the guy will be too small. This is evident when the actual effect of the flexing of the pole $B$ is considered. As the load on the wires (wind and ice) increases, the tension in the end span would tend to increase. This increase in tension applied to pole $B$ will cause it to deflect toward pole $A$. This, in turn, will increase the sag in the conductors, tending to reduce their tension. Equilibrium is reached when, under the assumed loading conditions, the sag in the conductors is just sufficient to produce a tension which will deflect the pole an amount necessary to produce that sag. The tension in these conductors will naturally be less than it would be if pole $B$ were rigid, hence the load actually held by the guy must be more than would be indicated by a calculation based on the assumption of rigidity. However, the strength necessary in pole $B$ will be appreciably less than would be required if no deflection occurred.

Figure 2 shows a dead-end pole guyed to an unguyed stub, with a guy on the pole ahead. Here the deflection of both pole $A$ and the stub, acting together, affects the conductor tension in the end span and allowance must be made for it if the sizes of pole $B$, the stub, and the 2 guys are to be accurately determined. Such a situation is frequently encountered in alleys in Detroit, wherein the stub is a telephone pole subject to joint use. Consideration of flexibility allows an appreciably smaller class of pole to be used for the stub than would be required under the usual assumption of rigidity.

Figure 3 shows a short run between 2 dead-end poles. Considering flexibility, it may be feasible to leave both poles unguyed, if guying is difficult. Figure 4 shows an unguyed angle in the line with the adjacent poles guyed. Here the effect of deflection is somewhat different due to the angle, but it can sometimes be used to advantage in determining the size of the corner pole and the guys. Figure 5 shows a street lamp supported on a span wire. Allowance for the reduction in stress resulting from pole flexibility may make guying unnecessary.

There are other similar situations wherein the allowance for flexibility will serve to give a better and more economical design, but these are typical and will serve to illustrate the problem.

## General Method of Solution

The general method of attacking the problem of making proper allowance for pole flexibility may be indicated by reference to the simple case shown in figure 1. The movement of the pole under a varying applied force, such as the tension in the wires, may be plotted in the form of line $B$ in figure 6. The relation between the tension in the wires and the span length or the change in span length (that is, the pole

A paper recommended for publication by the AIEE committee on power transmission and distribution. Manuscript submitted October 16, 1936; released for publication November 19, 1936.

HOWARD P. SEELYE and MYRON ZUCKER are engineers of the Detroit (Mich.) Edison Company.

movement) may also be plotted in the form of curve $A$ in figure 6. The point at which these curves intersect gives the solution at which equilibrium is reached, that is, the tension which is just sufficient to move the pole an amount which will sag the wire

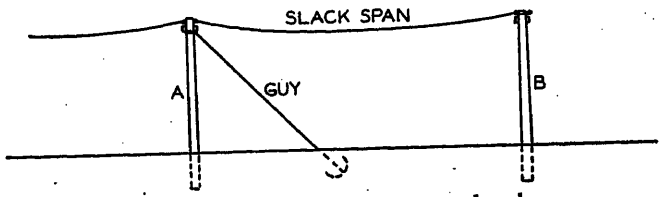

Fig. 1. Dead end on unguyed pole

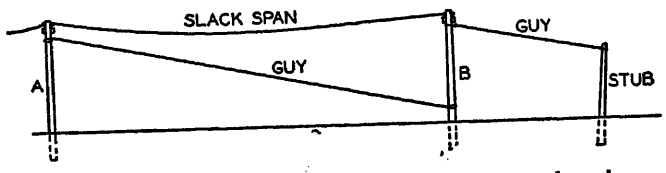

Fig. 2. Dead-end pole guyed to unguyed stub

sufficiently to produce that tension. This is the basis of the methods followed in this study.

Two methods will be described. The first is an elaboration of the general solution by the plotting of the 2 curves just discussed. This is accurate within the limits of accuracy of the methods used in determining tension-span relations but is somewhat cumbersome for general application to a variety of problems. The second method, which is more convenient to use, introduces several approximations, the errors involved being relatively insignificant, however.

## Exact Solution

*Pole Characteristic.* The derivation of the curves shown on figure 6 requires some explanation. In order to plot curve $B$, the relation between the flexure in a pole and the applied force must be determined. The theory for calculating this characteristic for any given pole is shown in the appendix. A "deflection constant" is derived which gives the number of pounds of applied horizontal load per foot of deflection, the butt being held fixed. It is recognized that in some cases there may be a movement of the pole in the ground which will add to the effect of its flexure. Allowance can be made for this in choosing the deflection constant if its magnitude is known. Since this quantity is indeterminate, however, and the data which are available are meager, and also since it is practicable to support the pole by blocking or concreting against any considerable foundation movement under the loads considered, the effect of such movement has been ignored in this paper. This relationship is assumed to be reasonably constant throughout an ordinary range of loading, within the elastic limit, hence the stress-strain curve (and curve $B$ of figure 6) is a straight line. The slope of the line is equal to the deflection constant $p$. For the condition illustrated, where the horizontal scale is in terms of movement from the position of initial loading, the intercept with the vertical axis (load for 0 movement) is $T_1$, which is the applied load or the tension in the wires under the assumed initial loading conditions. The intercept with the horizontal axis (pole position at zero load) is at a negative value equal to the deflection of the pole under initial conditions. The scale may be arranged to show total pole movement from the unloaded condition, if desired, in which case the intercept with the horizontal axis will be the zero point.

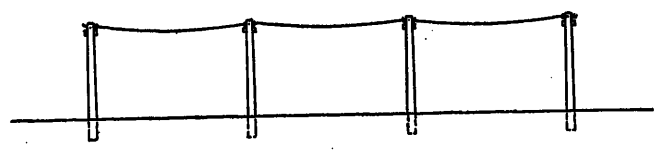

Fig. 3. Short line with neither end guyed

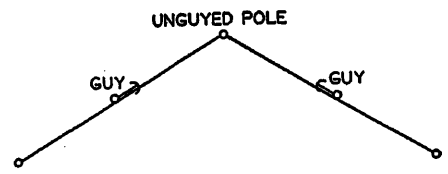

Fig. 4. Plan of angle with corner pole unguyed

*Wire Characteristic.* The $A$ curve may be derived by any of the well-known methods of determining sag-tension relations in a wire span. The Thomas chart has been found convenient for ordinary spans with copper wire. If composite conductors such as *ACSR* (aluminum-cable steel-reinforced) are used, or if greater accuracy is desired with copper, some of the more refined methods using stress-strain curves obtained by test may be necessary. The Thomas chart method will be described in the following.

It may be remembered that the Thomas chart uses a curve showing the relationship between tension and length of wire in the span. Specifically, the co-ordinates are a "stress factor" $(T/wS)$ equal to

$$\frac{\text{tension}}{\text{load per foot span} \times \text{span}}$$

and length of wire per foot span, $(L/S) = l$, as shown in figure 7. For a given span $S$, an initial loading $w_1$ per foot, and an initial sag, the initial value of $T_1/(w_1S)$ is calculated and the value of $l_1$ found from the chart. From this, a quantity $l_0$, the "unstressed length," is derived by subtracting from $l_1$ the elongation resulting from the tension in the wire

$$l_0 = \frac{l_1}{1 + \frac{T_1}{AE}}$$

where $A$ is the cross-sectional area of the wire and $E$ the modulus of elasticity. The line $l_0r_1$ plotted on the chart, figure 7, is the stress-stretch line of the

wire for loading $w_1$. For a change in load to $w_2$, a new stress-stretch line similar to $l_0r$ is plotted between $l_0$ and a point $r'$ whose co-ordinates are $T_1/(w_1S)$ and $l_0 + (w_2/w_1)\ (l_1 - l_0)$. The intersection of $l_0r'$ with the curve at $r_2$ gives the new value of $T_2/(w_2S)$ and hence of $T_2$.

For a change in temperature, the unstressed length $l_0$ changes to a new length $l_0' = l_0(1 + \alpha t)$, where $\alpha$ is the coefficient of expansion and $t$ the change in temperature, using the proper sign for $t$. The new stress-stretch line for load $w_1$ at the new temperature (not shown on figure 7) is parallel to $l_0r_1$; the new stress-stretch line for $w_2$ is parallel to $l_0r_2$.

Determination of the effect of a change in span as the result of pole movement is quite similar to that for temperature change. The actual unstressed length of the wire remains the same, but, since the span changes, $L_0/S$ (and hence $l_0$) will change. If the pole should move so that the span will be shortened

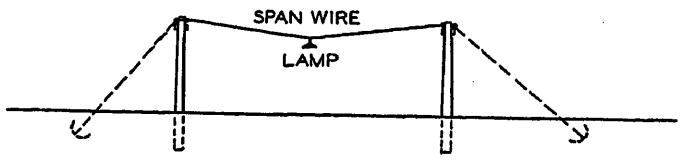

**Fig. 5. Street-lamp suspension with customary guys shown**

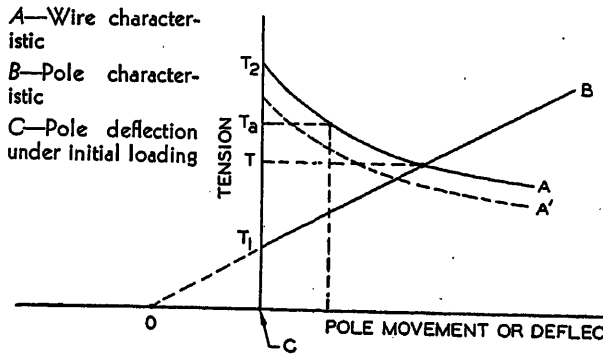

**Fig. 6. Construction of graphic solution for flexible span**

one per cent, $l_0 = L_0/S$ changes to $l_0'' = L_0/0.99S = l_0/0.99$. The stress-stretch line through this new point $l_0''$ for the new span will be parallel to the one through $l_0$ for the same loading, since the slope of this line is

$$\frac{T}{wS} \div \frac{L - L_0}{S} = \frac{T}{w(L - L_0)}$$

which is independent of span length. On figure 7, $l_0''r_a$ is parallel to $l_0r_2$, for loading $w_2$, and its intersection with the curve at $r_a$ gives the solution for $T_a/(w_2S_a)$ and hence $T_a$ for the reduced span.

This is the basis for plotting curve $A$ of figure 6. For example, if initial conditions $w_1$, $S_1$, and sag are given, $T_1$ and $l_0$ may be determined. The pole is initially deflected by $T_1$ an amount $T_1/p$. If the pole were held fixed at that point, $T_2$ for a new loading, $w_2$, would be found by figure 7. This $T_2$ will give the intercept of the curve $A$ (figure 6) with the vertical axis, since it is the tension in the wire for zero movement. Assume a certain reduction in span such as one foot or one per cent, and find the corresponding $T_a$ as herein described. Plot this as a second point on the $A$ curve. Assume other possible pole movements and find the corresponding values of $T_a$, locating other points on the $A$ curve until it is completely plotted. The intersection of this $A$ curve with the $B$ line is the solution for the loading $w_2$. For other loadings, such as $w_3$, another $A$ curve such as $A'$ in figure 6 can be similarly derived and the solution obtained. It should be remembered that the load applied to the pole is the total of all the wires carried, hence the $A$ curve must represent the sum of all the wire tensions. Where different sizes are present, separate curves may be plotted and totaled into one combined $A$ curve. The error is usually not great, however, if the combined curve is obtained by using the total cross-sectional area, loading, and tensions of all wires.

This method, although relatively accurate and not difficult for a specific problem, is somewhat cumbersome for general use, where various wire sizes, spans, and loadings are being considered. The second method to be described is sufficiently accurate for most purposes and is more easily handled for a variety of problems. This method and the resulting charts will also be found useful in solving spans with rigid supports as well as those with flexible supports.*

## Approximate Method

For this solution the parabolic formulas for wire-span relationship are used instead of the catenary

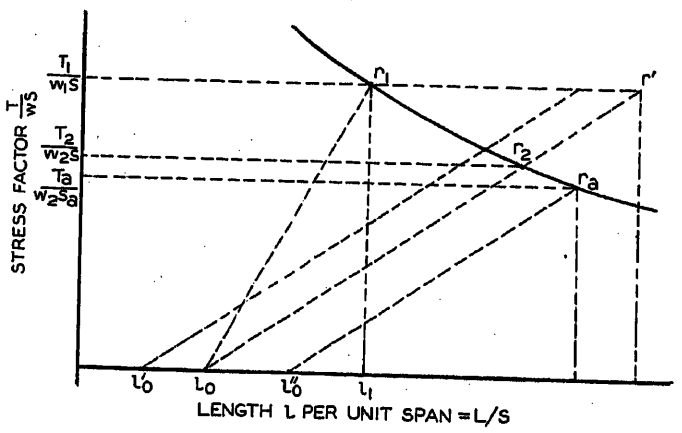

**Fig. 7. Thomas chart**

as being more convenient and not introducing serious error. For any wire hanging in a span, the following relationships exist:

$$\text{Length of wire} = L = S + \frac{8D^2}{3S} \qquad (1)$$

* Originality is not claimed for this method of solving spans with rigid supports since the principles are referred to in several previous publications, both in this country and abroad. See "Sag Problems Readily Solved by Aid of Alignment Chart," by D. C. Stewart, *Electrical World*, volume 96, September 20, 1930, page 518, and others. The detailed application here is somewhat different, however, and the development for flexible supports is believed to be new.

$$\text{Tension in wire} = T = \frac{wS^2}{8D} \qquad (2)$$

Where

$S$ = span in feet
$D$ = sag or deflection in feet
$w$ = load in pounds per foot

*Rigid Supports.* For the ordinary case of rigid supports, the span length is fixed, hence the relationship of equation 1 is between 2 variables, length of wire and deflection, the latter also being dependent upon loading and tension in accordance with equation 2. On account of its elastic characteristic, the length of wire varies with the tension; it also varies with the temperature. The unstressed length of the wire at a given temperature, that is, its length if removed from the span and laid on the ground is a fixed quantity, however, and can be used as a reference in determining the effect of various changes in conditions. The unstressed length can be obtained from equation 1 by subtracting from $L$ the elongation caused by the tension obtained from equation 2.

$$L = L_0\left(1 + \frac{T}{AE}\right) \qquad L_0 = \frac{L}{1 + \frac{T}{AE}}$$

For the present purpose it is somewhat more convenient to change this to a form which is approximately as correct:

$$L_0 = L\left(1 - \frac{T}{AE}\right)$$

Substituting equations 1 and 2, respectively,

$$L_0 = \left(S + \frac{8D^2}{3S}\right)\left(1 - \frac{T}{AE}\right)$$

$$L_0 = \left(S + \frac{8D^2}{3S}\right)\left(1 - \frac{wS^2}{8DAE}\right) \qquad (3)$$

Equation 3 is a general expression for the unstressed length of the wire for any given loading, sag, and temperature. The value remains the same for any other loading which may be imposed on the wire, provided the temperature does not change. Hence its value, determined for an initial loading $w_1$, may be used to find sags and tensions for other loadings such as $w_2$.

$$L_0 = \left(S + \frac{8D_1^2}{3S}\right)\left(1 - \frac{w_1S^2}{8D_1AE}\right) = \left(S + \frac{8D_2^2}{3S}\right)\left(1 - \frac{w_2S^2}{8D_2AE}\right)$$

This expression can be solved for $D_2$ if $L_0$ is obtained from $w_1$ and $D_1$.

If equation 3 is expanded, the expression becomes

$$L_0 = S + \frac{8D^2}{3S} - \frac{wS^3}{8DAE} - \frac{wSD}{3AE}$$

It will be found that the last term is of insignificant size compared with the others and may be dropped from the equation without appreciable error, leaving

$$L_0 = S + \frac{8D^2}{3S} - \frac{wS^3}{8DAE} \qquad (4)$$

For convenience equation 4 may be operated upon mathematically by subtracting the span length $S$ (a constant for any problem with rigid supports) from both members and also by dividing both members by $S$. The deflection per foot of span, $d = D/S$ is also introduced. This gives a quantity designated as $e$, which is the difference per unit span between unstressed length of wire and span length.

$$e = \frac{L_0 - S}{S} = \frac{8}{3}d^2 - \frac{1}{8d}\frac{wS}{AE} \qquad (5)$$

It is possible to plot a nomograph from this equation using as variables $e$, $d$, and $(wS)/(AE)$ as illustrated by figure 8. If the value of $(w_1S)/(AE)$ is computed for an initial loading $w_1$, a straight line from that point on the left-hand scale through the value of initial deflection $d_1$ on the middle scale

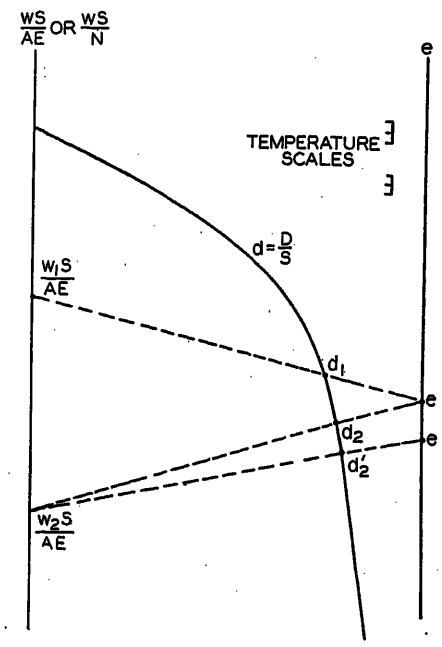

**Fig. 8. Nomographic method of solution for rigid or flexible span**

intersects the right-hand scale at the value of $e$. Since $e$ is constant (for a given temperature) another straight line from $e$ to the calculated value of $(w_2S)/(AE)$ for a new loading $w_2$ will give a new deflection $d_2$, from which the new tension can be computed from the formula

$$T = \frac{wS^2}{8D} = \frac{wS}{8d} \qquad (6)$$

A change in temperature changes the unstressed length, $L_0$, to some new value $L_0(1 + \alpha t)$ where

$\alpha$ = temperature coefficient of expansion
$t$ = change in temperature in degrees, positive for a rise, negative for a fall

If $L_0$ has been determined for given initial conditions including temperature $t_1$, $L_0'$ for some other temperature $t_2$ will be

$$L_0' = L_0[1 + \alpha(t_2 - t_1)] = L_0 + L_0\alpha t$$

Since the length $L_0$ is not greatly different from the span length $S$, no appreciable error is introduced if the last term is written $S\alpha t$.

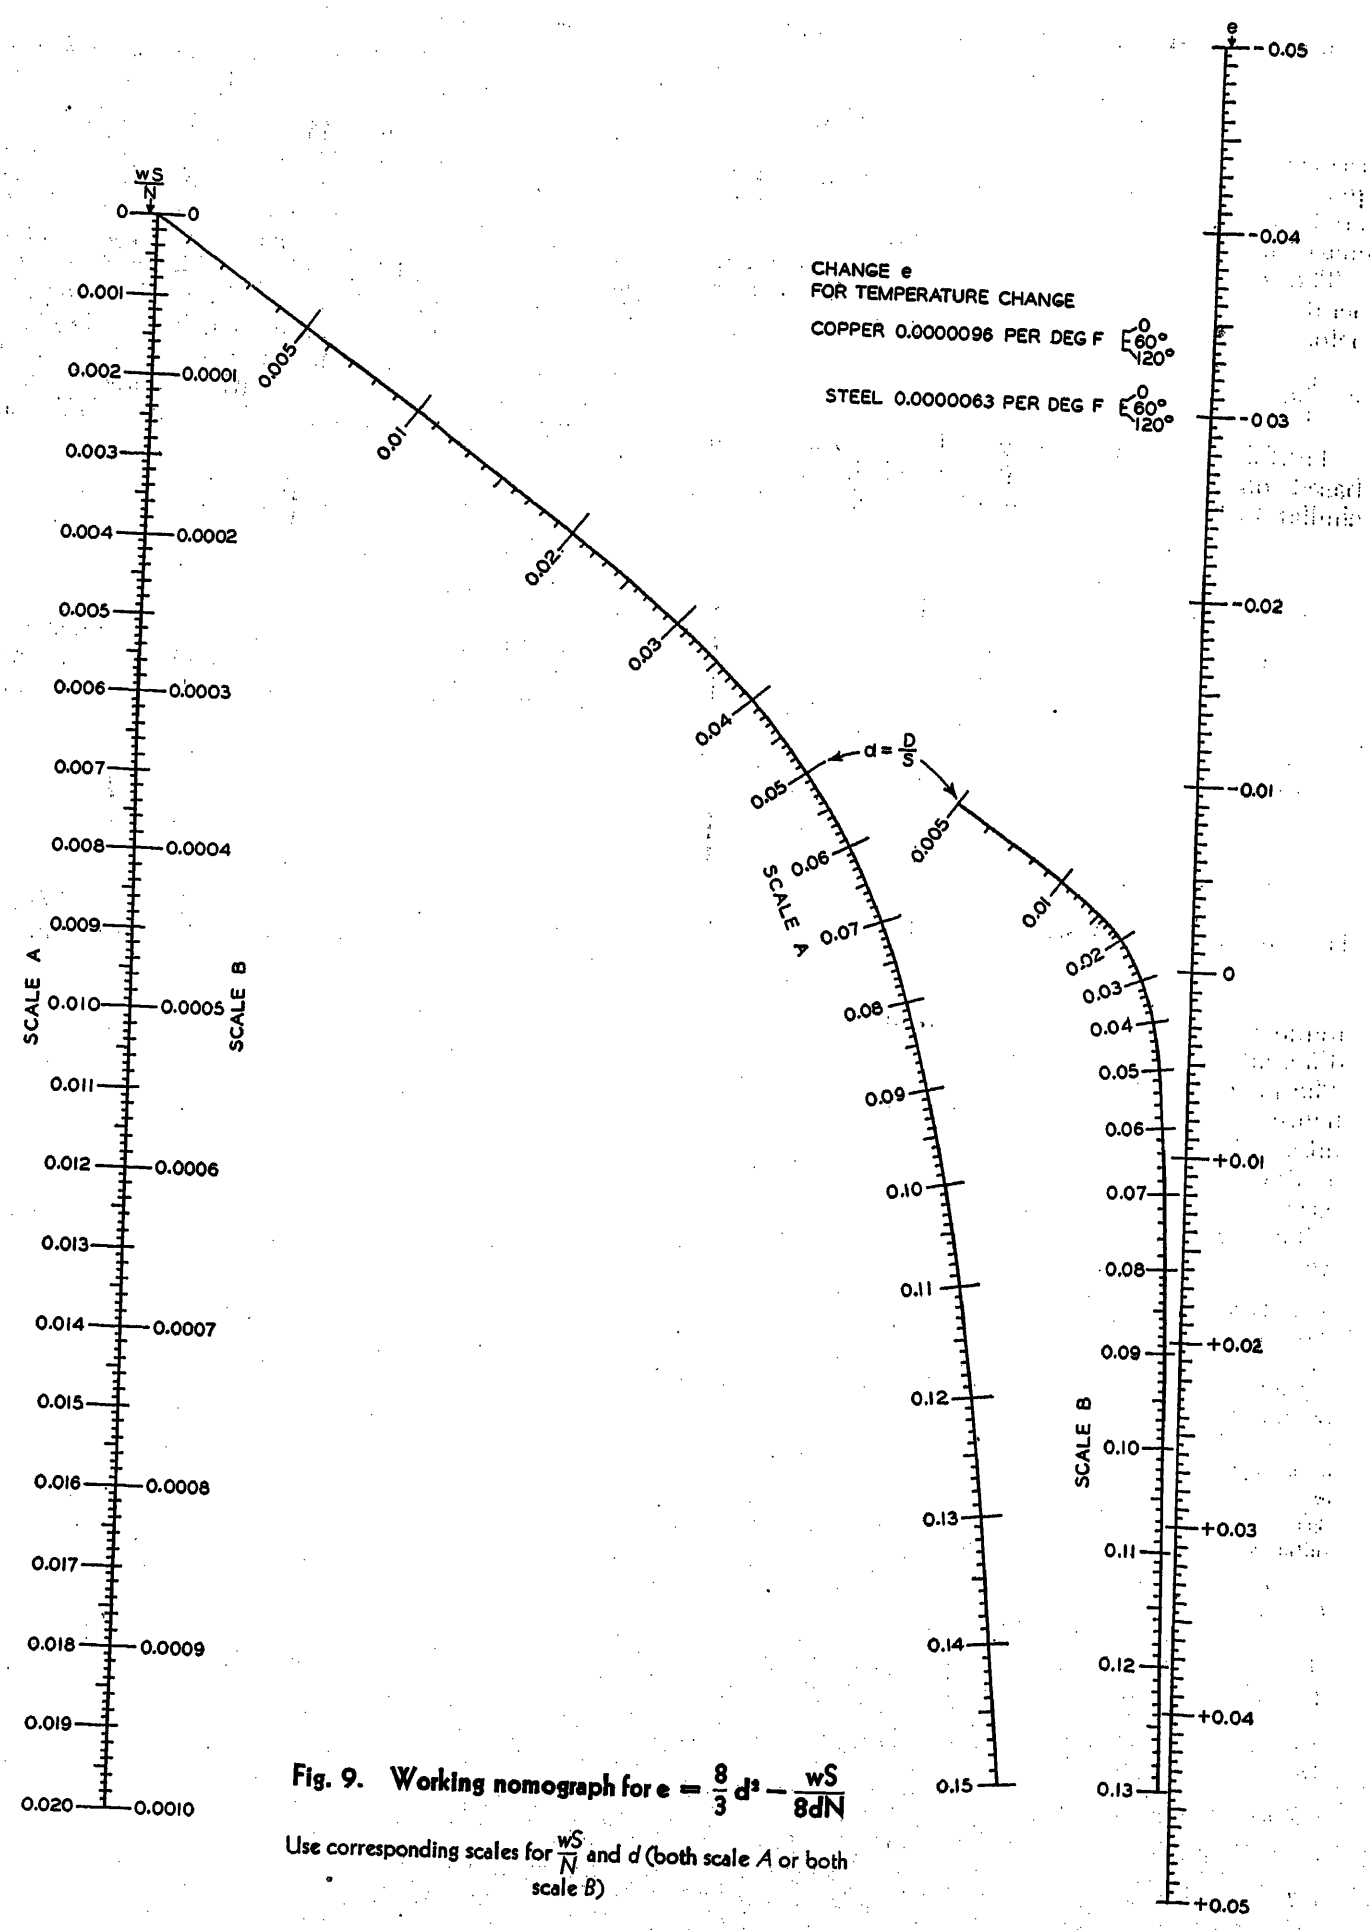

**Fig. 9. Working nomograph for $e = \frac{8}{3} d^2 - \frac{wS}{8dN}$**

Use corresponding scales for $\frac{wS}{N}$ and $d$ (both scale $A$ or both scale $B$)

Introducing this quantity into the equation for $e$,

$$e' = e + \alpha t \tag{7}$$

If $e$ has been determined from the chart as described, $e'$ can be found by adding or subtracting the quantity $\alpha t$. This may be done graphically, if desired, by using a small supplemental scale on the chart which shows $\alpha t$ for any value of $t$.

The value of $d_2'$ and hence $T_2'$ for the new temperature, $t_2$, can now be obtained from the chart as before, since the chart solves the equation

$$e' = \frac{8}{3}d_2^2 - \frac{1}{8d_2}\frac{w_2 S}{AE}$$

The following example is solved by a working chart based on the principles illustrated by figure 8, similar to that given in figure 9. It will usually be

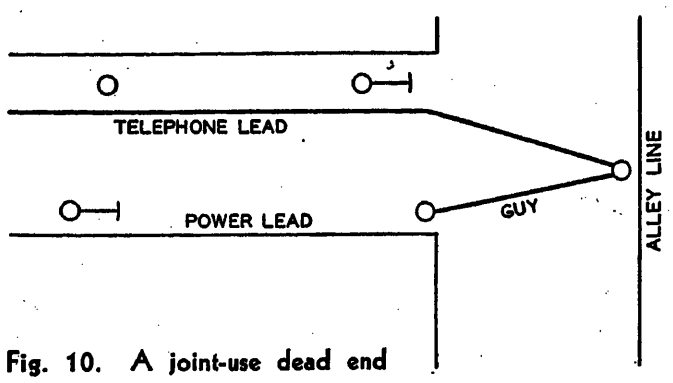

**Fig. 10. A joint-use dead end**

found convenient to plot several of these charts to different scales to cover different ranges of values. The present example can be solved by the chart of figure 9 with fair accuracy but since the latter was intended for the flexible span problems which follow, another chart with a smaller range was actually used.

This example is for 3 number 0 triple-braid weather-proof copper wires where

| | |
|---|---|
| Initial loading $w_1$ | = 0.424 pounds per foot |
| Heavy loading $w_2$ | = 1.55 pounds per foot |
| $AE$ | = 1,160,000 per conductor |
| Initial temperature $t_1$ | = 60 degrees Fahrenheit |
| Loaded temperature $t_2$ | = 0 degrees Fahrenheit |
| $t$ | = −60 |
| $\alpha$ for copper | = $9.6 \times 10^{-6}$ |
| $\alpha t$ | = $-5.76 \times 10^{-4}$ |
| Span | = 100 feet |
| Initial wire deflection $D_1$ | = 1.5 feet |

$$d_1 = \frac{D_1}{S} = 0.015$$

$$\frac{1}{AE} = 0.861 \times 10^{-6}$$

$$\frac{w_1 S}{AE} = 0.424 \times 100 \times 0.861 \times 10^{-6} = 36.5 \times 10^{-4}$$

$e_1$ (from chart) = 0.000298

$$e' = e_1 + \alpha t = 0.000298 - 0.000576 = -0.000278$$

$$\frac{w_2 S}{AE} = 1.55 \times 100 \times 0.861 \times 10^{-6} = 133.2 \times 10^{-4}$$

$d_2$ (from chart) = 0.0166

$T_2 = (w_2 S)/(8d_2) = 155/(8 \times 0.0166) =$ 1,165 pounds per wire or 3,495 pounds for 3 wires

*Flexible Span.* If the support is not fixed, but can move as the wire tension changes, the span becomes a variable in the equation instead of being a constant. Assuming the span fixed at one end, flexible at the other, with a pole deflection constant of $p$, for any tension $T$ the pole will move $T/p$ and hence the span will be shortened that amount. If the initial span is $S$, the span for any wire tension $T$ will be $S - (T/p)$.

Referring to equations 4, 5, and 7, the unstressed length $L_0$ under any such conditions would be obtained by use of the actual span length $S - (T/p)$ in the form

$$L_0 = S - \frac{T}{p} + \frac{8D^2}{3\left(S - \frac{T}{p}\right)} - \frac{w\left(S - \frac{T}{p}\right)^3}{8DAE}$$

The quantity $e$ is defined as the difference per unit of *original* span $S$, between unstressed length of wire and *original span*, since the original span is a constant.

$$e = \frac{L_0 - S}{S} = -\frac{T}{pS} + \frac{8D^2}{3S\left(S - \frac{T}{p}\right)} - \frac{w\left(S - \frac{T}{p}\right)^3}{8DAES}$$

No appreciable error is introduced if $(S - T/p)$ is changed to $S$ in the last 2 terms, giving the simpler form

$$e = \frac{8}{3}d^2 - \frac{wS}{8dAE} - \frac{T}{pS}$$

but, since $T = (wS)/(8d)$,

$$e = \frac{8}{3}d^2 - \frac{wS}{8d}\left(\frac{1}{AE} + \frac{1}{pS}\right) \tag{8}$$

It may be noticed that the expression in the last term $(1/AE + 1/pS)$ is a constant for a given problem. The equation can therefore be solved by the chart except that the scale for $wS/AE$ now becomes a scale for $wS/N$ where

$$\frac{1}{N} = \frac{1}{AE} + \frac{1}{pS}$$

$$e = \frac{8}{3}d^2 - \frac{1}{8d}\frac{wS}{N} \tag{9}$$

The problem is approached in exactly the same manner as previously described, going from an initial value of $(w_1 S)/N$ and $d_1$ to a value of $e$; adding the proper amount for temperature change to obtain $e'$; then solving for $d_2$ from $(w_2 S)/N$, and from $d_2'$ obtaining the final tension $T_2'$. In calculations involving more than one wire, of the same or different sizes, in the same span, the total cross-sectional area, total loading, and total tension should be used with this method as was indicated for the more accurate method previously described. If different sags are used for the different wires, a "weighted sag" can be obtained from the sum of the products

of sag and loading for each wire, divided by total loading.

The chart in figure 9 is a working chart for such problems. Taking as a typical example the same conditions used in the previous example, except for the rigidity of the pole, the solution is carried out as follows for 3 number 0 triple-braid weather-proof copper wires and 40-foot class 4 western-cedar pole:

Stringing load $w_1$ = $3 \times 0.424 = 1.272$ pounds per foot for 3 wires
Heavy loading $w_2$ = $3 \times 1.55 = 4.65$ pounds per foot for 3 wires
$AE$ = 1,160,000 per conductor
$\alpha t$ = $-60 \times 9.6 \times 10^{-6} = -5.76 \times 10^{-4}$
Deflection constant $p$ = 600 pounds per foot
Initial wire deflection $D_1$ = 1.5 feet

$$d_1 = \frac{1.5}{100} = 0.015$$

$$\frac{1}{N} = \frac{1}{AE} + \frac{1}{pS} = \frac{1}{3 \times 1{,}160{,}000} + \frac{1}{600 \times 100} = 16.954 \times 10^{-6}$$

$$\frac{w_1 S}{N} = 1.272 \times 100 \times 16.954 \times 10^{-6} = 0.00216$$

$$e = -0.0174$$

$$e' = e + \alpha t = -0.0174 - 0.000576 = -0.01798$$

$$\frac{w_2 S}{N} = 4.65 \times 100 \times 16.954 \times 10^{-6} = 0.00788$$

$$d_2 = 0.043$$

$$T_2 = \frac{w_2 S}{8 d_2} = \frac{465}{8 \times 0.043} = 1{,}350 \text{ pounds or } 450 \text{ pounds per wire}$$

It is apparent by comparing these results with those previously calculated for the rigid span that if the pole $B$ had been assumed rigid, its load would have been calculated as 3,495 pounds instead of 1,350 pounds. If the tension in the normal span to the left of pole $A$ (figure 1) were calculated at 2,000 pounds per wire, or 6,000 pounds total at full loading, the guy must actually assume 6,000 − 1,350 = 4,650 pounds instead of only 2,505 pounds which would result from a calculation with pole $B$ rigid. The improvement in design is evident.

## Special Conditions

In the early part of the paper a number of different cases were cited in which the effect of flexibility of supports was of importance. The application of the method of solution which has just been described to the conditions peculiar to some of these will be indicated.

*Both Poles Flexible.* The span is shortened by the flexure of both poles under the tension $T$, hence in computing $1/N$ both must be included

$$\frac{1}{N} = \frac{1}{AE} + \frac{1}{p_1 S} + \frac{1}{p_2 S}$$

where $p_1$ and $p_2$ are the deflection constants of the 2 poles.

*Two Flexible Poles at One End of a Span.* Where the dead end is made on a pole guyed to an unguyed

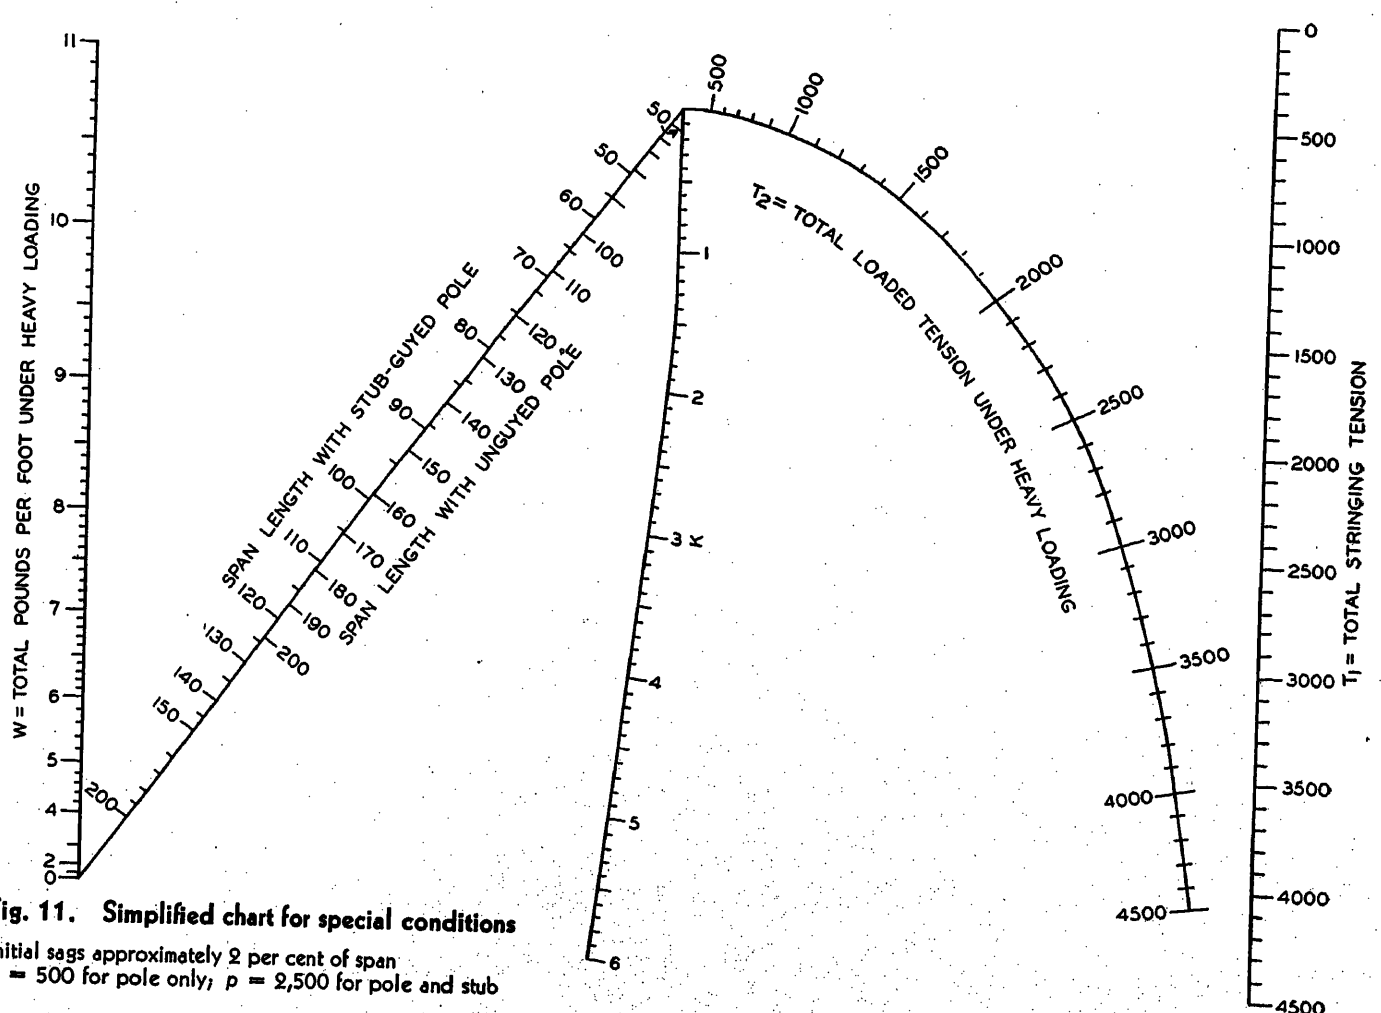

**Fig. 11. Simplified chart for special conditions**

Initial sags approximately 2 per cent of span
$p$ = 500 for pole only; $p$ = 2,500 for pole and stub

stub, both enter into the change in the span caused by flexure. In this case, if the guy is short and tight, the deflection constant of the 2 poles acting together is equal to the sum of their individual deflection constants.

$$\frac{1}{N} = \frac{1}{AE} + \frac{1}{(p_1 + p_2)S}$$

The load divides between pole and stub in proportion to their deflection constants.

*External Force.* Sometimes there will be forces other than the tension in the wire acting to bend the pole. An example of such a case would be a pole

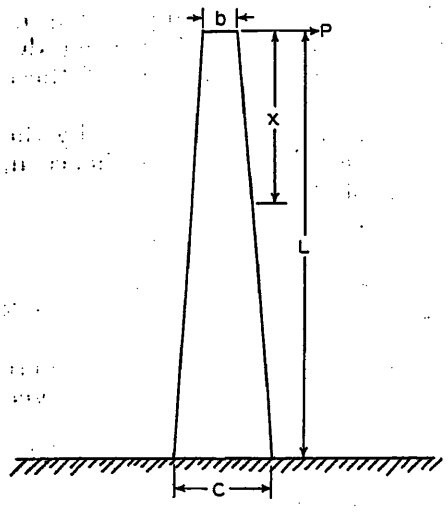

**Fig. 12. Representation of a pole as a cantilever beam**

carrying transverse wires which are acted upon by wind at the same time the wires in the span have ice loading only. If

$F$ = the force thus produced on the end pole

$\frac{F}{p}$ = the movement of the pole due to this force

$\frac{F}{pS}$ = the movement per unit of span

This quantity $F/(pS)$ is a change in the quantity $e$ given in the general equations. If $F$ tends to shorten the span, acting only when the loading $w_2$ is on the wire, $e_2$ will be greater than $e_1$ by an amount $F/(pS)$, since $e$ represents the difference between $L$ and $S$ for any condition and either a decrease in $S$ or an increase in $L$ tends to increase $e$.

$$e_2 = e_1 + \frac{F}{pS} \tag{10}$$

If $e_1$ is located on the chart for initial conditions, $e_2$ is found by adding $F/(pS)$ to it, and $d_2$ is then derived from $e_2$ as before. For example, in the example previously given, if there were an external force of 100 pounds acting to shorten the span at the time of $w_2$ loading,

$$\frac{F}{pS} = \frac{100}{60{,}000} = 0.00167$$

$$e_2 = -0.01798 + 0.00167 = -0.0163$$

$$d_2 = 0.0451 \qquad T_2 = 1{,}290 \text{ pounds}$$

*Joint Use.* In certain cases the pole which acts as a guy stub for the end pole acts also as a dead-end pole for telephone cable carried on a parallel lead (see figure 10). The tension in the messenger supporting the telephone cable changes with the loading. If telephone and power spans are of approximately equal length, the problem may be solved just as if all wires were on the same poles. If span lengths are different, however, a solution may be reached by a series of convergent approximations as follows: Consider the loaded tension $T_T$ in the telephone messenger first as a constant external force similar to that discussed in the preceding paragraph. It is assumed that the initial span for the power wires is that obtained after $T_T$ is applied to the end pole. The equivalent deflection constant for the whole system is the same whether $T_T$ and $T_P$ are applied to the same pole or to different poles, being equal to $p_1 + p_2$ for the total tension. The power span is solved in the usual manner and a value for tension in the power wires found. Returning to the telephone span, a solution is made similarly except that in determining $e_2$, an amount $(T_2 - T_1)_P/(pS_T)$ is added to $e_1$ to allow for the *increase* in tension in the power wires $(T_2 - T_1)_P$, $S_T$ being the telephone span. The resulting tension in the telephone messenger having thus been determined, the power span is recalculated, increasing $e_1$ now by the amount $(T_2 - T_1)_T/(pS_P)$ where $(T_2 - T_1)_T$ is the *increase* in messenger tension and $S_P$ the power span. Successive approximations will give the final result, but in most cases only the first few steps will be necessary for sufficient accuracy. The following is given as an example:

| | Power Span | Telephone Span |
|---|---|---|
| Wire | 3 number 0 *TBWP* copper† | 202-24 cable, on 6*M* strand‡ |
| Initial load $w_1$ per foot, pounds | $3 \times 0.424 = 1.272$ | 1.9 |
| Heavy loading $w^2$ per foot, pounds | $3 \times 1.55 = 4.65$ | 4.3 |
| $AE$ per conductor | 1,160,000 | 1,757,000 |
| Span, feet | $S_P = 100$ | $S_T = 60$ |
| Pole | 40-foot, class 4 | 30-foot class 2 |
| Deflection constant $p$, pounds per foot | 600 | 1,500 |
| $p_{eq}$ for both poles | $600 + 1500 = 2{,}100$ | 2,100 |
| $\frac{S}{AE}$ | $0.287 \times 10^{-4}$ (3 wires) | $0.341 \times 10^{-4}$ |
| $\frac{S}{p_{eq}S} = \frac{1}{p_{eq}}$ | $4.76 \times 10^{-4}$ | $4.76 \times 10^{-4}$ |
| $\frac{S}{N} = S\left(\frac{1}{AE} + \frac{1}{p_{eq}}\right)$ | $5.047 \times 10^{-4}$ | $5.10 \times 10^{-4}$ |
| $\frac{w_1 S}{N}$ | $1.272 \times 5.047 \times 10^{-4} = 6.42 \times 10^{-4}$ | $1.9 \times 5.10 \times 10^{-4} = 9.697 \times 10^{-4}$ |
| Initial deflection $d_1$, feet | 1.5 | 0.85 |
| $d_1 = \frac{D_1}{S}$ | 0.015 | 0.0142 |
| $T_1 = \frac{w_1 S}{8d_1}$, pounds | 1,060, or 353 per wire | 1,000 |

† Triple-braid weather-proof.

* Proceed from column 1 under "Power Span" to column 1 under "Telephone Span," to column 2 under "Power Span," etc.

Further approximations show no appreciable change in the tensions so the solution is 1,820 pounds for the power span (607 pounds per wire) and 795 pounds in the telephone span. It is evident that this calculation could be shortened somewhat if, after the trend of the change in the telephone span is discovered in the first approximation, a larger change is assumed at once rather than the actual change thus found. In the table given, the first step shows a reduction of 160 pounds; if this were arbitrarily increased to 200 pounds the final result would be obtained in the next calculation.

## Field Application

Although the methods of calculation and charts which have been presented are comparatively simple and easy to apply, they still involve an amount of calculation which would be troublesome in the everyday run of problems encountered in the field. Their chief use is for the development of working rules and charts which may not be general but may cover a range of conditions sufficient for the greater majority of the cases. Since there is so much variation in local conditions and standards of construction, such working rules should be set up for one's own system in accordance with the combinations of circumstances most often occurring on that system. Two examples of such specific instructions will be given as illustrations.

Study of many actual cases of unguyed end poles and pole-stub combinations in the Detroit territory, both with and without joint use with telephone lines, led to the working rule:

"The initial load on an unguyed end pole or pole-stub combination should not exceed one half the ultimate allowable load."

This does not give actual resulting load under storm conditions but it does assume that a severe overload will be avoided and also that too much stress and deflection will not be placed on the pole under ordinary loading conditions. For pole-stub combinations, the criterion will be the load on the weaker of the 2 poles of course.

Another chart, which is somewhat simplified for field use, is shown in figure 11. In preparing this the initial sags were fixed at a given percentage of span, and ordinary values for deflection constants were assumed. From the total heavy load per foot and the span length, a point on the turning scale is found, from which, and the initial tension, the total loaded tension is found. Still simpler charts for special conditions can be similarly prepared with a little study, although it must be recognized that with the large number of variables no very simple complete solution is possible.

**Table I—Pole Deflection Constants and Ultimate Strengths**

| Individual Poles | | | | Combinations | | | |
|---|---|---|---|---|---|---|---|
| Length, Feet | Class | p | Ultimate Strength, Pounds | Length, Feet | Class | p | Ultimate Strength, Pounds |
| 25 | 1 | 3,000 | 4,500 | 25 / 35 | 1 / 2 | 4,200 | 6,300 |
| 25 | 2 | 2,300 | 3,700 | | | | |
| 25 | 3 | 1,700 | 3,000 | | | | |
| 30 | 1 | 2,000 | 4,500 | | | | |
| 30 | 2 | 1,500 | 3,700 | 25 / 35 | 2 / 4 | 3,100 | 5,000 |
| 30 | 3 | 1,100 | 3,000 | | | | |
| 35 | 2 | 1,200 | 3,700 | | | | |
| 35 | 4 | 800 | 2,400 | 30 / 40 | 2 / 2 | 2,250 | 5,500 |
| 40 | 2 | 850 | 3,700 | | | | |
| 40 | 4 | 600 | 2,400 | | | | |
| 45 | 2 | 650 | 3,700 | 30 / 45 | 2 / 2 | 2,150 | 5,300 |
| 45 | 4 | 450 | 2,400 | | | | |

## Summary

It has been pointed out that the flexure of supports may constitute a major factor in the design of structures for supporting overhead lines, and examples of such cases have been given. The general method of attacking the problem was described and 2 specific ways of working out the solution were given in detail. Simpler field rules derived by these means are also mentioned. These methods have been used in practical applications and it is believed that they can be of considerable benefit to those who are interested in the careful and accurate design of their structures.

## Appendix—Determination of Deflection Characteristics for Wood Poles

Assume the pole to be in effect a tapered cantilever beam, with the load applied at the end (see figure 12). The increment deflec-

tion at the load end of the beam resulting from the stress at any point at distance $x$ from that end is

$$dQ = \frac{Mx}{EI}\,dx = \frac{Px^2}{EI}\,dx$$

The total deflection therefore is

$$Q = \int_0^L \frac{P}{EI}\,x^2 dx$$

$I = 0.0491\,d^4$ for circular cross section of diameter $d$

For a taper of $a$ per foot,

$$d = ax + b \qquad a = \frac{c - b}{L} \qquad I = 0.0491(ax + b)^4$$

Therefore

$$\frac{0.0491\,E}{P}\,Q = \int_0^L \frac{x^2}{(ax + b)^4}\,dx$$

$$= \frac{1}{a^3}\left[-\frac{1}{ax + b} + \frac{2b}{2(ax + b)^2} - \frac{b^2}{3(ax + b)^3}\right]_0^L$$

Substituting for $a$,

$$\frac{0.0491\,E}{P}\,Q = \frac{L^3}{(c - b)^3}\,\frac{(c - b)^3}{3bc^3}$$

$$= \frac{L^3}{3bc^3}$$

"Deflection constant" $p = \frac{P}{Q} = \frac{0.0491E \times 3bc^3}{L^3}$

$= 0.1473Eb(c/L)^3$ pounds per inch deflection

All quantities must be expressed in inches. The deflection constant in pounds per foot deflection will be 12 times that given by the equation.

Values of $E$ given in the 1935 "Wood Handbook" of the U.S. Department of Agriculture are as follows:

| | |
|---|---|
| Northern white cedar | 800,000 pounds per square inch |
| Western red cedar | 1,120,000 pounds per square inch |
| Southern yellow pine | 1,800,000 pounds per square inch |

## Example

35-foot class 4 western-cedar pole

$b$ = top diameter, average for class approximately 8.5 inches

$c$ = ground line diameter, average for class approximately 11.7 inches

$L$ = length from 2 feet below top to ground line = 35 − 8 = 27 feet = 324 inches

$$p = \frac{P}{Q} = 0.1473 \times 1{,}120{,}000 \times 8.5\left(\frac{11.7}{324}\right)^3$$

$= 66$ pounds per inch

$66 \times 12 = 800$ pounds per foot

For a pole and stub acting together, connected by a guy, the deflection of both is the same, hence the deflection constant of the combination is equal to the sum of their individual deflection constants. The ultimate strength of the combination is limited by the strength of the one which has the lower ratio of strength to deflection constant, since that one reaches its ultimate strength before the other one does. For example,

| | p | Ultimate Strength, Pounds |
|---|---|---|
| 35-foot class 2 pole | 1,200 | 3,700 |
| 25-foot class 1 stub | 3,000 | 4,500 |
| Combination | 4,200 | $4{,}200\,\frac{4{,}500}{3{,}000} = 6{,}300$ |

Table I gives deflection constants and rated ultimate strengths for a number of common sizes of western-cedar poles and stubs and some typical combinations.

# Ultrahigh-Speed Reclosing of High-Voltage Transmission Lines

(*Continued from page 90*)

In a large measure the field of application of this development will be determined, as would be expected, by the additional cost of ultrahigh-speed mechanisms as against standard mechanisms but here the reverse is also true that the cost will in turn be influenced to a considerable extent by the development of applications for the mechanisms and by whether quantity production will be possible. In any event it would appear that a very definitely new and ingenious tool has been made available to the transmission-system designer and operator that gives promise of improved service and lower costs.

## Conclusions

The authors believe that it is perhaps premature to draw final conclusions as to the nature, scope, and significance of the development described herein and such was not within the limited scope of this paper, but nevertheless it would appear that the following have been fairly well established:

1. On high-voltage lines, particularly on overhead lines, outages caused by lightning and possibly other outages can be materially reduced, perhaps to the extent of 75 per cent, by ultrarapid reclosing.

2. Apparently the occurrence in nature of intervals between multiple strokes is such as to give a fortuitously happy arrangement from the standpoint of possible reclosure. This, however, is a phase that needs not only further theoretical but a great deal of practical verification.

3. While a great deal of benefit can be obtained in the reducing of outage resulting from phase-to-ground troubles, phase-to-phase troubles are much more bothersome and a great deal of additional work needs to be done either in the way of bringing them within the range of treatment that can be so successfully applied to phase-to-ground faults or in the direction of reducing their frequency.

4. Finally, it appears that as is true in so many other cases of research and development, the by-product of the search for speed in circuit-breaker practice and speed on relay protection has given most fruitful results, perhaps equal to those obtained from the original line of research, and promises to yield a great deal more.

# Lightning Investigation on Transmission Lines—VI

By W. W. LEWIS
MEMBER AIEE

C. M. FOUST
MEMBER AIEE

**Continuing a series of papers reporting a study of lightning on transmission lines, the authors present herewith data obtained during 1935 and part of 1936 on 66-, 110-, 132-, and 220-kv lines. Values of lightning current are presented, and the effectiveness of overhead ground wires and low footing resistance in preventing tripouts is shown.**

IN PREVIOUS papers the authors have reported the results of an investigation of lightning effects on transmission lines, which began in the year 1926. The immediately preceding paper[1] gave the results for 1933 and 1934. The present paper will summarize the 1935 and part of the 1936 results. The participating power companies in this investigation are the Pennsylvania Power and Light Company, Appalachian Electric Power Company, Philadelphia Electric Company, Pennsylvania Water and Power Company, Public Service Company of New Jersey, Consumers Power Company, American Gas and Electric Company, and the Electric Bond and Share Company.

In the years 1935 and 1936 data were gathered by means of the surge crest ammeter[2] on lightning currents in tower legs and crossarms, overhead ground wires, counterpoise wires and lightning rods erected at the tops of towers. These data, together with supplementary data from lightning stroke recorders, surge indicators, and automatic oscillographs have permitted a rather complete picture to be drawn of the effects of individual strokes. Additional mass statistics permit further confirmation of the theories in regard to the behavior of overhead ground wires and counterpoise wires.

## Summary

Line performance data and current and voltage measurements now at hand give a reasonably clear qualitative and quantitative idea of the essential elements in the line protection problem.

First, it is apparent from line performance data that overhead ground wires reduce tripouts in the order of 20 to 1. Current measurements on the ground wire have demonstrated that it is serving as a lightning stroke terminal for many strokes which otherwise might reach the conductor and cause flashover. Measurement experience seems to bear out that the overhead ground wires also act to assist in reducing tower potentials for strokes to a tower.

The second important element has been shown by measurement to be the tower footing resistance. With marked consistency it has been shown that when a stroke terminates on a tower, flashover and tripout will quite likely result if footing resistance is high. The product of current and footing resistance must be below insulator flashover for the wave shape applied if flashover is to be prevented.

Both the parallel and radial type counterpoise wires have been shown to be effective in reducing the voltage drop at the tower footing. The tower-to-tower buried ground wire has been shown in one case to have entirely eliminated flashover of insulation at a point previously very susceptible to flashover. The radial counterpoise has been shown in one case to be effective for most lightning currents when some 150 feet long.

Simultaneous measurements of lightning currents have been made in counterpoise wires, in tower legs, in tower arms, in ground wires and lightning rods. Such readings have permitted the location of the general point of contact of the stroke to be known, the direction of flow of current from positive ground to negative cloud to be definitely determined, and have provided quantitative values of lightning current.

## Flashover on Lines With and Without Overhead Ground Wires

In table VII of paper IV of this series[3] data were given as to the insulation and conductor and ground wire arrangement for 9 systems in eastern United States, ranging from 66 kv to 220 kv, also data as to the number of tripouts on these lines for a period of years up to and including 1933. In table I of the present paper the same systems are listed, with the tripout data brought up to and including 1935. In addition, data for the section of the Wallenpaupack-Siegfried line without overhead ground wires are given.

Two of the lines have an almost perfect record of 0.4 tripouts per 100 miles per year. The other lines with overhead ground wires range up to 2.8 tripouts per 100 miles per year, while the one line without overhead ground wires had 47 tripouts per 100 miles per year, that is, 17 or more times as many tripouts as on the lines with overhead ground wires.

In table II are given the location of the flashovers which caused tripout on the Wallenpaupack-Siegfried line,[4] segregated with respect to the overhead ground wire construction and method of grounding, for the 10 years from 1926 to 1935 inclusive. Of the 112 faults whose locations are known, 108 occurred on the section of line

A paper recommended for publication by the AIEE committee on power transmission and distribution. Manuscript submitted October 30, 1936; released for publication December 1, 1936.

W. W. Lewis and C. M. Foust are electrical engineers with the General Electric Company, Schenectady, N. Y.

1. For all numbered references see list at end of paper.

## Table I—Tripouts on Transmission Lines, Data Up to and Including 1935

| | Line Name | Kilovolts | Miles | Average Length of Span, Feet | Footing Resistance, Ohms | Tripouts | Years | Tripouts per 100 Miles per Year |
|---|---|---|---|---|---|---|---|---|
| 1*a* | Wallenpaupack-Siegfried (Without overhead ground wires) | 220 | 36.9 | 1,100 | 5–325 | 13§† | 8 | 4.7 |
| 1*b* | Wallenpaupack-Siegfried (With overhead ground wires) | 220 | 27.8 | 1,100 | 1–1.5*<br>5–75** | 6† | 8 | 2.8 |
| 2 | Bushkill-Roseland | 220 | 47 | 1,150 | 5–300 | 4† | 4 | 2.1 |
| 3 | Siegfried-Plymouth | 220 | 49 | 1,270 | 5–60 | 6 | 8 | 1.5 |
| 4 | Conowingo-Plymouth (No. 1) | 220 | 57 | 1,170 | 5–100 | 8 | 8 | 1.8 |
| | Conowingo-Plymouth (No. 2) | 220 | 57 | 1,170 | 5–100 | 8 | 8 | 1.8 |
| 5 | Roseland-Plymouth | 220 | 72 | 1,050 | 5–100 | 9 | 5 | 2.5 |
| 6 | Safe Harbor-Westport | 220 | 70 | 1,050 | 2–85 | 1 | 4 | 0.4 |
| 7 | Philadelphia-Chester | 66 | 14 | 480 | Below 5 | 1 | 18 | 0.4 |
| 8 | Greenbush-Pleasant Valley | 110 | 64 | 735 | 1–175‡ | 7 | 4 | 2.74 |
| 9 | Pleasant Valley-Millwood | 132 | 40.5 | 620 | 5–800‡ | 4 | 4 | 2.47 |

* Section with continuous counterpoise.
** Section with radial counterpoise.
† The location of faults causing 53 tripouts on lines 1*a*, 1*b*, and 2 were not known definitely, but these have been assigned to section with or without ground wires in accordance with correlated information.
‡ Before counterpoise and ground rods installed.

without overhead ground wire and 4 on the overhead ground wire section. In 7 years the section with tower-to-tower counterpoise had no flashovers. It is interesting to know that in the same section in the years 1926, 1927, and 1928, before the counterpoise was installed, there was a total of 29 flashovers.

## Relation Between Tower Voltage and Flashover

In table III are given the data for 15 records of tower current exceeding 30,000 amperes, secured on the Wallenpaupack-Siegfried line during the years 1933 to 1935 inclusive.

It will be noted that 5 cases of flashover occurred on the section without overhead ground wire, and that the product of current and resistance in all but one case exceeded 1,500 kv. The assigned flashover voltage[5] for this line with standard test waves is as follows:

| Units | Positive Wave | Kilovolts |
|---|---|---|
| 14 | 1.5x40 | 1,265 |
| 14 | 1x5 | 1,565 |
| 16 | 1.5x40 | 1,425 |
| 16 | 1x5 | 1,775 |

An analysis of items 11 to 15, inclusive, indicates strokes to the towers in all cases. This analysis follows:

Item 11—The stroke was confined to a single tower. All 3 phases flashed over.

Item 12—The stroke was confined to a single tower. All 3 phases flashed over.

Item 13—A current reading of 4,000 amperes was obtained in the legs of adjacent tower *WT* 28–1. This tower had a footing resistance of 45 ohms. It is believed that the stroke hit tower *WT* 27–6 and flashed over to *Y*-phase conductor. This conductor was in turn raised in potential and flashover took place from this conductor to the tower at *WT* 28–1.

Item 14—Only one tower was involved in this stroke, and the flashover took place to 2 conductors. Current measurements were made on only one leg and the actual tower current may have been somewhat larger than estimated from the one leg reading. On the other hand, a long wave with low flashover value is possible.

Item 15—Five towers were involved in this stroke and the data pertaining to these towers follow:

| Tower | Footing Resistance | Tower Amperes | Product I × R, Kv | Flashed Phases |
|---|---|---|---|---|
| *SR* 9–2 | 15 | 10,000 | 150 | *W* |
| *SR* 9–3 | 28 | 29,000 | 810 | *W* and *Y* |
| *SR* 9–4 | 28 | 54,000 | 1,510 | *W* and *X* |
| *SR* 9–5 | 34 | 7,000 | 240 | *W* and *Y* |
| *SR* 10–1 | 15 | 8,000 | 120 | *Y* |
| | | 108,000 | | |

It would appear from this record that the stroke hit tower *SR* 9–4, causing flashover from this tower to conductors *W* and *X*. The surge then traveled to the 2 adjacent towers in both directions, flashing over from conductor to tower. There is some inconsistency in the phases affected at the different towers in that the surge started on *W* and *X* phases and wound up on *W* and *Y*

## Table II—Locations of Flashovers Causing Tripouts on Wallenpaupack-Siegfried 220-Kv Line Tabulated With Respect to Overhead Ground Wire Construction and Method of Grounding

| | | Overhead Ground Wires | | | |
|---|---|---|---|---|---|
| Year | Location Unknown | No Overhead Ground Wires | Tower-to-Tower Standard Grounding* | Tower-to-Tower Counterpoise | Radial Counterpoise | Total |
| 1926 | | 15 | | | | 15 |
| 1927 | 3 | 4 | 0 | | | 7 |
| 1928 | 11 | 2 | 1 | | | 14 |
| 1929 | 27 | 10 | 1 | 0 | | 38 |
| 1930 | 9 | 14 | 1 | 0 | 0 | 24 |
| 1931 | 0 | 20 | 0 | 0 | 0 | 20 |
| 1932 | 1 | 8 | 0 | 0 | 1 | 10 |
| 1933 | 2 | 13 | 0 | 0 | 0 | 15 |

**Table III—Relation Between Tower Voltage and Flashover, Wallenpaupack-Siegfried 220-Kv Line**

| Item | Tower Number | Overhead Ground Wire | Footing Resistance, Ohms | Amperes in Tower Legs | Product I × R, Kilovolts | Flash-over | Year |
|---|---|---|---|---|---|---|---|
| 1 | *WT* 12–3 | Yes | 1.4 | 38,700 | 54 | No | 1934 |
| 2 | *WT* 8–5 | Yes | 7 | 40,000 | 280 | No | 1933 |
| 3 | *WT* 8–4 | Yes | 8 | 35,000 | 280 | No | 1933 |
| 4 | *SR* 2–4 | Yes | 10 | 36,000 | 360 | No | 1933 |
| 5 | *SR* 2–1 | Yes | 15 | 38,000 | 570 | No | 1933 |
| 6 | *SR* 2–2 | Yes | 15 | 30,000 | 450 | No | 1934 |
| 7 | *SR* 4–4 | Yes | 19 | 35,000 | 665 | No | 1933 |
| 8 | *SR* 21–2 | No | 20 | 42,000 | 840 | No | 1933 |
| 9 | *SR* 8–4 | No | 20 | 49,000 | 980 | No | 1934 |
| 10 | *SR* 33–2 | No | 18 | 30,800 | 555 | No | 1933 |
| 11 | *SR* 31–3 | No | 34 | 51,000 | 1,730 | Yes | 1933 |
| 12 | *SR* 19–3 | No | 45 | 40,000 | 1,800 | Yes | 1933 |
| 13 | *WT* 27–6 | No | 58 | 36,000 | 2,100 | Yes | 1933 |
| 14 | *SR* 18–1 | No | 28 | 30,000 | 840 | Yes | 1934 |
| 15 | *SR* 9–4 | No | 28 | 54,000 | 1,510 | Yes | 1935 |

phases. It is barely possible that tower 9–3 was raised sufficiently high in potential by the flashover of phase *W* to involve phase *Y* in the trouble. It is also possible that flashover took place on *Y*-phase at *SR* 9–4 but left no marks that could be detected.

The Glenlyn-Roanoke line[6] of the Appalachian Electric Power Company is a double circuit line, approximately 65 miles long, with one overhead ground wire at the peak of the towers. It is not possible from the measuring equipment on this line to associate the point of flashover with a particular tripout as definitely as on the Wallenpaupack-Siegfried line.

The Glenlyn-Roanoke line is insulated with 10 units, spaced $4^3/_4$ inches apart, with flashover voltage approximately as follows:

$1^1/_2$x40 positive wave—820 kv
1x5 positive wave—970 kv

In 1934 there were 51 lightning strokes to this line. Tower potentials, that is, the product of tower current and tower footing resistance, for the towers which appeared to be the center of disturbance in each of the 51 strokes, ranged as shown in the following tabulation:

| Kilovolts Range | Number |
|---|---|
| 40– 200 | 13 |
| 201– 800 | 23 |
| 801–1,000 | 5 |
| 1,001–4,200 | 10 |
| Total | 51 |

In 15 of the 51 cases listed the tower potential was of sufficient magnitude to be in the flashover range. In 13 of the 15 cases a possible correlating tripout was reported. There were 3 other tripouts which may have correlated with tower potentials lower than the assigned flashover voltage.

In 1935 there were 32 strokes to the Glenlyn-Roanoke line. Potentials of the towers which were the apparent center of disturbance may be grouped as follows (excluding 3 cases in which the tower current was classified as a "trace").

| Kilovolts Range | Number |
|---|---|
| 20– 200 | 6 |
| 201– 800 | 17 |
| 801–1,000 | 0 |
| 1,001–2,610 | 6 |
| Total | 29 |

Of the 32 cases there were 6 cases in which the tower potential was of the order of the insulator flashover and 6 tripouts due to lightning occurred on this line during the period of measurements.

**Table IV—Range of Tower and Probable Stroke Currents in 4 Transmission Lines; 1933, 1934, and 1935**

## Current in Towers and Strokes

Table IV gives the range of current and the number of times these currents were recorded by surge crest ammeter for 4 systems during the years 1933 to 1935 inclusive.

Records of 358 strokes were obtained in these years. The table gives data for the tower with the highest current where several towers are involved in a stroke, and for the probable total stroke current, obtained by adding the currents in all the towers affected by a stroke.

Figure 1 summarizes in cumulative curves, the tower current and probable stroke current of the 4 transmission lines based on the data of table IV. It will be noted from figure 1 that although the tower currents go to approximately 130,000 amperes, only about one per cent exceed 100,000 amperes and about 6 per cent exceed 50,000 amperes, also that the probable stroke currents go to 220,000 amperes but only about 6 per cent exceed 100,000 amperes. Of the 358 strokes recorded approximately 95 per cent were of negative polarity, that is, top of tower negative with respect to bottom of tower and ground.

The use of surge measuring instruments of several types, and in many cases a great number of each type, permits analysis of results on a statistical basis as well as for single strokes. The statistical method establishes the range of stroke current, voltage, and frequency of occurrence, but the exact electrical mechanism of the stroke in the transmission structure can be established only through correlation of a great number of records for a single stroke. For instance, the single stroke surge voltage recorder data, obtained at a number of stations along the conductor resulted in the practical attenuation formula previously given.[7] Also each cathode-ray oscillogram of conductor voltage when examined with accompanying surge voltage recorder and surge indicator data for the same stroke provides a more complete record of the surge mechanism. The surge crest ammeter is peculiarly adapted to the se-

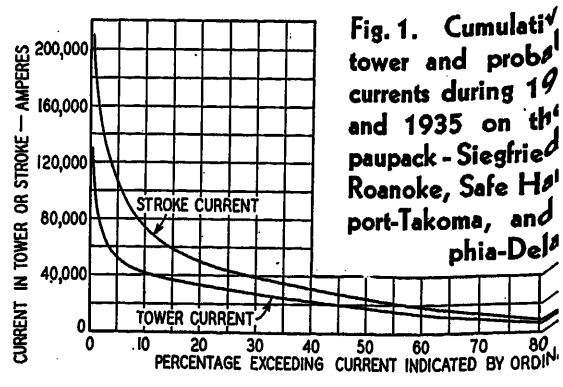

**Fig. 1. Cumulati tower and prob currents during 19 and 1935 on th paupack - Siegfrie Roanoke, Safe Ha port-Takoma, and phia-Del**

curing of a great number of current records at a the line structure for each stroke.

In figure 2 is shown a sample of current mea in the counterpoise, tower legs, tower arms, and ground wire. Polarity directions are indicate arrows pointing in the conventional plus to mi tion. The 2 counterpoise wires fed into the bas 10 from the adjacent earth some 15,800 ampe longer, or 150-foot, counterpoise gathered some peres per foot and this was about the same for of its length. The shorter, or 40-foot, counterp ered about 80 amperes per foot. Assuming tha and short counterpoise wires on which no mea were taken also carried 15,800 amperes, a total poise current of 31,600 is obtained. This agree upward current of the 4 legs which measured so amperes. This current flowed into the tower into the ground wire at the tower tip, being joine about 12,000 amperes coming from the lef currents together gave a crest of 33,000 amper overhead ground wire just a few feet to the rig tower tip. As the measurement station on th wire at the left of tower 9 showed 12,500 amper

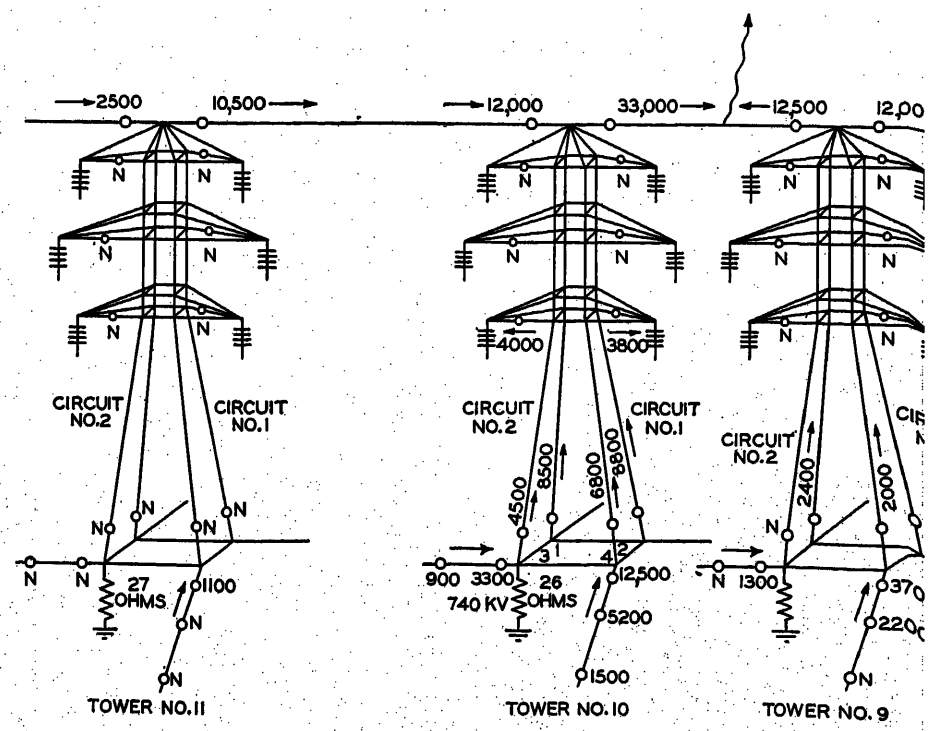

**Fig. 2. Current measurements obtained during stroke occurring on Glenlyn-Roanoke line, June 1936**

Circles indicate measurement stations

N—Current less than measuring range of station

in the opposite direction, the assumption of the stroke to the ground wire between these 2 stations appears justifiable. The current of the stroke is some 45,500 amperes. It will be noted that the individual currents do not add to exactly equal the measured sum. Two factors are important in this connection. First, the magnetic links are adjusted to read crest current to 10 per cent accuracy. Second, the measurement station at the right of tower 9 on the ground wire showed 12,000 amperes flowing to the right. Another stroke along the line in this direction is indicated, but this stroke occurred further to the right than tower 8, as this tower did not show any leg current within the measurable range.

To the left of tower 10 the measurement station in the ground wire on the right side of tower 11 gave a reading of 10,500 amperes. This 10,500 amperes is made up of 2,500 amperes coming in over the ground wire from tower 12 and some tower leg current in tower 11, which was below the measurement range of the magnetic link setting. The middle phase insulator assemblies of circuit number 1, towers 8 and 10, flashed over. The tower footing resistance at tower 10 of 26 ohms with 28,600 amperes flowing gives a tower potential of 740 kv. At tower 8 the high resistance of 147 ohms requires only 5,000 amperes to give insulator flashover voltage, and this value divided among the 4 legs evenly gives but 1,250 amperes per leg, a value below the measuring level of the magnetic links as installed.

Reviewing briefly this one set of records locates the point of contact of the stroke and gives the magnitude and direction of the component surge currents in the structure. The overhead ground wire shields the line conductors and the counterpoise wires operate to reduce footing resistance, but the high ground resistance gives a high tower potential which causes insulator flashover. Many similar records have been obtained of strokes to the ground wire and occasional records indicate strokes to the conductor and to the tower.

## The Counterpoise

On the Glenlyn-Roanoke line the counterpoises are made of 1/16 by 1.5 inch galvanized iron strap. Two lengths each 150 feet long extend out from diagonally opposite tower legs and run parallel with the conductors; 2 lengths each 40 feet long extend at right angles to the line from the other 2 tower legs. The counterpoise conductors are buried approximately 18 inches under the surface of the ground. The counterpoise wires on 20 towers near each end of the line were equipped with current measurement means as follows:

In 1934 one 150-foot wire and one 40-foot wire, each had one magnet bracket installed at approximately 3 feet from the tower leg. In 1935 the equipment on the short cable was unchanged, but on the long cable 2 additional brackets were mounted at approximately 80 and 147 feet from the tower leg.

In 1935 readings were obtained in 26 cases of current at all 3 points on the 150-foot counterpoise. These readings are given in table V. In all cases but one, the polarity indicates current flowing from the free end of the counterpoise toward the tower.

In figure 3 are plotted a summation of counterpoise currents for each of the 3 stations located along the wire. This summation was made by arranging the data in order of increasing current magnitudes for the station nearest the tower, and beginning at the lowest current adding each time the next higher current value.

| Summation | | 124,750 | 68,850 | 14,200 |

* For the purpose of this tabulation a trace is assumed to be 500 amperes.

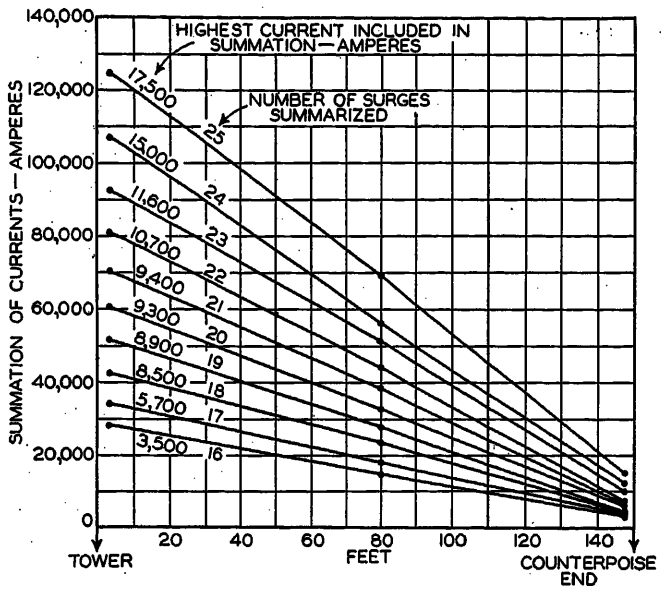
** In this case the polarity indicates current flowing from tower to free end of counterpoise. In all other cases current flows from free end of counterpoise toward tower. Values for this reading have been omitted from the summation.

N. I. = not installed.

**Table VI—Relation Between Current in Long (150-Foot) and Short (40-Foot) Counterpoise Wires, Glenlyn-Roanoke 132-Kv Line, 1935**

| Reference Number | Tower Number | Amperes | | Ratio Long to Short |
|---|---|---|---|---|
| | | Long Counterpoise | Short Counterpoise | |
| 1–3 | 25 *G* | 8,500 | 1,900 | 4.48 |
| 2–1 | 7 *R* | 3,500 | 1,200 | 2.92 |
| 2–1 | 8 *R* | 8,900 | 1,300 | 6.85 |
| 3–3 | 18 *G* | 3,300 | 1,100 | 3.0 |
| 3–3 | 19 *G* | 2,600 | 700 | 3.72 |
| 3–3 | 20 *G* | 9,400 | 1,600 | 5.87 |
| 3–3 | 21 *G* | 10,700 | 2,400 | 4.46 |
| 3–3 | 22 *G* | 17,500 | 6,800 | 2.58 |
| 3–3 | 23 *G* | 11,600 | 2,900 | 4.0 |
| 3–3 | 24 *G* | 2,500 | 750 | 3.34 |
| 1–2 | 9 *G* | 15,000 | 2,600 | 5.77 |
| 1–2 | 10 *G* | 5,700 | 900 | 6.33 |
| 6–1 | 12 *G* | 9,300 | 1,100 | 8.46 |
| Summation | | 108,500 | 25,250 | 4.3 |

Ratio of counterpoise lengths 3.75. Total counterpoise current approximately double above values. In all cases the polarity indicates current traveling from free end of counterpoise toward tower.



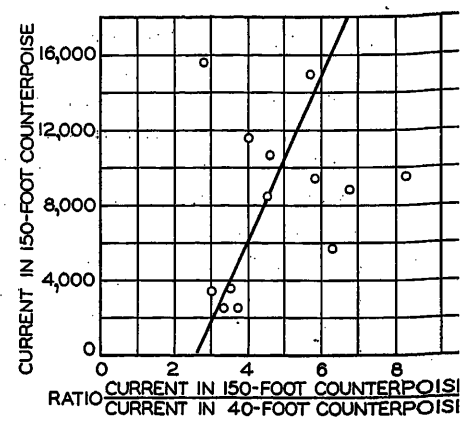


**Fig. 3. Summation of currents in 150-foot counterpoise wire at different distances from tower**

The figure shows that for all current levels the collection of current from the ground by the counterpoise is about the same for each foot of its length. There seems to be an indication, however, that at lower currents the portion nearer the tower collects a greater proportion per unit length than that away from the tower while for the higher currents the remote sections gather in the greater proportion of currents. Although not brought out clearly by the figure, a consideration of all the data indicates that the 150-foot counterpoise takes care of about 10,000 amperes with uniform collection of current throughout its entire length. This gives about 70 amperes earth current collected per foot of wire. Such an even ground current must be accompanied by good uniformity in distribution of earth potentials and an elimination of points of high earth current density and great earth potential differences, which result in high tower potentials. An effective utilization of the entire length of the counterpoise wire is therefore indicated at approximately 10,000 amperes. If the current ranged above this value more length would appear to be desirable, while for lower currents the remote end of the 150-foot wire would be of questionable value. On this basis 4 radial 150-foot wires would take care of a 40,000-ampere tower current, which is considerably above the average in magnitude.

In 13 cases simultaneous readings were obtained on the long and short counterpoise wires. In Table VI are given the readings in the short counterpoise and in the long counterpoise at the 3-foot station. Comparing the summation of all the readings on the long and short counterpoise wires, we find the ratio of current in long counterpoise to current in short counterpoise to be about 4.3. The ratio of lengths is 3.75, indicating that the current taken by a radial counterpoise of this sort, all conditions being equal, is practically in proportion to its length.

In figure 4 are plotted the ratio of current in the 150-foot counterpoise to the current in the 40-foot wire as

**Fig. 4. Relation between current in 150-foot and 40-foot counterpoise wires**

abscissas against the current in the 150-foot counterpoise as ordinates from the data of table VI.

With these data a tendency for the higher counterpoise currents to give higher ratios can be noted. This agrees shows the remote section of a buried ground wire to gathering in a proportionally greater amount of current at higher stroke currents. At some 5 to 6 thousand amperes the 2 wires are carrying currents in the same proportion as their lengths. Below this value on an average the short counterpoise carries a greater proportional part and above it the longer wire carries the greater proportion. Now, it seems to be a reasonable rule that the wire will carry the most current which performs most effectively in reducing earth potentials. This reduction of earth potentials is also the mechanism whereby the counterpoise serves to hold down the tower potential and prevent insulator flashover. Accordingly, a reasonable conclusion from the ratio data appears to be that currents below 5 to 6 thousand amperes the 150-foot wire is more than necessary and for higher currents the 40-foot wire too short. These considerations, of course pertain to relative length and it is important to observe that the ratio-current magnitude trend is not clearly demonstrated by the available data. The variations in soil conductivity quite likely partially obscure this trend.

Table VII shows the relation between the total current

(*Concluded on page 189*)

**Table VII—Relation Between Current in Tower Legs and Counterpoise Wires, Glenlyn-Roanoke 132-Kv Line, 19**

| Reference Number | Tower Number | Total Tower Current, Amperes | Total Counterpoise Current, Amperes | Ratio To Current Counterpo Curre |
|---|---|---|---|---|
| 1–3 | 25 *G* | 30,300 | 20,800 | 1.46 |
| 2–1 | 7 *R* | 7,000 | 9,400 | 0.75 |
| 2–1 | 8 *R* | 10,800 | 20,400 | 0.53 |
| 3–3 | 20 *G* | 16,700 | 22,000 | 0.76 |
| 3–3 | 21 *G* | 22,000 | 26,200 | 0.84 |
| 3–3 | 22 *G* | 52,100 | 48,600 | 1.07 |
| 3–3 | 23 *G* | 21,500 | 29,000 | 0.74 |
| 3–3 | 24 *G* | 9,000 | 6,500 | 1.39 |
| 1–2 | 9 *G* | 34,200 | 35,200 | 0.98 |
| 1–2 | 10 *G* | 17,000 | 13,200 | 1.29 |
| 6–1 | 12 *G* | 20,000 | 20,800 | 0.96 |
| Summation | | 240,600 | 252,100 | 0.95 |

In all cases the polarity indicates current traveling from free end of counterpoise to tower and from bottom of tower to top.

# Arc Characteristics Applying to Flashing on Commutators

By R. E. HELLMUND
FELLOW AIEE

**This paper gives the results of experimental investigations relating to arc characteristics as they apply in commutator flashing. A knowledge of these characteristics is necessary for the application of the theory outlined in a previous paper[1] on flashing of commutators by the same author, as well as for the investigation of flashing due to other causes.**

IN A previous paper,[1] a method of analyzing flashing on commutators caused by jumping of the brushes was given. This method assumes that an arc ($S$) is formed between segment ($a$) and brush ($b$) when the brush leaves the commutator, as indicated in figure 1$A$. This arc is likely to persist as shown in figure 1$C$ after the commutator has moved a certain distance and the brush has returned to the commutator. The method consists essentially in comparing during successive periods the voltage necessary for sustaining the arc with the voltage induced in the armature coils and existing between the arc terminals. For a practical application of this method, a knowledge of the arc characteristics applying to the commutators is therefore a prerequisite, and it is the purpose of the present paper to give the results of experimental investigations of this nature.

The data given will also be of value in investigations of flashing brought about by other causes. In railway motors, for instance, flashing is caused at times by certain transient conditions applying when the voltage of the motor is suddenly re-established while the motor is running and after an interruption of power supply caused by section breaks in the line, trolley bouncing, etc. Flashing is further caused by transient conditions applying in generators when a short occurs in the line, or in large motors when there is a short-circuit in the system and the motors temporarily act as generators feeding current into the short. Under these various operating conditions, flashing is caused by an appreciable voltage being induced in the short-circuited armature coil ($g$) during these temporary or transient conditions. When, as shown in figure 1$B$, this short-circuit current is opened because of segment ($a$) leaving the brush ($b$), an arc ($S$) is formed. As in the case of brush jumping, the sustaining of this arc depends upon the relative values of the voltage necessary for sustaining it and the voltages existing between the terminals of the arc for various successive positions of the commutator segment ($a$). Therefore, we are again interested in a knowledge of the arc characteristics around the commutator. This case may be somewhat complicated by the fact that a new arc is formed on each segment leaving the brush, resulting possibly in the formation of a number of different arcs on the several commutator segments, as indicated in figure 2 by $S$, $S_1$, $S_2$, and $S_3$. However, a knowledge of the arc characteristics of the individual arcs formed should prove a desirable first step toward a complete analysis of the various transient conditions.

In order to study the arc characteristics around the commutator, a simple arrangement as shown in figure 3 was used in our experimental work. A number of connected segments ($a$) of a commutator ($C$) were connected to a slip ring ($D$). A d-c voltage source was connected through an adjustable resistance ($r$) to the brushes ($b$ and $b_1$). Whenever the segments ($a$) are in contact with the brush ($b$), current flows and is interrupted by means of an arc ($S$) when the last segment ($a$) leaves the brush ($b$). With this operating condition, oscillograms were obtained giving the current as well as the voltage across the arc terminals. An example of these oscillograms is shown in figure 4. Tests were carried out with different initial current values and also for different speeds of the commutator. From an analysis and careful scaling of these oscillograms, curves such as shown in figures 5 and 6 were derived for a number of different speeds of the commutator.

The results for only 2, but widely different, speeds are given in these 2 figures. The full-line curves show the relation between arc current and arc voltage as scaled directly from the oscillograms. The test points thus obtained and entered in the figures gave in most cases rather smooth curves, which is to be expected because of the fact that the oscillograms gave rather smooth curves, as indicated in figure 4, and were void of erratic irregularities frequently encountered in connection with arc phenomena. Whatever discrepancies do exist are due essentially to difficulties in scaling the oscillograms, some of which were not taken on as large a scale as that of figure 4. It was furthermore observed that in spite of the widely diverging speeds at which these tests were made, the solid-line curves of figures 5 and 6, when compared for an equal initial current, did not vary appreciably from each other for different speeds. In considering all the curves drawn, it is difficult to find any marked tendency of variation with speed in one direction or another in the solid-line curves. Further analysis revealed, however,

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted October 29, 1936; released for publication December 1, 1936.

R. E. HELLMUND is chief engineer of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

1. For all numbered references see list at end of paper.

that with a given current, a certain arc voltage corresponds to different arc lengths with different operating speeds. By means of the timing curves taken with the oscillograms, it was possible to calculate the arc length corresponding to any test points. This was done

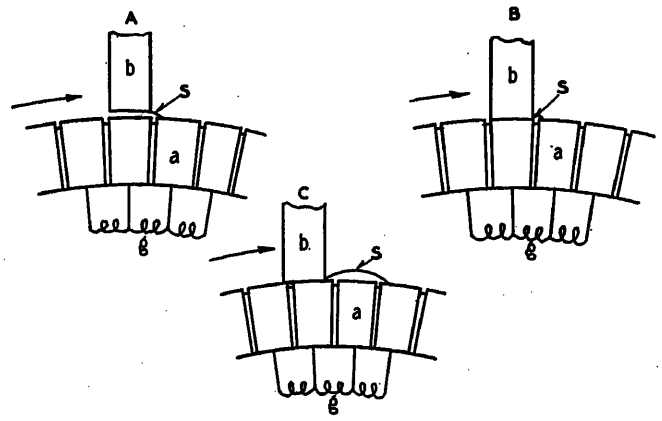

**Fig. 1. Illustration of arc formation prior to flashing on commutators**

and the points entered in figures 5 and 6 corresponding to a certain arc length were marked by like designations; thus the dotted-line curves each corresponding to a given arc length, as indicated, were obtained.

The agreement of the test points with the dotted-line curves is not quite so good as with the solid-line curves, nevertheless the consistency of the results is quite remarkable, taking into consideration the usual difficulty in obtaining consistent results with arc phenomena. The reason for this seems to be that in these tests the condition of the air currents near the arc was more or less definitely established by the nature of the air film carried around near the surface of a rotating cylinder for any given speed. Usually arc phenomena tested in open air are subject to varying air currents caused by convection and other causes, and they frequently are further influenced by electromagnetic effects, all of which lead to irregularities. Furthermore, the electrode spots are often moved about by these irregularities, which further increases

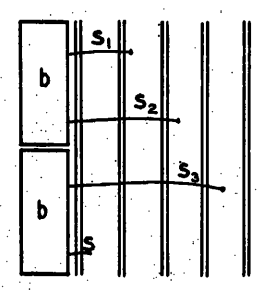

**Fig. 2. Illustration of multiple arcs forming on commutators under certain conditions of flashing**

the difficulty of obtaining consistent results. (This is noticeable on some of the oscillograms given toward the end of the paper which show very irregular curves during periods when the location of the electrode spots is changing. See figure 12.)

In considering the phenomena further, it must be appreciated that while the dotted-line curves somewhat simulate the usual arc characteristic curves, they do not represent a static relation between current and voltage because the points to which the curves are drawn are in all cases the points from a transient arc condition obtained by starting with a certain value and lengthening the arc while the current decreases and the voltage increases. By means of the full-line curves, it is possible to determine the starting currents corresponding to the current values at the points of intersection between the

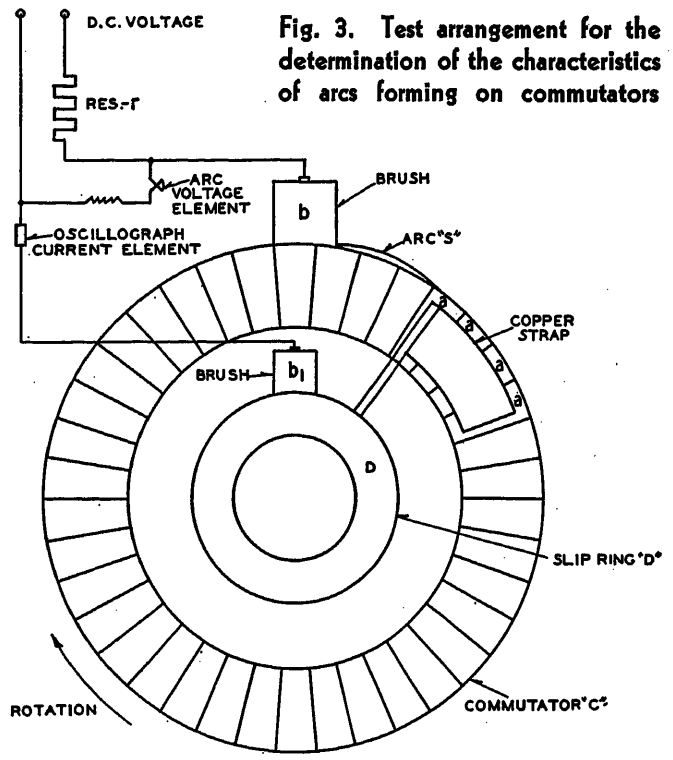

**Fig. 3. Test arrangement for the determination of the characteristics of arcs forming on commutators**

solid-line and the dotted-line curves. Normally, that is with constant length of arc and without high air velocity around the arc, it is to be expected that with a diminishing arc current the voltage will be the lower the shorter the time interval allowed for the decrease in current. The reason for this is that during a shorter time interval, less deionization will take place. Comparison of definite points between the low- and the high-speed curves in figures 5 and 6, respectively, shows that the opposite condition applies here. If we consider, for instance, the 20-ampere point for the $2^1/_2$-inch arc length in figure 5, which corresponds to a starting current of about 28 amperes, we find a voltage of 167 volts for the slow speed. If we then consider the 20-ampere point for the $2^1/_2$-inch arc length in figure 6, we find a higher voltage of 215 volts in spite of the fact that the time of drawing this arc was only $^1/_3$ that of figure 5 and that the starting current was over 30 amperes. Likewise, if we consider the 14-ampere point of the 1-inch arc length, with a starting current of about 18 amperes the voltage indicated is 115 volts for the low speed, while with approximately the

same starting current, a voltage of 155 is obtained for the high speed. The conclusion drawn from this is that the speed at which the commutator is rotating has a marked influence upon the deionization, resulting in higher voltages for a given current with the higher speed. This is more clearly shown in figure 7, which gives the arc voltages for certain arc lengths at different speeds for instantaneous arc currents of 10 and 60 amperes. As should be expected, the speed is of relatively minor influence with the shorter arcs but is, in general, of greater influence with the longer arcs. It will be further noted that with the heavier currents the influence of the speed is not very marked, while with the small currents it is appreciable. Since the voltages for the transient currents for which the curves of figure 7 are plotted may be influenced by the initial currents

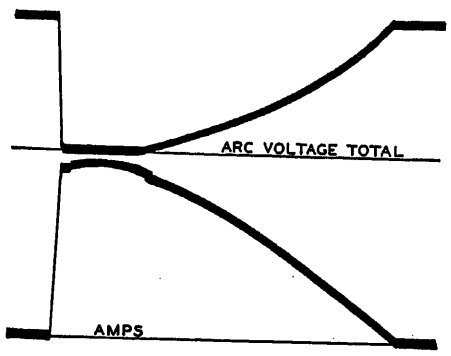

**Fig. 4. Tracing of oscillogram giving arc current and arc voltage**

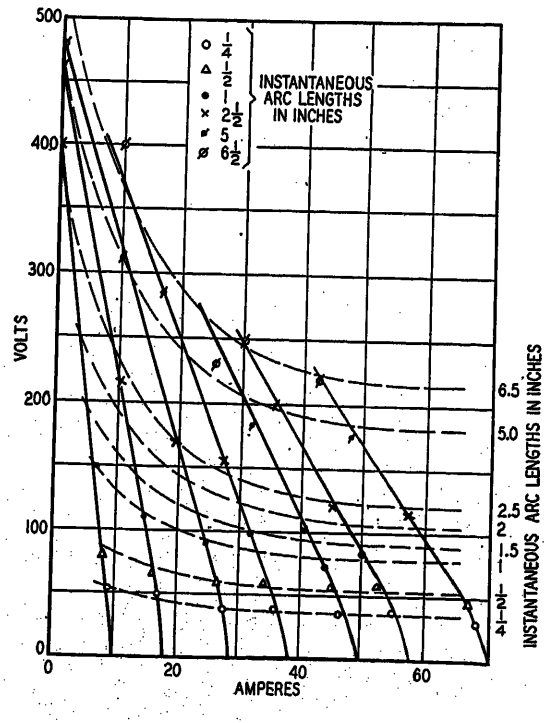
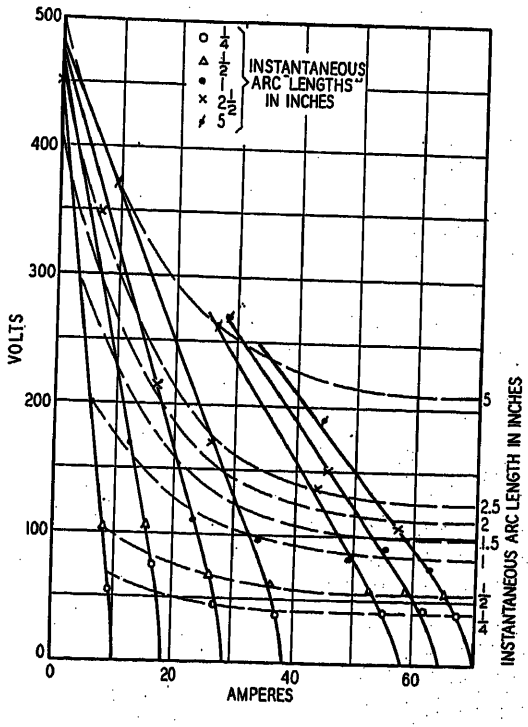


and the corresponding ionization, the values of the initial currents are of interest. The values of these initial currents happen to be practically constant for each of the curves and therefore the difference in voltages evidently is caused by the difference in speed; these values are shown at the right of the curves in figure 7.



Although, as already pointed out, the curves in figures 5 and 6 cannot be considered as representing static arc characteristics, figure 8 has been prepared showing a comparison of some of the curves of figures 5 and 6 with the static-arc characteristics as calculated from a formula given by Rüdenberg.[2]

In commutator flashing we do not at any time deal with constant arc currents, but the conditions are much the same as the test conditions of figure 3. What we are really interested in, especially in the light of the theory advanced in my previous paper,[1] is the arc voltage for different lengths of arc for any given initial arc current and for various commutator speeds. The curves in figures 9*A* and 9*B* show this. These curves can be directly applied as the arc voltage curves designated *A*-*B* in the previous paper and compared with the curves of the voltages induced in the armature between the arc terminals. Figure 10 gives a number of these voltages as compared with the curves applying to given initial currents indicated for a speed of 2,200 feet per minute. The distance to the points at which the arc-characteristic curves and the induced-voltage curves cross each other should, therefore, be a direct indication of the comparative likelihood of motor flashing at 2,200 feet per minute for the different initial currents and for the 3 different curves of induced voltage corresponding to different main-pole shapes.

In order to check any influence which different brush locations might have upon the arc characteristics, a number of tests were made with the brush mounted at the bottom of the commutator. The results thus obtained did not differ materially from those obtained with the brush mounted at the top. Visual inspection indicated that the arc formed close to the surface of the commutator with the brush in either position, and, in general, the phenomena seemed to be the same.

With the testing arrangement in figure 3, it is evident

**Figs. 5 (left) and 6 (right). Curves showing relation of voltage to current as obtained from oscillograms such as shown in figure 4 (full lines), and curves showing relation of voltage to current for various lengths of arc (dotted lines)**

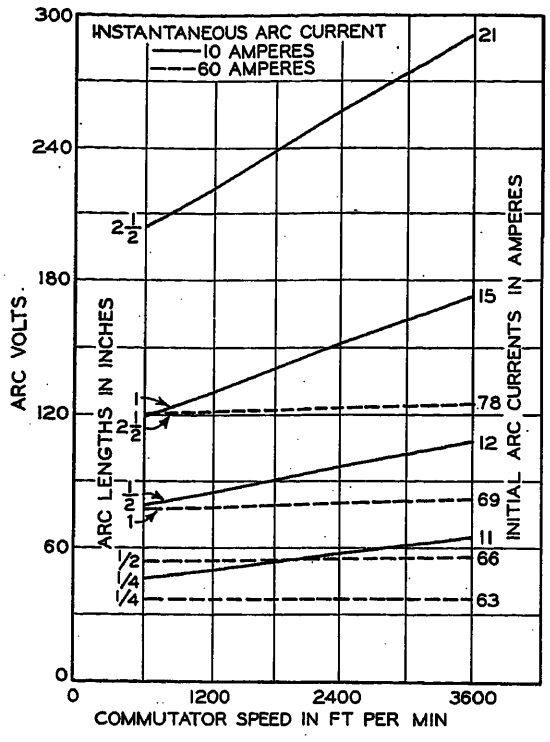


**Fig. 7 (left). Curves showing arc voltage as influenced by speed for various currents and arc lengths**

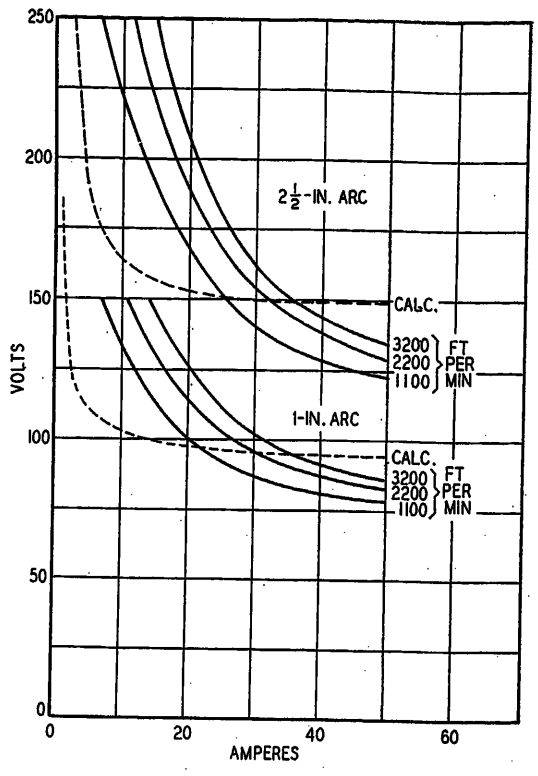

**Fig. 8 (right). Comparison of calculated static arc characteristics with transient characteristics tested on commutators**

that the hot-cathode spot would very likely remain on the last segment (*a*) for the entire duration of the arc, unless there were appreciable air currents or magnetic effects to disturb conditions. However, in checking some tests made on motors with artificially produced brush jumping, it seemed that at times flashing did not occur when according to the basic theory given in my previous paper[1] it should have occurred. This theory assumes that the hot-cathode spot remains on the segment on which it originally forms. The only possible explanation therefore seemed to be that in reality the hot-cathode spot moved from the original segment in a backward direction to other segments, thus preventing the drawing of the arc into the high-voltage regions of the commutator. In order to check this a test arrangement as shown in figure 11 was devised. A number of segments (*a*, *z*, *y*, *x*) were connected together as in the previous tests and the current from these segments was conducted through a slip ring (1). The 2 segments (*b* and *c*) following the interconnected segments were also connected to slip rings 2 and 3, respectively. The voltage of the arc was recorded as before by the oscillograph and the currents in the 3 slip rings were also recorded by the current elements of an oscillograph. On the commutator surface 2 strips of insulating material were arranged as shown in figure 11 to lift the brush slightly off the commutator when it was about to pass segment (*a*). This, of course, resulted in the formation of an arc (*S*), the current of which was measured through the current of slip ring (1) and it is evident that in case the hot-cathode spot would move to segments *b* and *c*, this would be indicated by currents in the slip rings 2 and 3. In order to determine the effectiveness of this arrangement, some tests were first made with the brush negative—that is, with the hot-cathode spot on the brush and the anode end of the arc forming on segment (*a*). Figure 12*A* is a tracing of an oscillogram taken under this condition. As is well known, the anode spot moves readily and it will be seen that the arc formed on segment (*a*) at the left end of the oscillogram, persisted for a short period, and then transferred to segment (*b*). Subsequently the current was divided for a time between segments (*b*) and (*c*) and finally transferred entirely to segment (*c*). In the case of the second arc on the same oscillogram, the current again is on segment (*a*) for a certain period, then is transferred for a short time to (*b*); and then instead of dividing as in the first case, is entirely transferred to segment (*c*). The latter condition is obtained in the majority of cases with a negative brush.

After these preliminary tests, the brush was made positive and a total of 22 arcs was recorded. It was found that in only 2 of these 22 cases a transfer of the arc from segment (*a*) to other segments took place. In view of the fact that the brush is wider than segment (*a*), it could not be safely assumed that the original arc always formed on segment (*a*), there being the possibility that the brush when lifted by the insulating strips would tilt and therefore make contact last with segment (*z*) preceding (*a*). In a case like this, the subsequent move of the arc to segment (*a*) would not be recorded by the oscillograph. For this reason the brush was beveled, as shown by dotted lines, sufficiently to insure that it would make its last contact with segment (*a*). A total of 7 arcs were recorded with this arrangement and it was found that a transfer of the hot-cathode spot occurred in 2 cases. Figure 12*B* shows the currents in 3 of the arcs formed. It will be seen that in 2 of the 3 cases in this oscillogram no transfer took place, but in the third a transfer occurred and the current split between segments (*b*) and (*c*) for the remainder of the arc duration.

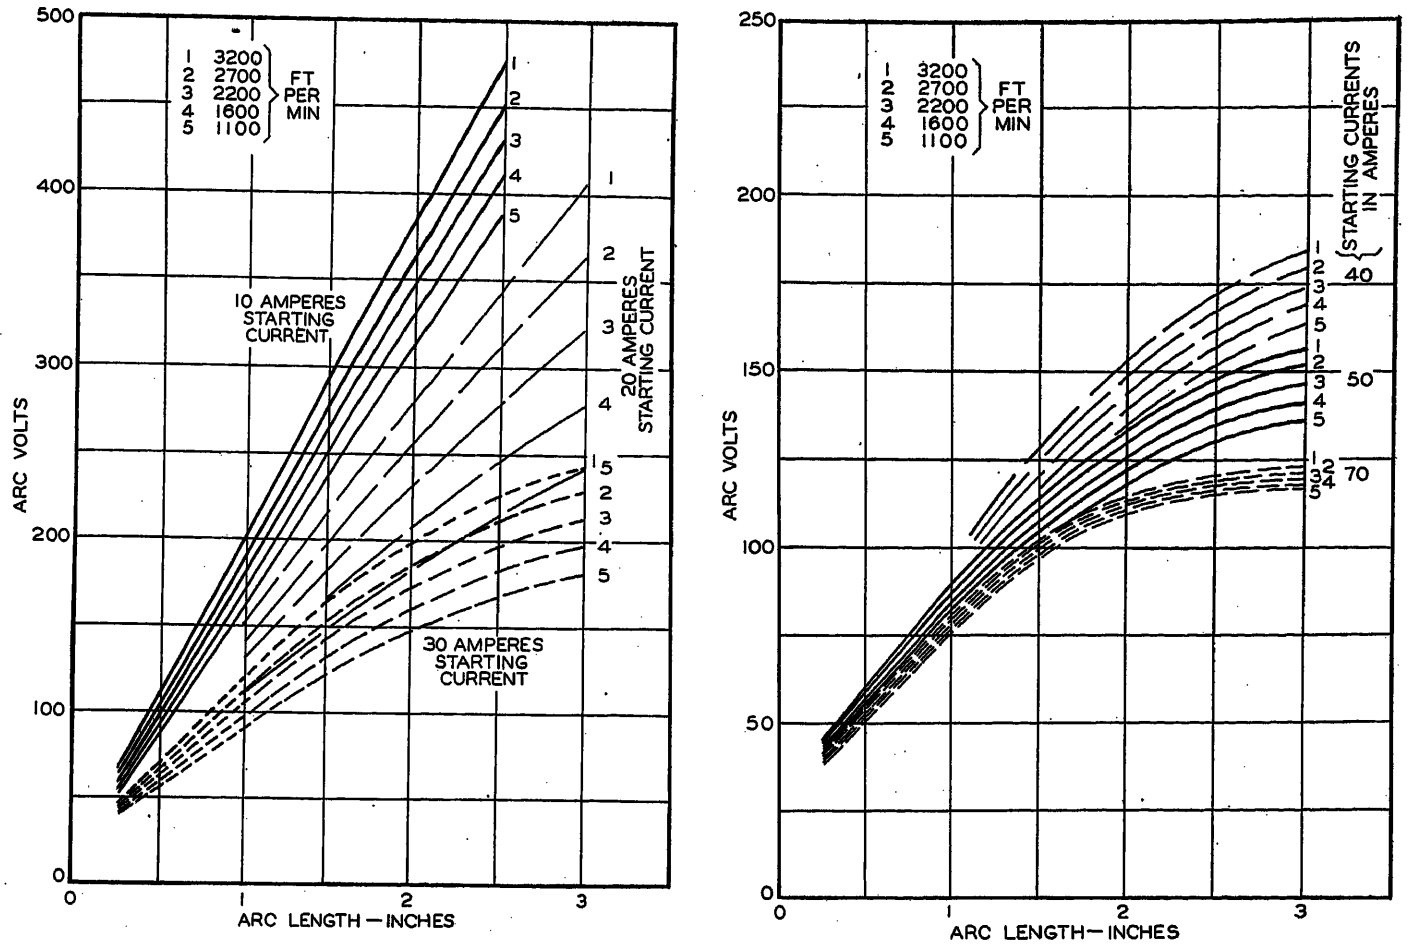

**Fig. 9A (left) and 9B (right). Curves showing relation of arc voltages to arc lengths for various values of speeds and initial currents**

In order to provide for the possibility of the arcs transferring to segments following segment (*c*), the arrangement was changed so that segment (*c*) was connected to a number of succeeding segments (*f*, *g*, and *h*), as indicated by the dotted connection in figure 11. A typical oscillogram taken under this condition is shown in figure 12*C*. It will be seen that with the first 2 arcs no transfer took place; with the third a transfer of current to segment (*b*) occurred, and subsequently to the sector including segment (*c*). The sudden breaks in the current of slip ring (3) seems to indicate a further shift of the hot-cathode spot from one of the connected segments to another. The formation of the fourth arc seems to be similar to that of the third, except that the arc transferred from the leading to the lagging sector without touching the intermediate bar.

In another oscillogram shown in figure 12*D*, it will be noted that a transfer from the leading to the lagging segment took place in 2 instances, while no transfer occurred in the third. It will also be noted that the time at which the transfer took place in the first 2 cases differs. The oscillogram shows no definite evidence of an intermediate time during which segment (*b*) carried the current.

Summarizing: It is found that of 125 arc formations recorded, no transfer took place in 84, or 67 per cent of the total. Eliminating the tests with unbeveled brushes because of the uncertainty as to whether transfer took place between segments (*z*) or (*a*), it is found that of the remaining 103 arc formations there was no transfer of any kind in 64, or about 62 per cent of the cases. Current values of 30 and 65 amperes were used in the tests. With the 30-ampere current, transfer took place in 21 out of 55 cases, or 38 per cent; with the 65-ampere current, in 20 out of 71, or 28 per cent. Considering only the tests with beveled brushes, with the 30-ampere current a transfer took place in 44 per cent of the cases; with the 65-ampere current, in 33 per cent. There is, therefore, a general indication that with a lower current the tendency to transfer is greater, though it may be inadvisable to draw such a definite conclusion without carrying on a greater number of tests. At speeds of about 1,600, 2,200, and 3,200 feet per minute, the percentages of cases in which transfers took place were 43 per cent, 19 per cent, and 44 per cent, respectively, when all tests are considered; at speeds of 1,600, 2,200, 3,200, 4,300, 4,900, and 5,400 feet per minute, the percentages are 53 per cent, 18 per cent, 47 per cent, 11 per cent, 22 per cent, and 45 per cent, respectively, when only the tests with the beveled brushes are taken into account. These figures do not indicate any very definite tendency to transfer with increasing speed.

It was thought that the tendency of the arc to transfer might be influenced somewhat by the undercutting of the commutator and some tests were therefore run with under-

cutting and some without. However, the percentage of transfers under the 2 conditions was practically the same.

For the purpose of determining whether the position of the brush had any marked influence, tests were made with the brush on top and also at the bottom of the commutator. With 65 amperes, the percentage of transfers was 44 with the brush on top and 40 with the brush at the bottom; with 30 amperes, the percentages were 40 and 62.5, respectively. Since the number of tests for each of the 4 conditions is not very large, it would be unwise to conclude that there is any decided difference between the 2 brush locations; as a matter of fact, it seems that the location of the brush makes very little, if any, difference.

Some of the above data are given merely for the purpose of answering certain questions that may occur to those interested in the problem. The essential fact brought out by the rather extensive series of tests is that a transfer of the hot-cathode spot from the segment on which it is first formed to other segments takes place at times, but that this is more or less a matter of chance and certainly cannot be depended upon for reducing the tendency of a motor to flash. In other words, in order to be safe the designer should assume that the hot-cathode spot may travel with the segment on which it is first formed, which condition in turn is the one most likely to bring about objectionable flashing conditions.

In conclusion it may therefore be stated that with curves as presented in this paper and the fundamental method outlined in my previous paper,[1] it is possible to analyze the inherent electrical tendency of motors to flash when the brushes jump. It is appreciated that this phenomenon is also greatly influenced by the length of time the brush is off the commutator, which in turn is influenced by a great many mechanical factors, such as workmanship in the building of the commutators, seasoning of the commutators, balancing of the armature, mounting of the motor as a whole and resultant mechanical vibrations, commutator irregularities brought about by commutation characteristics and the type of brush used, brush tension applied to the brushes, weight and elasticity of the brushes, etc. It is obvious that the great variety of influencing factors makes it practically impossible to determine theoretically the time the brush is likely to leave the commutator at different commutator speeds and that a complete and exact theoretical analysis of this flashing problem therefore seems impossible. However, the method and data given are useful and of practical value in a comparative quantitative analysis of different motor designs and, in particular, of their field distributions. Moreover, some of the variables enumerated, such as the commutation characteristics, the choice of brushes, etc., can be handled by the designer in such a way as to eliminate them as factors of practical importance. On the other hand, the variations caused by manufacturing and maintenance operations can, with reasonably controlled shop processes, be reduced to chance phenomena of a limited amplitude of variation. Consequently, the comparative analysis outlined furnishes a means by which the adequacy of new designs can be predicted with a considerable degree of assurance. As already indicated at the beginning of the paper, the experimental results given here will also be useful in other types of flashing. A more complete analysis of these will require experimental investigations regarding the initial current that may exist at the brush when a short-circuited coil passes from under the brush under different conditions of load and commutation. Furthermore, it would be necessary to make a quantitative analysis of the transient current, field, and

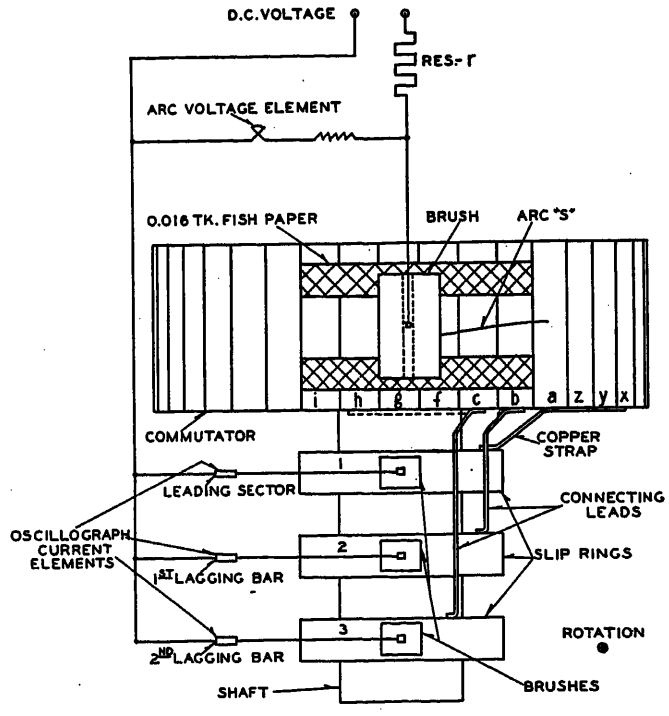

**Fig. 11. Test arrangement for investigating the tendency of the arc to shift from one segment to another**

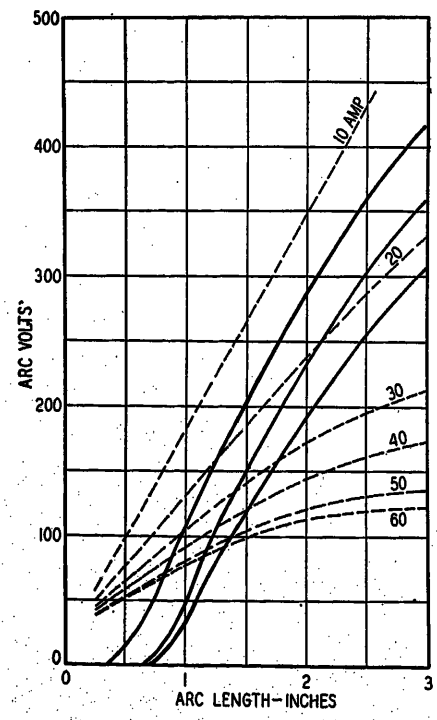

**Fig. 10. Curves comparing arc voltages with voltages as induced in armature with various field forms**

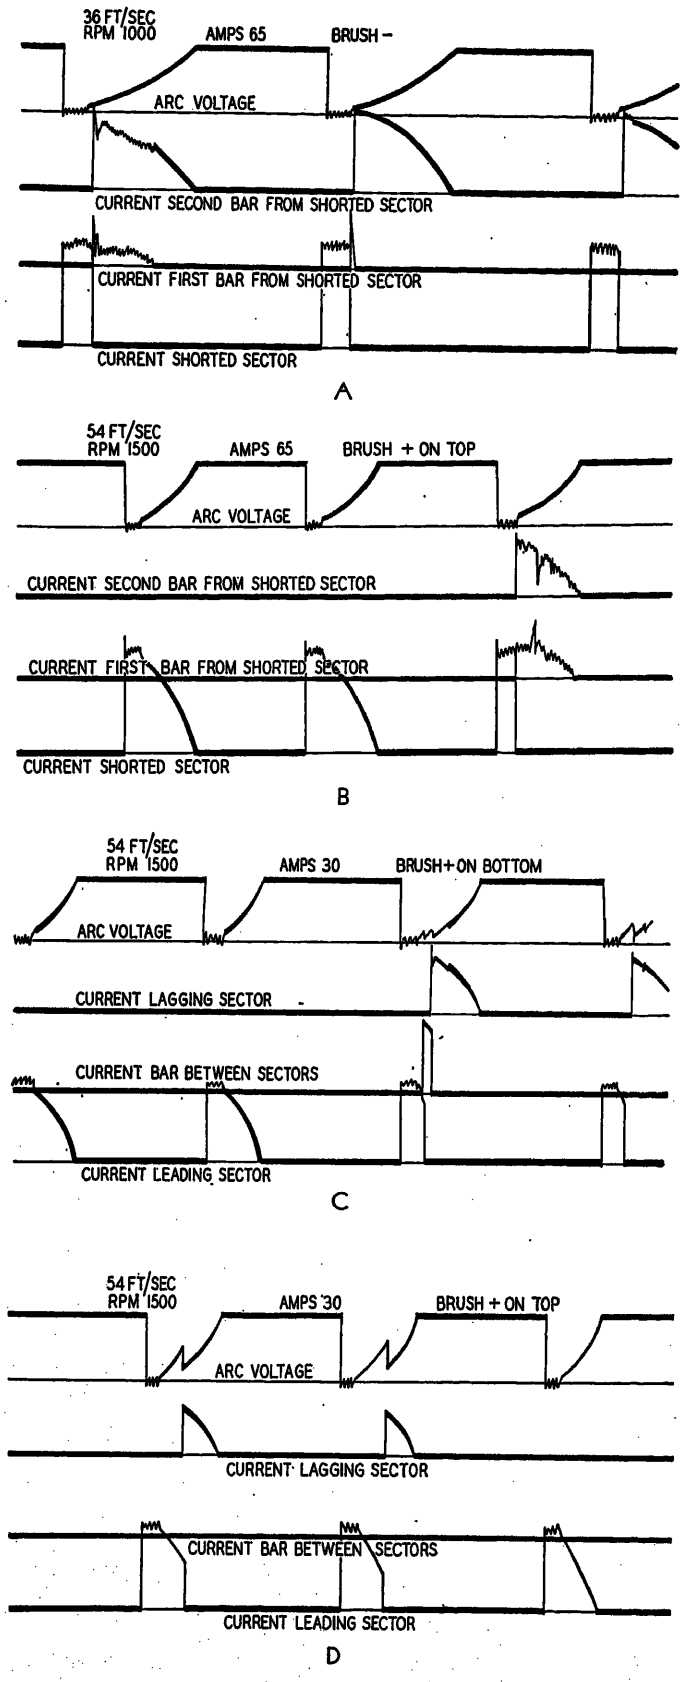

**Fig. 12. Oscillograms showing tendency of arc to shift from one segment to another**

voltage conditions existing in the machine at the time when flashing is likely to occur. However, through the judicious use of a qualitative analysis of these factors given by the author in an earlier article,[3] together with the considerations and data given in this and the previous paper,[1] considerable progress has been made in predicting the flashing characteristics of motors during transient conditions such as may exist after temporary interruptions of power supply to the motors.

# A Single-Element Polyphase Directional Relay

(*Continued from page 80*)

## Appendix III

### Conductor Voltages at Location of Arc Fault

| Three-Phase Fault | Phase-to-Phase Fault |
|---|---|
| $E_1 = I_1R$ | $E_2 = -I_2(Z_2 + Z_L)$ |
| $I_1$ is in phase with $E_1$ | $E_1 = -I_2(Z_2 + Z_L + 2R) = I_1(Z_2 + Z_L + 2R)$ |
| | $-I_2$ and $I_1$ lag $E_2$ and $E_1$, respectively |

## Appendix IV

### A. Connections Figure 3a

The total input to the relay is

$$P_R + jQ_R = E_c\bar{I}_b + \underline{E_b\bar{I}_b} - E_b\bar{I}_c + E_a\bar{I}_c - E_a\bar{I}_b - \underline{E_b\bar{I}_b} + E_b\bar{I}_a - E_c\bar{I}_a$$

The underlined terms cancel and

$$-E_a\bar{I}_b + E_c\bar{I}_b = (E_c - E_a)\bar{I}_b = -E_B\bar{I}_b$$
$$-E_b\bar{I}_c + E_a\bar{I}_c = (E_a - E_b)\bar{I} = -E_C\bar{I}_c$$
$$-E_c\bar{I}_a + E_b\bar{I}_a = (E_b - E_c)\bar{I}_a = -E_A\bar{I}_a$$

Therefore

$$P_R + jQ_R = -E_A\bar{I}_a - E_B\bar{I}_b - E_C\bar{I}_c$$

### B. Connections Figure 3b

The total power to the relay is

$$P_R + jQ_R = -E_C\bar{I}_a - E_A\bar{I}_a + E_A\bar{I}_c + E_B\bar{I}_c - E_B\bar{I}_a - E_A\bar{I}_a + E_A\bar{I}_b + E_C\bar{I}_b$$

since $E_A + E_B + E_C = 0$

$$E_A\bar{I}_b + E_C\bar{I}_b = (E_A + E_C)\bar{I}_b = -E_B\bar{I}_b$$
$$E_A\bar{I}_c + E_B\bar{I}_c = (E_A + E_B)\bar{I}_c = -E_C\bar{I}_c$$
$$-E_C\bar{I}_a - E_A\bar{I}_a - E_B\bar{I}_a - E_A\bar{I}_a = -(E_C + E_A + E_B + E_A)\bar{I}_a = -E_A\bar{I}_a$$

therefore

$$P_R + jQ_R = -E_A\bar{I}_a - E_B\bar{I}_b - E_C\bar{I}_c$$

# A Review of Overhead Secondary Distribution

By W. P. HOLBEN
MEMBER AIEE

**This paper provides a comparison of results of 5 economic studies* that were made to determine the economic relationship between conductor sizes and distribution transformer sizes for various load densities and rates of load growth. The progressive method of distribution design, which provides additions rather than replacements, has been found most economical. Increase in load density can be handled most economically by the subdivision of secondary mains and the installation of intermediate transformers. Numbers 4, 3, or 2 conductors and 15-kva transformers should be favored for overhead secondary distribution in residential areas in cities and towns. Rural lines and service to rural communities are not considered in this comparison.**

SPECIAL interest in the economics of secondary distribution design has developed during recent years among the various electric utility companies. Extensive studies covering technical and practical features of secondary design have been made and reports completed to show the results of these studies in a most interesting and enlightening manner. Through the courtesy and co-operation of 5 operating companies, and the authors of the respective reports, it is now possible to present the combined results of these studies in a comparative form.

The comparisons of the conclusions reached in the various investigations are especially interesting, since they represent a variety of operating conditions, locations, and engineering and operating opinions. There is sufficient similarity in the conclusions reached to indicate that all these reports are based on sound engineering principles and that, in general, the economic and technical solutions of such problems are not restricted by local conditions or individual opinions. On the other hand, certain qualified conclusions indicate the effects of good engineering judgment to meet special local problems, and provide ample reason for separate and independent studies based on conditions and practices in the various operating territories.

While no technical analysis will be undertaken in this paper, it is proposed to present the essential data and results in a concise manner, adding explanatory discussion only as may appear necessary to provide a better understanding of the variety of conditions and variables encountered in these investigations. Several of the reports include the complete technical analysis and tabulated results of each step of their computations. Each of these reports provides excellent reference material for any one interested in the economics of distribution design. Many of the fine points developed in the reports cannot be reviewed in this paper, but the writer highly recommends the use of the methods and the technique for similar studies. Each of the reports uses a somewhat different form of graphical analysis but all of them are extremely interesting.

A paper recommended for publication by the AIEE committee on power transmission and distribution. Manuscript submitted October 29, 1936; released for publication November 30, 1936.

W. P. HOLBEN is engineer in the engineering and construction department of the Duquesne Light Company, Pittsburgh, Pa.

* This paper represents a composite review of the findings resulting from 5 separate studies on the subject of "Economics of Overhead Distribution Design." The author is therefore indebted to the company managements and the authors of the respective company reports, without whose contributions a paper of this type would be impossible at this time. The author is especially grateful for the constructive suggestions made as a result of the review of the paper in preliminary form. The following contributed to the studies on which this paper is based:

Boston Edison Company; report by A. H. Sweetman and St. George T. Arnold, dated December 29, 1934.

Detroit Edison Company; report by H. P. Seelye and E. L. Leinbach, dated September 1, 1935.

Duquesne Light Company; report by C. T. Sinclair and W. P. Holben, dated January 16, 1934.

Philadelphia Electric Company; report by A. H. Kidder, dated November 5, 1934.

West Penn Power Company; report by Merrill DeMerit and R. C. McKee, dated June 1928.

## Summary

1. The progressive method of secondary circuit design, which provides additions rather than replacements, has been found most economical, and provides for growing loads on the basis of small increments of system capacity.

2. The economical conductor sizes are reported to be numbers 4, 3, and 2. The majority recommendation is number 2 where the reduction of appliance load flicker is a major need.

3. For load densities less than 20 kw per 1,000 feet, numbers 6 and 4 conductors show some advantage in annual costs but in some cases fail to meet flicker requirements. Over 20 kw per 1,000 feet, numbers 3 and 2 meet both the economy and flicker conditions.

4. For concentrated or high density load in commercial districts these recommendations do not apply, as lack of sufficient transformer poles or other congested conditions frequently necessitate larger conductors or special construction.

5. For overhead distribution in average residential districts in cities and towns, 15 kva transformers are generally most economical, with a later change to 25 and 37½ kva for higher densities resulting from growth in load and other special conditions.

6. For average residential loads, transformer loadings may range from 75 per cent at installation to 165 per cent at replacement, with the majority average recommendation 90 per cent to 150 per cent. (The overloading becomes permissible because of the usual low ambient temperature at the time of the winter peak load on transformers on overhead lines.)

7. Growing loads in overhead distribution areas can be handled most economically when the secondary system is designed on a progressive basis to allow for subdivision of secondary mains and the installation of intermediate transformers as required, including possibly some transformer relocations.

## Comparison of Methods, Assumptions, and System Conditions

Table I outlines the methods, conditions, and assumptions that were considered by the authors in their respective investigations, to arrive at the most economical secondary design.

### Type of System

The comparison in item 1 shows that each of the 5 companies has studied the problems and economics relating to a 3-wire single-phase overhead radial system of secondary distribution. Companies *A* and *B* have selected the "straight line" plan of distribution with continuous secondaries on streets with long blocks, using the 2-way feed from transformers. Three- and 4-way feeds are rare because of difficulty in locating transformers on corner poles. Cross ties between secondary mains and "H" construction are generally considered unnecessary and uneconomical as a result of these studies, except where closed radial loops or banked secondaries are in use. Company *D* reports the use of some radial loop construction, although not used extensively, while company *E* uses banked secondaries as well as radial circuits, with the former predominating. Company *C* does not state a preference. Where short branches from secondary mains are in use, the load on such branches may generally be considered located at the point of connection to the main, while the longest branch may be regarded as part of the main. For most of the studies, the load density has been considered in kilovolt-amperes or kilowatts per thousand feet, distributed uniformly along the main at the respective pole locations.

### Method of Comparison

Item 2 indicates that companies *A*, *B*, and *D* have based their investigations on a study of annual costs and companies *C* and *E* on a study of investment costs. Company *E* also includes capitalized losses in the total costs. It is interesting to note that company *B* has included also the annual lost revenue due to secondary drop.

Annual costs include the following items:

(*a*). Fixed annual charges (included by all companies)
1. Interest
2. Dividends
3. Taxes
4. Insurance
5. Depreciation

(*b*). Energy losses (included by all companies)
1. Transformer iron losses
2. Transformer copper losses
3. Secondary copper losses

(*c*). Operation and maintenance for (included by company *A*)
1. Transformers
2. Secondaries

(*d*). Lost revenue due to secondary drop (included by company *B*)

Depreciation as expressed in item (*a*)-5 is dependent in part on the life of transformers and secondaries resulting from failure, inadequacy, and obsolescence, but must also provide for retirement to meet new conditions resulting from growth in load. Replacement before the end of a normally useful life requires a larger retirement re-

### Table I—Comparative Statement of Methods, Assumptions, and System Conditions

| | | Company | | | | |
|---|---|---|---|---|---|---|
| | | A | B | C | D | E |
| 1. | Type of system | 3-wire 1-phase overhead radial straight-line | 3-wire 1-phase overhead radial straight-line | 3-wire 1-phase overhead radial | 3-wire 1-phase overhead radial straight-line, 2-way and 4-way | 3-wire 1-phase overhead radial and banked |
| 2. | Method of comparison | Annual costs | Annual costs incl. lost revenue due to secondary drop | Investment costs | Annual costs per peak kilowatt | Investment costs incl. capitalized losses |
| 3. | Cost of losses | | | | | |
| | Secondary copper | 0.0164 | | | 0.00456 and 0.01 | 0.005 |
| | Transformer iron | 0.0073 | 0.0035 and 0.007 | | 0.003 and 0.01 | 0.005 |
| | Transformer copper | 0.0155 | 0.0070 and 0.014 | | 0.00456 and 0.01 | 0.005 |
| 4. | Losses capitalized @ | | | | | 15 per cent |
| 5. | Equivalent hours of full load use per year | 1,500 | 1,095 and 2,190 | | 1,200 | 1,095 |
| 6. | Voltage regulation | | | | | |
| | Secondary drop, per cent | 2–3 | 3 | | | 2½ |
| | Total regulation | | | 121 volts (first customer) 109 volts (last customer) | 4–7 per cent (113–121) | |
| 7. | Allowable flicker | | | | 5 per cent of 115 volts 20 amp @ 50% power factor | 2–4 per cent of 115 volts 20 amp @ 50% power factor |
| | Noticeable flicker | | 2 per cent of 115 volts 15 amp @ 50% power factor | | | |
| 8. | Wire cost, triple-braided weatherproof, cents | 12 | 20 | | | 5, 10, 20, and 30 copper |
| 9. | Standard wire sizes | Nos. 6, 3, 1/0, and 4/0 | Nos. 6, 4, 2. 1/0, 2/0, and 4/0 | Nos. 6, 4, 2, and 2/0 | Nos. 6, 4, 2. 2 No. 1/0 and 1 No. 2 2 No. 4/0 and 1 No. 2/0 | Nos. 6, 4, 2 1/0, and 4/0 |
| 10. | Type of load | Residential and light commercial | Residential | Residential including ranges | Residential | Residential |
| 11. | Load growth rates, per cent | 7½ | 5, 10, and 15 | 5 | 5 linear 5 and 10 compound | "*a*," "*b*," and "*c*" |
| 12. | Load density, kilowatts per 1,000 feet | 10 to 110 | 10 and 20, initial load | | 7½, 15, 22½, and 30 | 10 to 100 |

serve, and most of the companies have therefore extended their investigations to include accumulated annual charges over a considerable period of years, ranging from 15 to 25 years.

### Cost of Losses

There is a wide variation in cost of energy losses used by the various companies in calculating this portion of the annual cost. This is apparently due at least in part to one being twice as great as the other, with cost curves resulting that are similar in form and an average variation in total costs of 7 per cent.

### Rate of Capitalizing Losses

Company *E* based their study on the total cost of transformers and secondaries in place on the system and included losses capitalized at 15 per cent. Company *C* refers to their comparison of investment costs but does

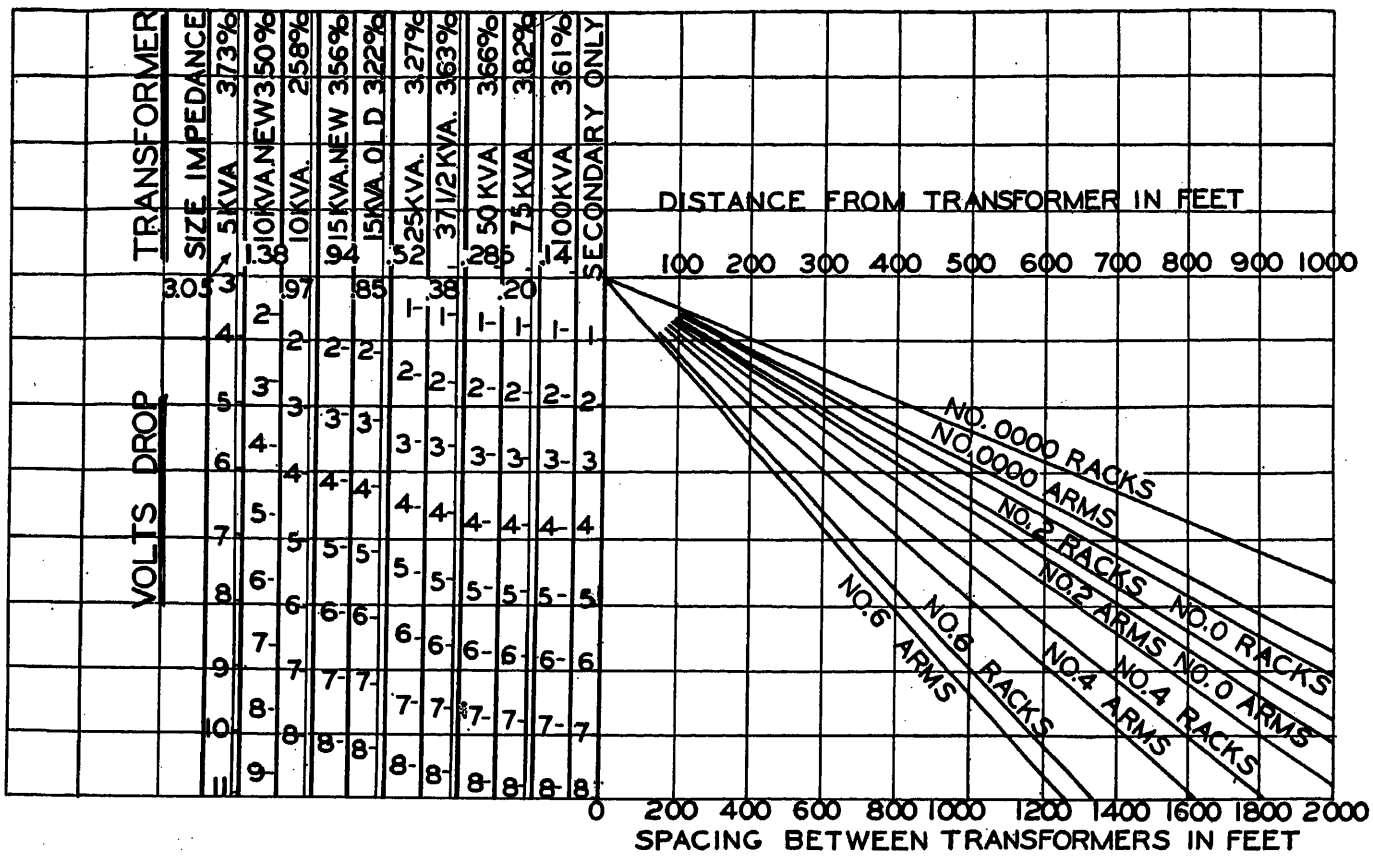

**Fig. 1. Flicker chart showing voltage drop with 20 amperes at 115 volts and 50 per cent power factor (company E)**

Use scale at left corresponding to transformer used for radial secondaries. This chart may be used for banked transformers by dividing scale readings at voltage drop by 2 if motor is midway between transformers

a difference in opinion regarding the demand charge factor as well as the load factor for such energy losses. Generally speaking, there should be very little difference in generating costs on these representative systems, but there will be a substantial variation when different points on the system to which the energy is to be delivered are taken into consideration. For example, since the secondaries are the remote part of the system, the unit cost for energy at that point will be a great deal more than at the generating station

It is unnecessary, however, to be greatly concerned about this point since losses represent less than 20 per cent of the total annual costs and regardless of the values used, the form of the annual cost curves are similar and therefore do not materially affect the choice of conductor or transformer sizes. This fact was substantiated by company *B* which included as part of their study the effect of using 2 values, not state the percentage for capitalizing losses. It is suggested however that a good practice to follow on this point provides a percentage for capitalizing losses equal to the annual fixed charges.

### Load Factor

The load factor based on the equivalent hours of full load use per year for the calculation of losses is reasonably uniform, as shown in table I, with one company somewhat more optimistic about their load curve for distribution transformers.

### Voltage Regulation

The allowable voltage drop in the secondaries represents a fairly uniform practice among all the companies. The total voltage regulation at the customer's service is the important consideration, and must include the voltage

drop in primary conductors beyond the regulating point on the main, the transformer drop, and the drop in the secondaries to the point of service. When transformers are located near the regulating point or when not fully loaded, it is possible to allow a greater drop in the sec-

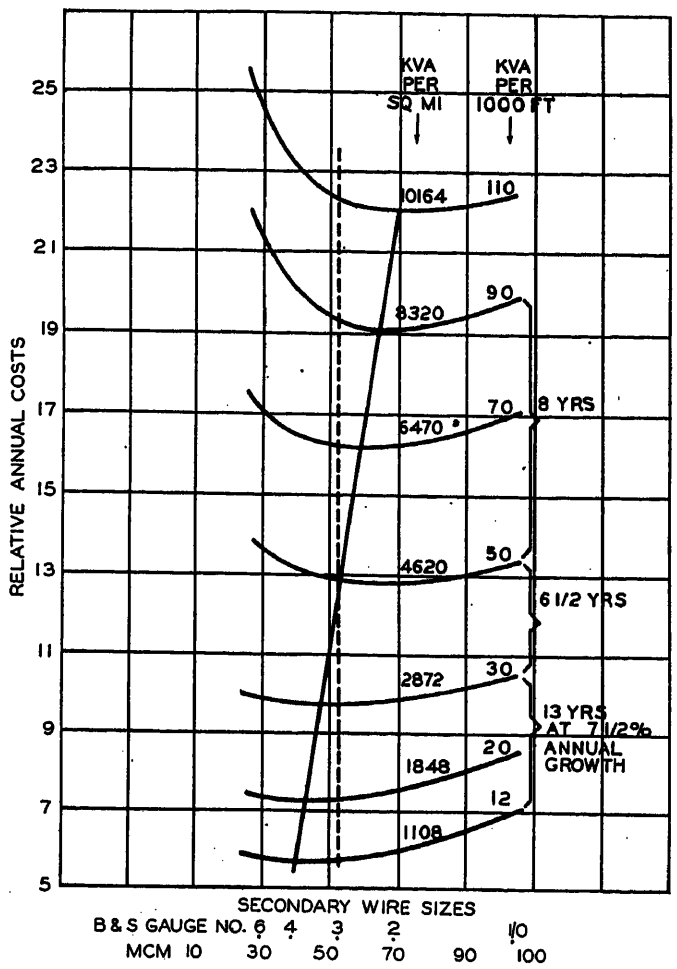

**Fig. 2. Annual costs of transformers and secondaries for various conductor sizes, pole spacing 100 feet, 2 per cent secondary regulation, and transformers 100 per cent loaded (company A)**

ondaries and still maintain satisfactory voltage at the customer's service, within the limits specified by company practice, or public service commission requirements.

A great deal of discussion has resulted from the claim that the feeder regulators may be used to correct transformer regulation. It should be noted that 2 conditions react against complete success in the use of regulators for this purpose:

1. The daily load cycle is not the same for all the transformers on a primary distribution circuit. Large present-day distribution circuits include transformers to supply residential, commercial, and industrial load.

2. The per cent loading of distribution transformers on any primary circuit is not the same, partly due to the difference in rate of growth and also because of the need to handle a large variety of load conditions and densities, therefore resulting in the use of a variety of transformer sizes.

### Allowable Flicker

The allowable flicker has been investigated by companies *B*, *D*, and *E*. The results in each case indicate that sudden voltage variations in excess of 2 per cent are noticeable and if they occur frequently will become the cause of complaints. Refrigerator motors and similar appliances are subject to starting currents of 15 to 20 amperes at 115 volts and 50 per cent power factor. As the density of these appliances increases, the question of flicker becomes a problem of major importance, and directly affects the choice of wire sizes and transformers as well as transformer spacing. Figure 1 has been prepared by company *E* to show voltage flicker due to appliance motors.

### Wire Costs

The effect of considerable variation in wire costs has been thoroughly investigated by company *E*. While an increase in wire price shows the effect of favoring smaller wire sizes, it is not a controlling factor in the choice of wire sizes. There is, of course, a natural reason for favoring larger conductors when copper prices are low but it cannot be adopted as a standard practice over an extended period of time. The use of an average price, such as 15 cents per pound for comparative studies, appears to be logical as a result of the facts developed in this investigation.

Iron losses 0.007 per kilowatt-hour for 8,760 hours annually

Copper losses 0.014 per kilowatt-hour for 1,095 hours annually

Sizes of wire for main sections designated on each curve. Number 4 wire used in all cases for short sections on side streets

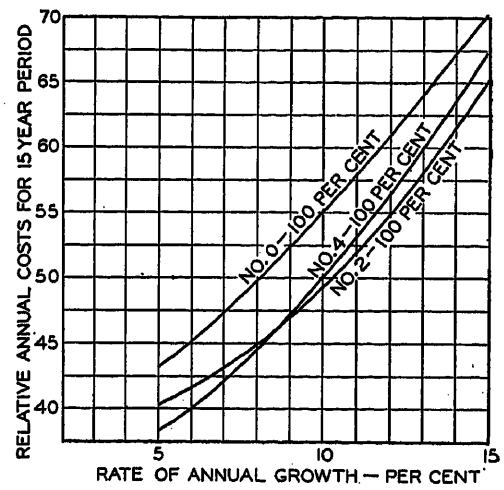

**Fig. 3. Total annual charges with varying yearly growth of load for straight line secondary distribution (company B)**

Initial loading on transformers 100 per cent, maximum loading approximately 150 per cent, and maximum secondary voltage drop of 3 per cent or less; initial load density of 20 kva per 1,000 feet. Total life of each layout 15 years with assumption for transformer life 30 years and wire 15 years

### Standard Wire Sizes

It will be noted that 4 of the companies use the even numbered wire sizes, while company *A* stocks and uses numbers 6, 3, 1/0, and 4/0. This naturally has some ef-

fect on the selection of the economical wire size as will be noted later, especially in the lower load densities.

### Type of Load

All of the studies apply to loads and economical designs in residential districts, but at the higher densities may apply equally well to light commercial districts, unless pole congestion and street conditions enter into the picture. Electric range load was studied by one company and is an important factor in some parts of the country. As ranges increase in number, the diversity and demand factors are expected to show a substantial improvement, and will be less of a problem than in the early stages of scattered and isolated installations.

### Load Growth Rates

Estimated load growth must necessarily include an element of speculation, although over a limited period of years, experience records show some fairly definite trends. Depressions have a serious effect not only on load growth records and charts but also result in greater caution in the selection of per cent load growth.

It should be noted that in residential districts growth in load may result from:

1. Increased usage
2. Additional customers
   - (*a*). Along existing secondary mains.
   - (*b*). Beyond but adjacent to existing mains.

These items do not follow the same trends in all districts and are the result of a large variety of conditions including changes in population, living and business conditions, new inventions, sales activities, and rates. Secondary design when intended to meet conditions over a long period of time must necessarily meet the composite or total result of all these factors.

Company *B* has gone into this matter of load growth very thoroughly by using 3 rates, 5, 10, and 15 per cent, respectively, as the basis for most of their charts. All of the companies have selected rates of load growth in connection with their computations of accumulated annual charges as indicated in table I.

Company *E* defines the rates of load growth *a*, *b*, and *c* as follows:

(*a*). Load 10 kw per 1,000 feet at beginning of first year
20 per cent load growth for first 5 years
7.5 per cent load growth for next 15 years

(*b*). Load 10 kw per 1,000 feet at beginning of first year
10 per cent load growth for first 5 years
5 per cent load growth for next 15 years

(*c*). Load 30 kw per 1,000 feet at beginning of first year
10 per cent annual growth to load density, 75 kw

### Load Density

Load density, both for static and increasing load conditions, has a very decided effect on the economics of secondary design. The density range has accordingly been covered from $7\frac{1}{2}$ to 110 kw per 1,000 feet of line, by the various companies as indicated in table I.

## Comparison of Results

Table II outlines the results of each of the studies, and the conclusions by the respective authors. These results represent the combined effect of economics, voltage regulation, flicker, load growth, load density, estimated life of conductors and transformers, copper costs, and available wire and transformer sizes. It is interesting to note 3 companies reporting flicker as one of the controlling factors in secondary system design at the low load densities, but voltage regulation and annual cost as the predominating factors at densities over 20 kw per 1,000 feet.

### Wire Sizes

Each of the companies reports results of a comprehensive study of costs to determine economical conductor sizes and 4 reports demonstrate in graphical form the

procedure followed in reaching their conclusions.

Both companies showing number 4 as the economical conductor size at low load densities, recognize the flicker limitations, but until complaints become numerous they seem to be willing to recommend the use of that size. This

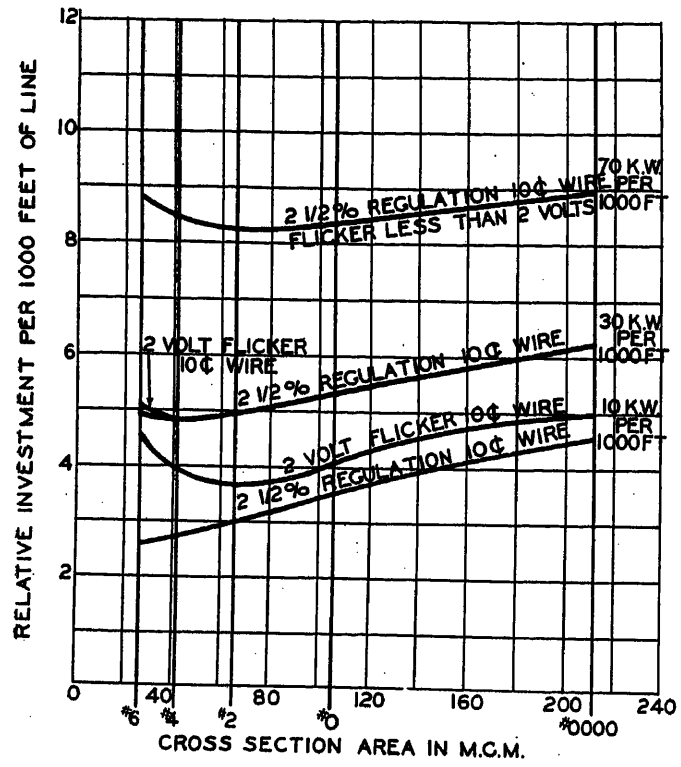

**Fig. 4. Variation in investment in secondary distribution with 2 volts allowable flicker for banked transformers and 4 volts for transformers not banked (company E)**

Assumptions include starting current of 115 volt motor, 20 amperes at 50 per cent power factor, voltage dip computed to customer's service pole, and wire price 10 cents. Motor location assumed to be midway between transformers

disadvantage may be offset to some extent by closer spacing of transformers. The other 3 companies report number 6 or number 4 conductors economical under 20 kw per 1,000 feet, but do not recommend them in order to avoid an early change to a larger size. Company *E* states the additional cost of number 2 is small and avoids flicker as well as the expensive operation of replacing secondary conductors. The choice of number 3 by company *A* is, of course, influenced considerably by the fact that numbers 4 and 2 are not stock sizes for them. This item of the respective reports shows unusual similarity of results. While conditions are recognized that may necessitate larger conductors for special applications, the consensus of engineering opinion favors these wire sizes over a large range of load densities.

Figures 2, 3, 4, 5, and 6 are typical graphs that were developed to demonstrate the relative economy of various conductor sizes. Company *C* did not include the charts used in reaching the conclusions stated in their report. Companies *B*, *D*, and *E* include an extensive series of charts for various conditions, but only typical charts are shown here.

### Transformer Sizes

On the question of transformer sizes the reports are not specific in their conclusions, except in the case of company *A*. This report illustrates by means of figure 7 the economy of 15-kva transformers up to 60 kw per 1,000 feet, 25-kva for 60 to 100, and 37½-kva above 100 kw per 1,000 feet for 2-way feed. Company *B* does not state any recommended size of transformer, but apparently uses the voltage drop and loading limitations to determine transformer sizes. Company *C* is very specific in stating the maximum size they consider most desirable, but do not indicate the extent of economical use for smaller sizes. Company *D* finds 15- and 25-kva transformers most economical and are explicit in recommending 37½-kva as the

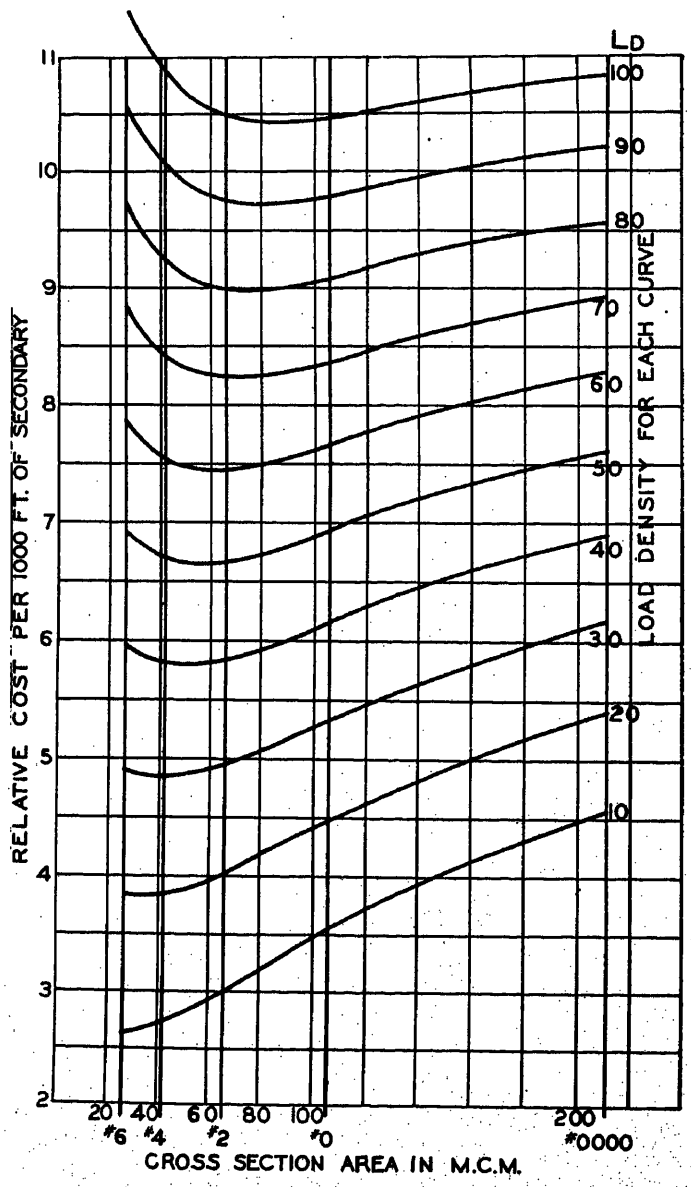

**Fig. 5. Relative total cost per 1,000 feet of secondaries and transformers, with wire at 10 cents per pound and capitalized losses included (company E)**

maximum size to be used. Figures 6*A* and 6*B* illustrate this conclusion. Company *E* finds 4 sizes, namely, 10-, 15-, 25-, and 37½-kva transformers, are needed to meet the various stages of load growth, stating however that 15- and 25-kva transformers are generally favored for average load densities. Figures 8*A* and 8*B* illustrate the relative economy of various transformer sizes as developed by company *E*.

### Transformer Loading

On the item of transformer loading there is an unusual variety of results and recommendations. Although companies *A*, *B*, and *D* are fairly uniform in their recommendations, company *E* seems to be extra conservative, but company *C* recommends an unusual percentage for initial loading at installation. This company assumes 5 per cent annual load growth which probably influences their conclusion.

These conclusions are based principally on the fact that peak loads on distribution transformers are expected during the winter season when ambient temperatures are low, whereas transformer ratings are based on temperature rise with 40-degree ambient. The increasing use of appliances may gradually change this condition and should therefore be checked from time to time. It should be noted also that this recommendation applies only to overhead transformer installations, and not to transformers in building or underground vaults, where the low ambient temperatures may not be available.

Generally, voltage regulation, rather than per cent overload, dictates the need for transformer replacement or respacing of transformers to reduce length of secondary mains. Increased transformer regulation is usually accompanied by a relatively high secondary drop hence both of these items will require attention, unless primary regulation is extremely favorable. The total voltage variation should be studied in each case, as well as the component voltage drops, to determine the best solution. It is evident therefore that the thermal capacity of distribution transformers is only part of the loading problem.

For small transformers, the annual transformation cost is materially reduced by overloading even up to 200 per cent. The exact effect on the life of the transformer under such conditions is not fully known, although

claimed by some to be satisfactory. There is no consensus of opinion on this point. Fortunately, on the 15-kva transformer and larger, the most economical loading ranges less than 150 per cent of name plate rating, hence there is less reason for risking failure on these larger units. In any event, the higher loadings may be expected to be troublesome and therefore result in increased operating and maintenance costs. The economics of transformer loading has been developed in a very interesting manner by company *D*, as shown in figures 6*A* and 6*B*.

It will be especially interesting to note the results of the various practices followed on transformer loading over a period of years. A further comparison of operating experiences will be desirable at a later date.

## Transformer Spacing

Transformer spacing is largely determined by load density and secondary voltage drop, especially after the selection of the economical wire size has been made. Companies *B* and *C* do not state their findings on this point. While companies *A*, *D*, and *E* have developed this item very thoroughly, the spacings listed represent preferred distances between transformers under ideal pole conditions and uniform load density. Experience indicates that it is well to favor these spacings, but actual field conditions and existing facilities will frequently change the secondary design including the transformer spacing. Company *E* illustrates by means of figures 8*A* and 8*B* the economics of transformer spacing. The limits for 2½ per cent voltage drop and 4 per cent flicker for radial secondaries are shown.

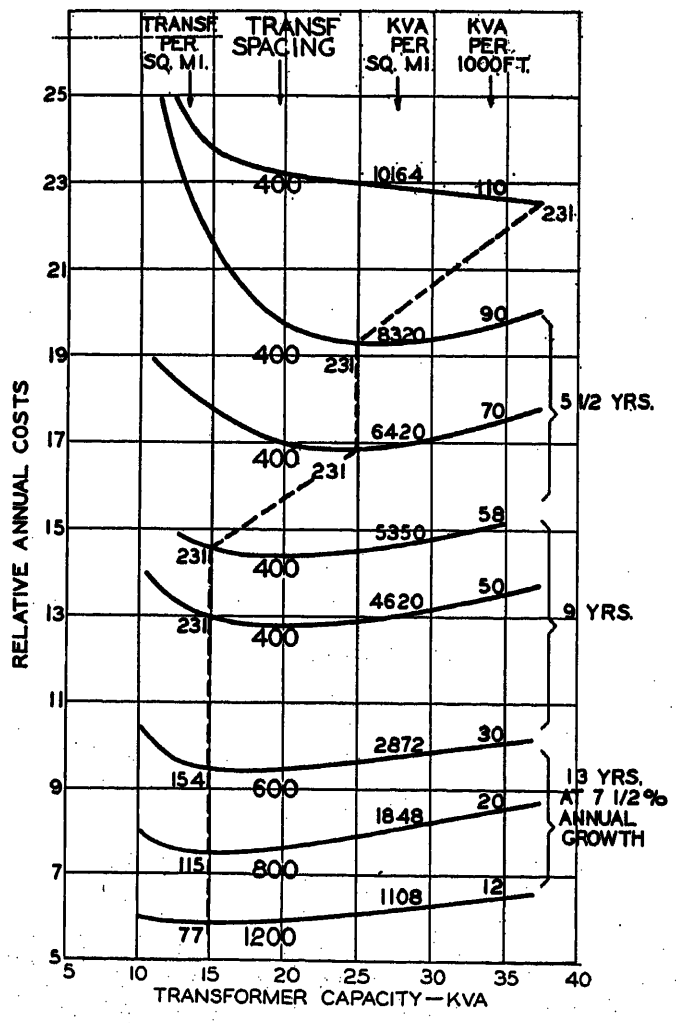

**Fig. 7. Relative annual cost of transformers and secondaries for various transformer sizes, number 3 secondary conductors, pole spacing 100 feet, and transformer and secondary regulation approximately 4.5 per cent (company A)**

### Table III—Transformer Costs in Relative Units

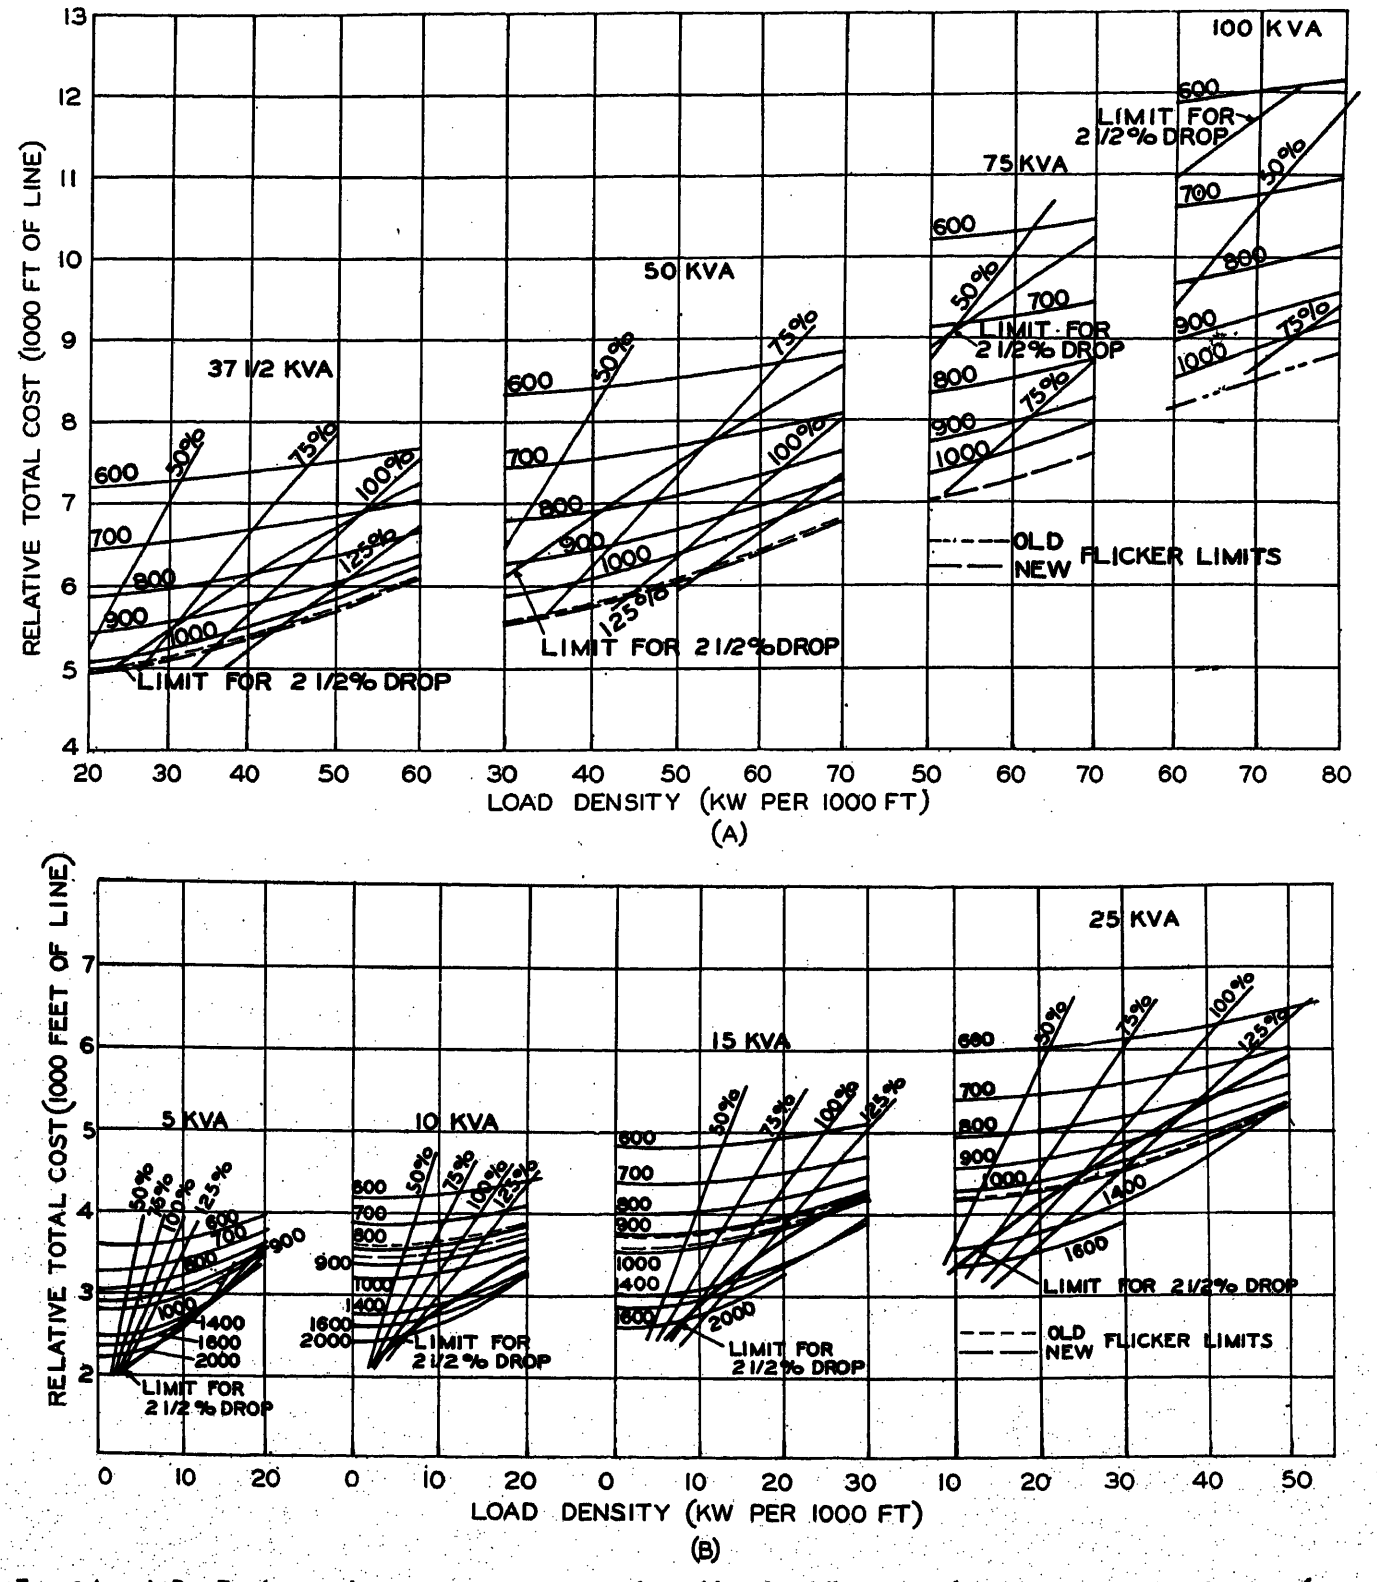
| Total net cost after applying credit for depreciation reserve (not compounded) less retirement cost | | 108 | | | 112 | | 111 (*A*-*D*) |



* Transformer annual cost expressed in per cent of total net cost for 20 years using a 15-kva (column 3).
† The change to a 15-kva transformer was made at this time.
‡ The depreciation reserve is included as a part of the annual cost, therefore, any part not used for retirement costs may be applied as a credit to determine total net cost.

## Load Growth

Various methods of handling load growth have been carefully studied to obtain the lowest total cost over a long period of years. This has been done by studying the accumulated annual costs for a number of possible methods. The method that involves the least retirements is usually most economical.

The subdivision method including the installation of additional or intermediate transformers is used by all the reporting companies but is especially favored by com-

(*Concluded on page 189*)

# Contact Drop and Wear of Sliding Contacts

By R. M. BAKER
ASSOCIATE AIEE

G. W. HEWITT
Membership Application Pending

**The results of a series of experiments, in which the processes of contact voltage drop and ring wear in sliding contacts are demonstrated by means of a direct method, are presented in this paper. The results show that the wear of metal-graphite brushes and the rings upon which they operate can be reduced if they be operated in an oxygen-free gas instead of air.**

THE relatively small amount of accurate knowledge gained through the enormous amount of effort expended in the study of sliding contacts is evidence enough of the complicity of the processes involved. This paper is intended to be only another step forward toward the ultimate goal of a perfect understanding. Each such step makes it just that much easier for the design and operating engineer to analyze and solve those practical problems with which he is continually confronted. It is felt that the experiments described represent a real advance in our understanding of contact drop and wear of sliding contacts. In order to conserve space and eliminate repetition, certain concepts developed in earlier published works will be used without explanation, and the reader not familiar with these concepts is referred to the original publications.[1,2,3,4] A general bibliography also is included at the end of this paper.

## Contact Resistance

The fact that the contact between a carbon brush and a copper slip-ring offers a high resistance to the flow of small currents has been attributed to the insulating effect of the oxide film which forms on the surface of the ring. Further, it is believed that increasing the current through the contact breaks down this high resistance film over certain areas, thus allowing the brush to make better contact with the metal of the ring and in this way lower the contact resistance.

This concept has been fairly well established[3] by experiments which show that the resistance of the contact between a carbon brush and a ring on which no oxide can form (a gold or carbon ring) is independent of current and remains low even for currents as low as 0.001 ampere. Although these experiments are convincing it seemed desirable to illustrate the correctness of the assumptions by some more direct method, and this has been accomplished by a special test arrangement which will be described below.

The apparatus used is shown in figure 1. It consisted of copper rings 13 inches in diameter driven by 2 motors; one a d-c motor and the other a synchronous motor connected in tandem. With such an arrangement it was possible to drive the rings at synchronous speed (1,800 rpm) or at any other speed differing slightly from synchronous speed. Each ring carried only one brush ($^3/_8$ inch thick and $^3/_4$ inch wide) of a soft electrographitic grade. Since the rings were electrically connected, the current flow at any instant was from one brush into its ring and from the other ring out into its brush. All tests were made with a resistance in series with the contacts and since the supply voltage was 40 volts, 60 cycle alternating, the current through the contacts was essentially sinusoidal and in phase with the applied voltage. The effective value of brush current was 12 amperes (42.8 amperes per square inch). The brush current was supplied from the same circuit which supplied the synchronous driving motor, thus insuring synchronism between the rotation of of the rings and the current supplied to the brushes. A stroboscopic lamp was used to bring the rings into synchronism always with a definite phase relation to the brush current. This lamp was also used when it was desired to let the rings slip one or more revolutions before being thrown back into synchronism again. When it was desired to operate the rings nonsynchronously, the synchronous motor was disconnected from the line and the rings were driven by the d-c motor. It now will be shown how this apparatus was used to illustrate the part played by oxide films in determining contact resistance.

With the rings running synchronously (1,800 rpm) it is obvious that the 60-cycle current through the brushes became zero 4 times each revolution of the rings. As the positions of current zero occurred at the same points on the ring surface each revolution, there were 4 sections of the ring surface which were never called upon to carry current. (This is not strictly true because of the finite brush width but the discrepancy is of small consequence.) Other points of the ring surface were called upon once each revolution to carry some value of current between zero and the maximum current through the brushes (17 amperes or 60.5 amperes per square inch), and it is especially important to observe that the same section of the ring surface was subjected to exactly the same value of current each time it passed under a brush. The condition can be pictured best perhaps by thinking of a standing wave of current around the ring. One quarter of the ring surface carried all values of positive current, the next quarter all values of negative current, and so on around the ring.

If the oxide film on the ring is responsible for the commonly observed large variation of contact resistance with

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted November 11, 1936; released for publication November 20, 1936.

R. M. BAKER and G. W. HEWITT are both research engineers for the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

1. For all numbered references, see list at end of paper.

current, it would be expected that the film on the ring surface near each of the 4 points of zero current might have a very high resistance, for it is never called upon to carry heavy current and therefore does not become broken down. Thus, it would be expected that with a sinusoidal current passing through the brushes, the variation of contact drop would be represented by a flat topped wave. That is, one would expect a relation between current and voltage similar to that obtained in the static characteristic. To what extent this prediction is fulfilled by experiment is shown by the oscillograms of figure 2, all of which were taken with the rings running synchronously.

Figure 2*a* shows the current through the contacts and the voltage drop in each contact just after the ring surfaces had been cleaned with very fine alundum cloth. It will be seen that the contact drop was low and almost sinusoidal. The oxide film was still so thin that it was not appreciably affecting the contact resistance anywhere around the ring.

The oscillogram shown in the figure 2*b* was taken about $1^1/_2$ hours later and it can be seen that the curves of contact drop were beginning to flatten somewhat. The oxide film was forming on the ring surface and was increasing the contact resistance more in the regions of low current than in the regions of high current.

The oscillogram of figure 2*c* was taken after the rings had operated synchronously for several days. The oxide film was fully formed and the curves of contact drop had become quite flat, especially over those sections of the ring where the current flowed from the ring to the brush. The resistance of the contact near current zero is very high but drops off rapidly at first and then more gradually until it reaches a minimum at the point of maximum current.

One might ask at this point what happens if the rings are not running in exact synchronism. In this case, every section of the ring surface is called upon to carry all possible values of current from zero to the maximum brush current. Thus, all sections of the film on the ring surface are broken down to the same extent and all offer the same resistance to the flow of current. If a sinusoidal wave of current is forced through the contacts, it would be expected that the curves of contact drop also would be essentially sinusoidal. An oscillogram taken after the rings had run for some time out of synchronism is shown in figure 3*a*.

It is especially interesting and instructive to compare the contact drop curves of figure 3*a* with those of figure 2*c*. In both cases the brushes carried the same value of alternating current, so it is fair to assume that the condition of the brush face was the same in both cases. It follows, therefore, that the large variation of contact resistance with current during synchronous operation is due to a condition on the ring surface rather than to some property of the brush face. This is an especially important conclusion for it follows that the same must be true in general for all sliding contacts which show a large change in contact resistance with current.

To demonstrate this fact in another way, a separate experiment was made. After the rings had been running synchronously for several days with alternating current in the brushes, the brush current supply was switched off and replaced by a dry cell in series with a 6-ohm resistor and an oscillograph element as shown by the diagram of figure 4. The oscillogram, figure 4*a*, was taken as soon as possible after the change was made. The peaked current record shows that each time the brushes passed over a part of the ring surfaces which previously carried low current, the current through the oscillograph element decreased. This can be interpreted to mean only that the condition of the ring surface over these parts was such as to produce a high contact resistance. Thus one sees that it was possible to set up a standing wave of resistance around the ring, during synchronous operation, perma-

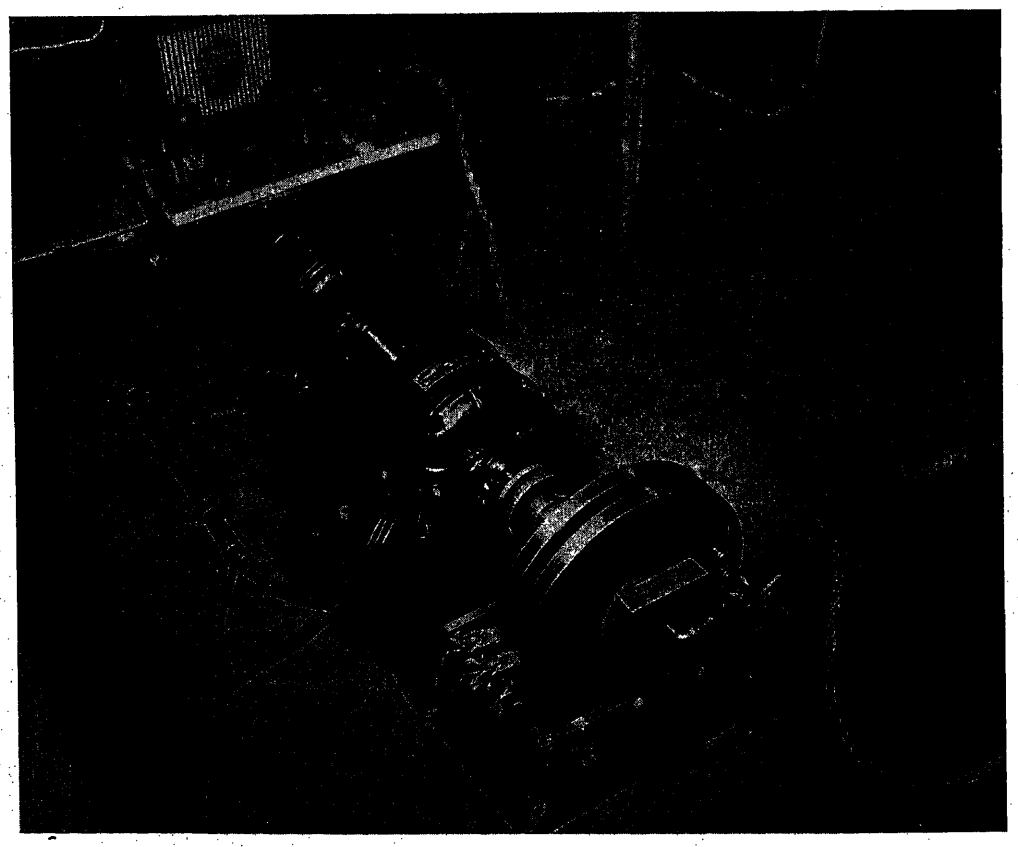

**Fig. 1. Test equipment used for studying brush performance during synchronous and asynchronous operation**

nent enough to be recorded or measured in a separate circuit some minutes after the a-c current supply had been disconnected from the brushes.

The record of figure 4*b* was taken after 10 minutes of operation with the dry cell connected in the brush circuit. In this time the oxide film on the ring surface had repaired considerably to produce an average increase in contact resistance. The high-resistance regions were gradually destroyed by the 1.5 volts applied across the contacts.

Figure 3*b* shows the current and contact drop curves with the rings stationary. The contact drop curves under this condition are practically sinusoidal, indicating constant resistance in the contact. The peculiar breakdown phenomena observed on the one ring (upper record) probably occurred because the ring happened to come to rest in such a position that the contact between the brush and the ring was especially poor. Such a record is seldom obtained and is included only as an oddity.

If one were to plot a curve between current and contact drop from the curves of figure 2*c*, the result would

(*b*)—Taken after operation of 1½ hours
(*c*)—Taken after operation of several days

look very much like the static volt-ampere characteristic commonly taken by the tedious step-by-step method. In fact this might be a satisfactory and easy method of obtaining a static volt-ampere characteristic on a brush grade. It is in effect a method of operating a number of rings simultaneously with different currents and observing in rapid succession the contact drop in equilibrium with each value of current. The brushes are actually carrying alternating current but the individual sections of the ring surface have no way of detecting this unless the nature of the brush face is influenced by the current it carries. There is undoubtedly a difference in the polish of the brush face with different currents flowing but experiments indicate that this effect is small in comparison to that produced by the conditions on the ring surface.

A brush which is hard, or one which contains enough abrasive to prevent the formation of a uniform oxide film on the ring surface, will not build up such a high contact resistance at the very low current densities as will a soft nonabrasive brush such as used in the investigation described above. Neither will a hard abrasive brush produce contact drop curves with such sharp corners as those of figure 2*c*.

Previous experiments[3] have indicated that the breakdown of the oxide film and the resulting decrease in contact resistance occurs almost instantaneously when a high current is forced through the contact. It was expected therefore that allowing the rings to slip one revolution following synchronous operation before pulling them back into synchronism again would subject all sections of the ring surface to high current and make the surface uniformly conducting all around the ring. However, contrary to expectations, a record of contact drop taken immediately after the rings had slipped one revolution and were running synchronously again, showed curves

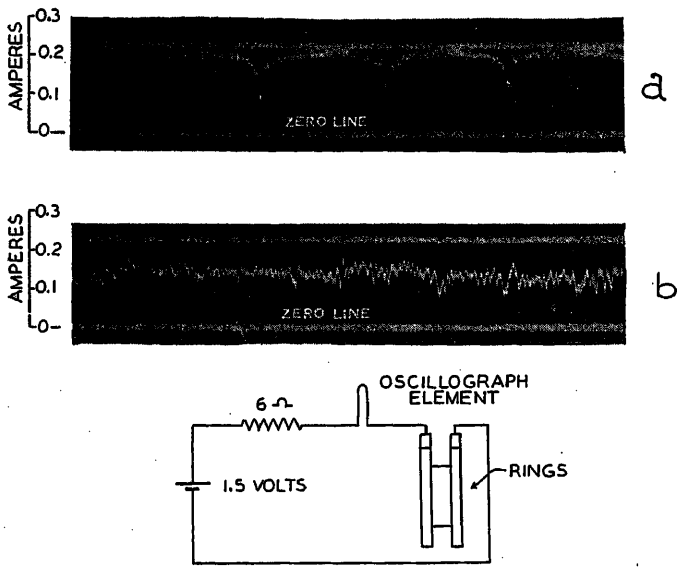

**Fig. 4. Distribution of film resistance around periphery of ring**

of contact drop almost identical with those of figure 2*c*. Only by allowing the rings to slip 10 revolutions (50 seconds nonsynchronous operation), could rounded contact drop curves similar to those of figure 3*a* be obtained. No attempt will be made at present to explain the unexpected results. It was necessary to operate the rings synchronously for half an hour or more to repair the damage done to the film during the 50 seconds of nonsynchronous operation and to obtain again contact drop curves similar to those of figure 2*c*.

## Ring Wear

The track produced on the surface of a copper ring by a carbon or graphite brush is definitely characteristic of the direction of current flow through the contact. If the current flows from the ring to the brush, the track has a light color and may even be bright and show signs of threading. If the current flows from the brush to the ring, the track is dull and in some cases seems to be covered with a thin film of carbon. These effects are generally observed on rings operated with direct current but it was discovered in the present investigation that they may be observed also with alternating current in the brushes. It will be recalled from the early part of this paper that during synchronous operation of the rings, certain parts of the ring surface always experienced current flow from the ring to the brush. These parts showed the typical brush track for this direction of current flow. Other parts of the ring surface always experienced current flow in the opposite direction and showed the characteristic track for that direction of current flow. The contrast was so sharp that one could determine by visual observation of the ring surface, the exact point at which the direction of current flow reversed.

This observation is of considerable importance for it establishes the fact that the nature of the track produced at one polarity or the other is effected by the direction of current flow across the contact (an instantaneous process) rather than by some condition of the brush face, such as fine copper picking or the loosening of carbon particles as is sometimes supposed.

Another interesting observation connected with the difference in ring surface over different parts of the ring after synchronous operation, was the occasional appearance of burned spots or brush photographs on the ring surface. These generally occurred only with a hard brush grade which did not ride well on the ring surface. This is such a common phenomenon that it would not be worth mentioning except for the fact that these spots always occurred at points of zero current on the slip-ring surface. This is not so surprising when it is remembered that just at the point of zero current there is an abrupt change in the

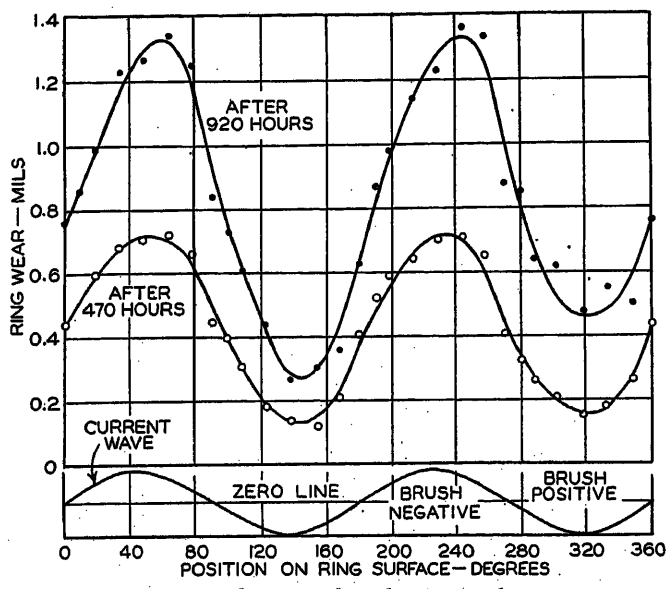

**Fig. 5. Curves showing that the wear of rings is in synchronism with the brush current**

"Brush negative" indicates current flow from ring to brush
"Brush positive" indicates current flow from brush to ring

appearance of the ring surface. This abrupt change in appearance is probably associated with a change in friction which causes the brush to dance just a little and burn the ring at this point.

The appearance of brush tracks, which already has been discussed at some length, is closely related to ring wear. The negative ring (current flow from ring to brush), which usually exhibits a bright clean-looking track, is the one which always shows rapid wear. The positive ring on the contrary usually shows a dull track and very much less wear. This is true when the rings operate with either graphite or metal-graphite brushes, although the wear is usually much more rapid with metal-graphite brushes than with graphite brushes.

The synchronous ring arrangement used throughout this set of experiments seemed likely to show some interesting facts regarding ring wear if enough wear could be produced to be measurable at all points around the ring. Since all values of current and both polarities would

be represented on the one ring surface, a single set of wear measurements should give a fairly complete story.

A test was made using metal-graphite brushes containing about 80 per cent of copper by weight. The brushes carried 35 amperes of 60-cycle alternating current. The rings ran synchronously at 1,800 rpm throughout the test.

The rings were measured at the beginning of the test, at the end of 470 hours, and again at the end of 920 hours. A special device was used to measure the ring wear with an accuracy of plus or minus 0.00002 inch.

The results of the test are shown in figure 5. The current wave shows the distribution of current around the ring surface, or more exactly, the current carried by each section of the ring surface as this section passed under the brush. The wear curves indicate the ring wear, measured at various angular positions around the ring. These curves show at once that the total wear of the ring surface is made up of 2 components, the one constant around the ring and the other alternating and almost exactly in phase with the distribution of current around the ring. Apparently the constant component of ring wear is caused by mechanical abrasion of the ring surface by the brush, while the alternating component is caused by the transportation of material across the contact by the current. The fact that the material transferred is roughly proportional to the current, indicates that the transfer might occur by an electrolytic process. Whether or not this is true is not definitely known. It is interesting however, to calculate what current, flowing electrolytically in parallel with the main brush current, would be required to transfer the amount of material indicated by the wear curves of figure 5. A simple calculation shows that if only 0.004 per cent of the total brush current flowed across the contact by electrolytic conduction, the material transfer would be sufficient to explain the wear curves obtained.

The results of this experiment show that a large percentage of the ring wear commonly observed with direct current in the brushes is due to an instantaneous process associated with the transfer of current across the contact. The curves of figure 5 show greater ring wear at the points of zero current than at the points of maximum current where the direction of flow is from the brush to the ring. Apparently metal is in some way picked up from one part of the ring surface and put down at another to bring about this result.

The maximum ring wear occurs on those sections of the ring where the current flows from the ring to the brush; the minimum wear occurs on those sections where the current flows from the brush to the ring. These observations agree with the fact that in direct current operation, the wear of the negative ring is much greater than that of the positive ring. As shown by figure 5, the ratio of maximum wear to minimum wear on the synchronous rings was 5.4 after 470 hours operation and 5.7 after 920 hours operation. This leads one to believe that if the rings had been operated with direct current in the brushes, the wear of the negative ring would have been about 5.5 times as rapid as that of the positive ring.

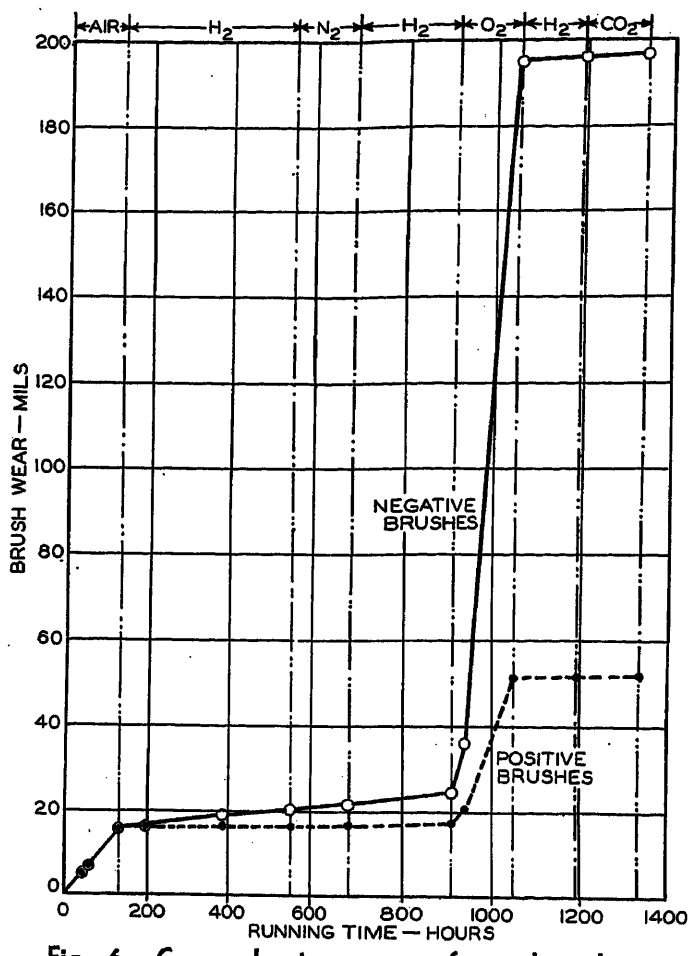

**Fig. 6. Curves showing wear of metal-graphite brushes in various gases**

However other factors which cannot be discussed here would probably make this ratio considerably greater if the test operated 1,000 hours or more.

## Brush Wear in Various Gases

Previous experiments[4] have shown that carbon brushes wear very slowly when operating in an atmosphere of hydrogen. This observation led to the belief that oxygen in the atmosphere around the brushes was responsible for the brush wear commonly observed in service and that this wear could be greatly reduced if the brushes were surrounded by some oxygen-free atmosphere. The greater demand for a longer life of metal-graphite brushes led to the choosing of this type of brush for a special test which will be described below.

Copper slip rings and a driving motor were inclosed in a gastight housing which could be filled with any gas desired. The rings were 9.5 inches in diameter and operated at a speed of 1,750 rpm. Each ring carried 2 metal-graphite brushes, $1/2$ inch wide by $1\,3/4$ inches thick. The brushes operated on direct current, 160 amperes per ring (80 amperes per brush). The current flowed into one ring and out the other. The temperature of the gas inside the housing was about 55 degrees centigrade.

The results of a series of tests are shown in figure 6. These curves show brush wear plotted as a function of

running time, so the slope of the curves at any point is an indication of the rate of wear. The brushes and rings operated in room air, in hydrogen, in nitrogen, in hydrogen again, in oxygen, in dry hydrogen, and finally in dry carbon dioxide. This series of tests shows that the rate of brush wear for the particular brush grade tested is about 10 times as rapid in air as in any of the commercial oxygen-free gases. It also shows that the brush wear is more rapid in oxygen than in air. Most of the tests were made with commercially pure gases taken directly from the high pressure cylinders. Only in the last 2 tests (figure 6), one in hydrogen and one in carbon dioxide, were the gases especially dried. It will be noticed that the rate of wear is still further reduced by drying the gases.

It is important to make one more comparison in order to show that brush wear is greatly reduced by the removal of oxygen even when the brushes carry no current.

A test made in dry oxygen with no current in the brushes indicated a brush wear of 8 inches per year or a greater rate of wear than was observed in commercial oxygen with current flowing. This high wear was due apparently to the extreme dryness of the oxygen for when some moisture was purposely introduced, the coefficient of friction decreased about 50 per cent and the rate of wear became 2.8 inches per year. In dry carbon dioxide the rate of brush wear with current flowing (last test, figure 6) was only 0.028 inches per year. Since it is unlikely that the brush wear in carbon dioxide with no current flowing is any greater than the rate of brush wear with current flowing, it appears that the brush wear with no current in the brushes is about 100 times greater in oxygen, under the most favorable conditions, than it is in dry carbon dioxide.

The noticeable effect of moisture in reducing wear of the brushes during operation in oxygen is just opposite to the effect observed during operation in the oxygen-free gases. The evidence is that moisture is beneficial during oxygen operation and perhaps also during air operation, for it results in a decreased friction and a lower rate of brush wear. This is in line with field experience, where short brush life is often associated with low air humidity.

Although no actual measurements of ring wear were made, visual observation indicated that the ring wear during tests in oxygen-free gases was extremely low and that this wear was rapid (especially on the negative ring) when air or oxygen was introduced. This was also observed on another test in which graphite brushes operated on copper-alloy rings.

The brushes used to study brush wear in various gases contained 70 per cent copper and 30 per cent graphite by weight and were bonded with pitch. This specification is given because another grade bonded with bakelite showed less improvement with the introduction of an oxygen-free gas.

The results of the experiments described in this paper have been interpreted in so far as it was consistent with the limitations of space and our present knowledge. For the most part the results agree well with the ideas and experimental evidence presented in previous works to which the reader was referred in the introduction.

# Watt-Hour Meter Bearings

By I. F. KINNARD
MEMBER AIEE

J. H. GOSS
ASSOCIATE AIEE

**Bearings for the moving element in watt-hour meters have received considerable study in recent years in order that maintenance might be reduced. The requirements for the bearing, the materials available and their characteristics, lubricants, and the various designs of bearings are discussed in this paper.**

A GREAT DEAL of interest has always been exhibited in watt-hour meter design by the users as well as the manufacturers, because the watt-hour meter is so vital a factor in the sale of electrical energy. The emphasis has gradually shifted from one part of the meter to another as each has been perfected in turn to a high degree, until within the last few years much attention has been focused on the subject of bearings. Interest in meter bearings has been accentuated due to the tendency to increase the length of periodic test intervals and the necessity of eliminating as much servicing and as many replacements as possible. There are so many factors involved and it is so difficult to obtain conclusive data, that it is not surprising that there has existed a divergence of opinion on the part of many who have studied the problem.

The purpose of this article is to analyze the many factors that bear upon the design and operation of watt-hour meter bearings and to attempt to consolidate and clarify fundamental information on this subject. In searching for a complete explanation and evaluation of the various factors and their relative importance, a large amount of work has been done. The results of much of this work will be covered in this article, and it is the hope of the authors that it will assist in making a more complete understanding of the subject possible.

## Historical Review

The groundwork of bearing design for electrical instruments and meters was, no doubt, laid by the designers of chronometers. For centuries prior to the birth of the electrical industry, builders of clocks and watches were faced with the problem of building rugged low-friction bearings to carry the weight of moving parts and to have long life. Much work had been done on the geometry of bearings as well as on the component parts to select the best combination of materials available.

With the advent of the electrical industry in the latter part of the 19th century, it was only natural that the builders of electrical instruments and meters turned to the watch industry as a guide in selecting materials and designs of bearings to carry the moving systems. A wide variety of bearings has been proposed and used in various instruments, meters, and measuring devices. Figure 1 shows a number that are, in general, applicable to watt-hour meters, but are also applicable to some forms of instruments. All of these arrangements can be resolved into either the pivot or the ball type, and for a theoretical consideration of the friction of the bearings the ball type and the pivot type lend themselves to the same analysis.

## Important Considerations in Bearing Design

There are 2 bearings that are of primary importance from the standpoint of design and operation of a watt-hour meter. These are the top and bottom bearings of the moving element. The lower bearing carries the weight and the top bearing maintains the vertical alignment of the shaft.

For clarity of treatment this discussion will be divided as follows:

*A.* Mechanical design
*B.* Materials
*C.* Lubrication

Each of these factors will be examined in turn in relation to the lower bearing, as it is really the essence of successful long time operation of a watt-hour meter. A brief discussion of the top bearing will follow since it also performs an important function.

## Mechanical Design

### Friction Torque

The primary consideration in the design of a watt-hour meter lower bearing is the reduction of friction to a minimum value that can be maintained. If the weight of the moving system is designated by $W$ and the coefficient of friction by $\mu$, then from the definition of the coefficient of friction the frictional force of the bearing will be proportional to $W\mu$. It has been shown that the friction torque $T_f$ is proportional to $WR\mu$, where $R$ is the lever arm at which the force acts.[28] If it were possible to reduce $R$ to zero which could be done if a true point contact could be provided, then the friction torque would be zero and there would be no friction effect. Unfortunately, this would require the bearing material to carry or sustain an infinite stress which is impossible. All materials deform under load until the area in contact is sufficient to carry the load. The contact area then has an equivalent $R$ that determines the friction torque ($T_f$) of the bearing. As $R$ cannot be reduced to zero, the next best

A paper recommended for publication by the AIEE committee on instruments and measurements. Manuscript submitted October 30, 1936; released for publication November 28, 1936.

I. F. Kinnard is executive engineer in charge of engineering department, and J. H. Goss is head of laboratory, General Electric Company, West Lynn works, Lynn, Mass.

28. For all numbered references see list at end of paper.

thing is to make it as small as possible which can be done by carrying the load of the moving element on a pivot point of small radius or ball of small radius in contact with a flat plate or a cupped jewel of a larger radius of curvature than the ball or pivot. As pointed out in a previous article[1] due to wear the initial condition cannot be maintained throughout the useful life of a watt-hour meter bearing. The friction torque is made low so that an increase of several times the initial value will not materially affect the meter calibration. Figure 2 shows the initial error due to friction that must be compensated for, as a function of the radius of the pivot point. The values shown in figure 2 have been confirmed experimentally both by V. Stott[2] and by the authors.

### Rate of Wear and Shock Resistance

There are 2 important considerations aside from the fact that the geometrical requirement is that the contact area should be as small as possible for minimum initial friction. One of these is that the rate of increase of this area should be reduced to a minimum, and the other is that the bearing should have sufficient strength to withstand installation abuse and service abuse.

Figure 3 shows the manner in which the friction torque varies as a function of pivot radius for a given decrease in pivot length resulting from wear. The friction increases rapidly with an increase in the radius. This curve was drawn assuming the pivot in contact with a flat plate. V. Stott[2] has shown that little error is introduced by this assumption if the area in contact is small. The method of computing the friction torque as a percentage of the watt-hour meter load torque is given in a previous article.[1]

Figure 4 shows the relative shock resistance as a function of the radius of curvature for glass-hard steel pivots running in sapphire jewels. It is evident from a study of this curve that the shock resistance of a pivot falls off rapidly below 0.0175-inch radius and that in order to reduce impact failures under severe conditions to a minimum, a pivot should not have a radius below this value. The method of test will be discussed later in relation to the required shock resistance of bearing material.

A further treatment of the mechanical design of the types of bearings shown in figure 1 will be deferred until after materials and the subject of lubrication have been considered.

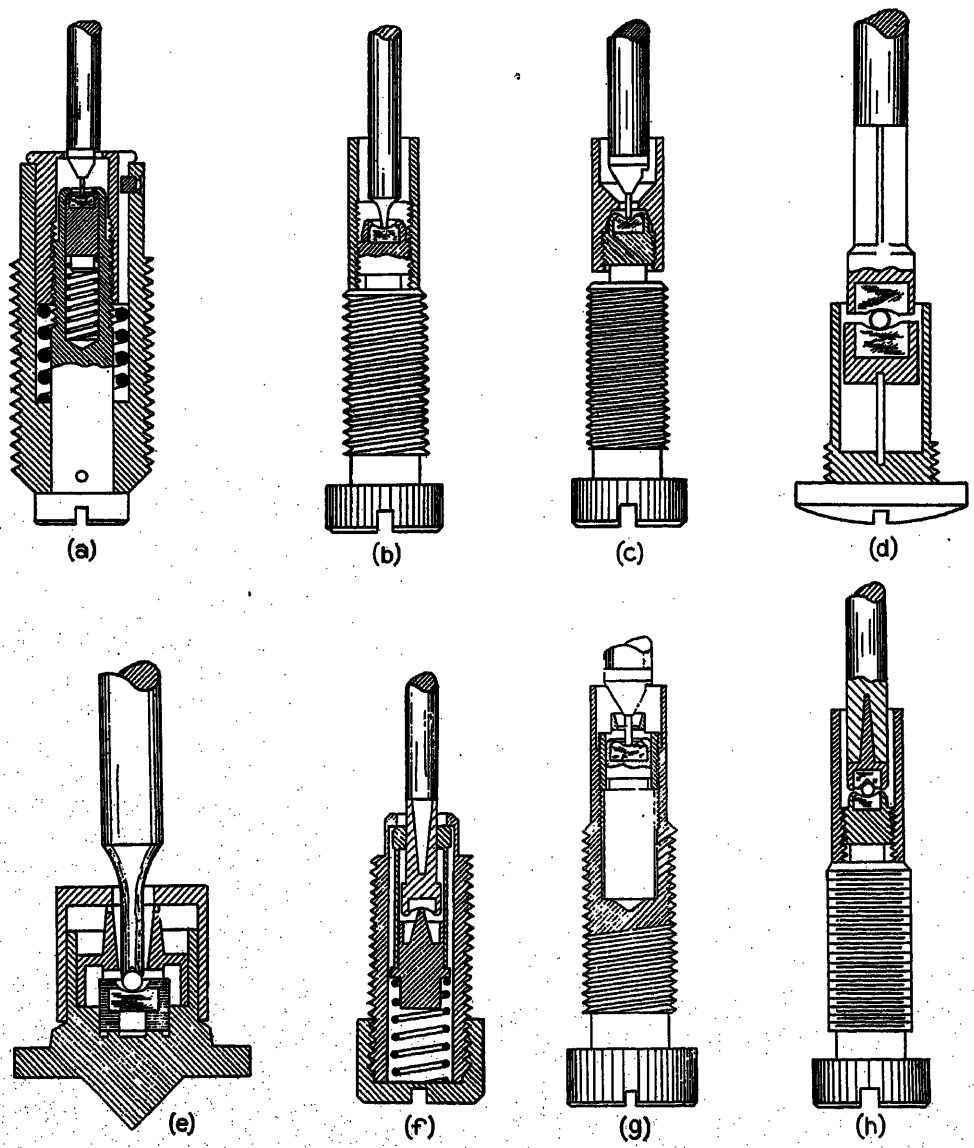

Fig. 1. Typical bearings for watt-hour meters

## Materials

The material for any of the bearing designs shown in figure 1 must meet practically the same requirements and as the geometry of a watt-hour meter pivot is limited to a ball or spherical point, improved materials offer the best possibilities in developing bearings with increased life.

### Jewel Material

The material for the jewel cup should have the following characteristics:

1. Hardness—That gives high resistance to wear.
2. Toughness—That will protect the surface against shattering under shock.
3. Low coefficient of friction—Should have a low friction coefficient in contact with the pivot or ball.
4. Workability—Should be such that the jewel cup can be produced at a cost which will not be prohibitive.

It is extremely difficult to give quantitative data of the above requirements for a given material, due to the lack of an accurate method of measuring perform-

ance. In the past hardness has been measured in accordance with the Moh scale which is based on the ability of one material to scratch another. . This scale makes no allowance for the toughness of the material which is also a factor in wear resistance just as hardness is a factor in protecting the surface against shattering.

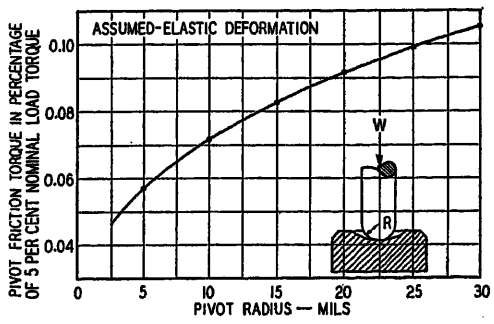

**Fig. 2. Calculated friction torque as a function of pivot radius**

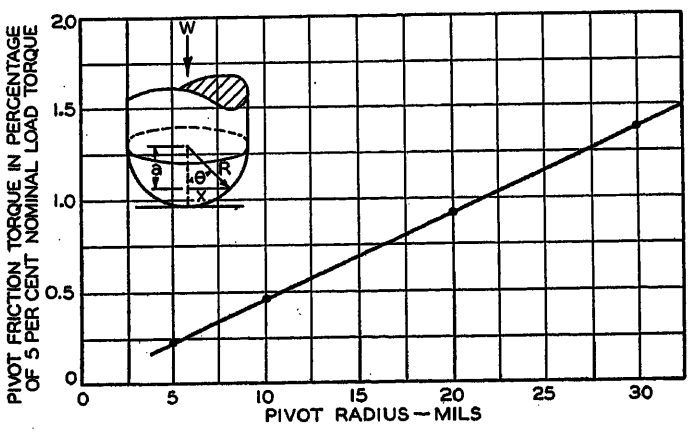
Recently work has been done[3] and results published that have given an illuminating picture of the Moh scale when applied to bearing material. Instead of the scratch hardness, the ability of a given material to resist abrasion was taken as a measure of its hardness. This is precisely the thing of interest in a bearing material. The Moh scale and the new wear hardness scale are plotted in figure 5.

It is evident from this curve that the Moh scale of hardness gives erroneous results when used as a basis for



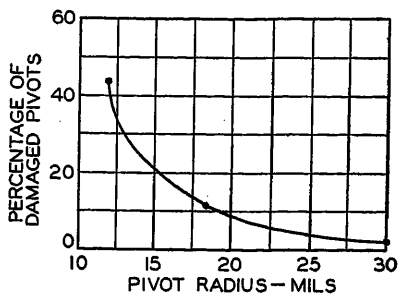


**Fig. 3. Friction torque as a function of radius for a given decrease in length of the pivot due to wear**

Decrease in length is $(R - a)$

judging the relative wear resistance of materials. The new scale based on abrasion resistance gives a much better indication of the relative performances of the materials as is borne out by the results obtained in service with diamond jewels for severe applications as compared with sapphire jewels. The Moh scale if assumed to be linear would indicate a small difference between sapphire and diamond (sapphire 9, diamond 10), while on the scale of wear hardness the diamond is superior in the ratio of over 4 to 1.

**Fig. 4. Curve showing the variation of pivot shock resistance as a function of pivot radius**

Data obtained from short-circuit test using high carbon steel pivots and natural sapphire jewels

Diamond, according to figure 5, should be the most desirable material to satisfy specification 1, and if it is assumed that wear hardness is also a measure of toughness diamond is the most desirable from specification 2. Both diamond and sapphire take a good polish and satisfy specification 3. It is, however, difficult to grind a cup into diamond, and the cost of the raw material plus the high cost of working it into cups makes the cost prohibitive except for meters yielding a large revenue.

Silicon carbide and boron carbide are seen to be between diamond and sapphire on the wear hardness scale. Jewel cups made from these materials are not commercially available although much work has been done to investigate their properties. Present practice, the outgrowth of long experience, shows that sapphire approaches nearer to the perfect material as defined by the specifications than any other material and is the best available.

### Pivot or Ball Material

Glass-hard steel approximately 1.25 per cent carbon, running in a polished sapphire jewel cup, has from the beginning of meter and instrument manufacture been the most widely used combination of materials. A large amount of operating data has been obtained on meters operating with bearings of these materials both with and without lubrication. Based on these data certain specifications have been drawn up as desirable for a pivot material.

1. Non-corrosive—Material should not corrode under operating conditions.

2. Non-abrasive—Products of wear should be non-abrasive. (Most important when pivot operates on a sapphire without lubrication.)

3. Wear-resistive—Should have a low rate of normal wear. (To be considered with and without lubrication.)

4. Shock-resistive—Should be capable of resisting high impact loads caused by rough handling of the watt-hour meter during transportation and installation and impact loads imposed by short circuits while in service.

5. Low coefficient of friction—Initial friction should be low in combination with sapphire.

6. Workable—Should be capable of being produced in the form of pivots and balls at a reasonable price.

Table I shows some of the more promising pivot materials rated in accordance with the above specifications.

To check materials to this set of specifications, one test was to run the bearings in meters at an accelerated speed without lubrication to see how well they stood up

**Table I—Properties of Pivot Materials**

| Material | Corrosive | Non-abrasive | Wear-Resistive | Shock-Resistive | Workable | Low Coefficient of Friction | |
|---|---|---|---|---|---|---|---|
| Steel (1.25 per cent carbon) | Yes. | Poor | Good. | Good. | Satisfactory | Satisfactory | |
| Nitralloy | Yes. | Poor | Good. | Good. | Satisfactory | Satisfactory | |
| Chromium plated steel | No. | Poor | Good. | Good. | Probably satisfactory. | Satisfactory. | Initially wears well with or without lubrication but plate wears off |
| Cyanided stainless steel (18–8) | No. | Poor | Good. | Fair. | Probably satisfactory. | Satisfactory | |
| Tantalum | No. | Fair. | Fair. | Poor. | Probably satisfactory. | Satisfactory. | Hard outer shell breaks down under impact |
| Beryllium copper | No. | Poor | Fair. | Poor. | Satisfactory | Satisfactory | |
| Beryllium nickel | No. | Fair. | Fair. | Fair. | Satisfactory | Satisfactory | |
| Cobalt-tungsten | No. | Good. | Good. | Good. | Satisfactory | Satisfactory | |

in comparison with high-carbon steel. The high-carbon steel and even alloys with a small percentage of iron were found to form appreciable quantities of iron oxide which, due to its highly abrasive character, rapidly wore away the pivot point. It is interesting to note that a bearing that is adequately lubricated with the proper lubricant does not form this oxide. The formation of the iron oxide has been investigated by Shotter[6] and has been shown to be dependent upon the presence of a certain amount of water vapor which may in a measure serve to explain why a bearing that is properly lubricated does not form the abrasive oxide.

In table I the material approaching nearest to the requirements is an alloy of cobalt and tungsten (75 per cent cobalt and 25 per cent tungsten). This alloy is the development of Sykes[4,5] who has applied it for wire-drawing dies to resist the high temperatures necessary for the drawing of tungsten wire for lamp filaments. The material belongs to the group of precipitation-hardening alloys. Figure 6 shows a typical hardening curve for actual pivot samples.

## Accelerated Tests of Cobalt-Tungsten

It is very valuable to be able to check a material against the specifications in terms of values obtained by actual measurements. This can be done under stated conditions as there are several methods of obtaining data on watt-hour meter bearings.[1] In the preparation of the results for table I and figure 7, an accelerated test was used.

Figure 7 shows the results of the test run to compare the wear rate of the cobalt-tungsten material with that of high-carbon steel and to check the abrasion characteristics of the wear products in accordance with specification 2. The worn area on the end of the pivot is approximately circular in shape and its diameter can be measured readily by means of a microscope with a calibrated eye-piece. From time to time as the test progressed the pivots were removed and the diameter of the worn area was measured. These measurements as a function of revolutions of the watt-hour meters are shown in figure 7.

Without lubrication the cobalt-tungsten pivots averaged $34 \times 10^6$ revolutions for a worn area diameter of 0.003 inch as compared to $12 \times 10^6$ for high carbon steel. This shows a ratio of 2.8 to 1 for cobalt-tungsten over steel. The mean diameter of the worn area of the jewels run with the steel pivots and the jewels run with the cobalt-tungsten pivots were as shown in table II.

These results show definitely that the cobalt-tungsten material has a life well over twice that of steel when run without lubrication and that the jewel wear is approximately $1/8$ as much with cobalt-tungsten as with steel based on this test.

Figure 7 also shows the worn area of cobalt-tungsten in a well lubricated bearing tends to approach a limiting value and become stable. While it is difficult to measure the small amount of wear of the jewels with the 2 materials running in well lubricated bearings, the cobalt-tungsten definitely showed less wear on the jewels than did the steel pivots. Further tests made on a large number of watt-hour meters in actual service have confirmed the conclusions drawn from the accelerated test. For example, a field test in which 175 steel pivots and 153 cobalt-tungsten pivots operated with lubricated bearings for a one year

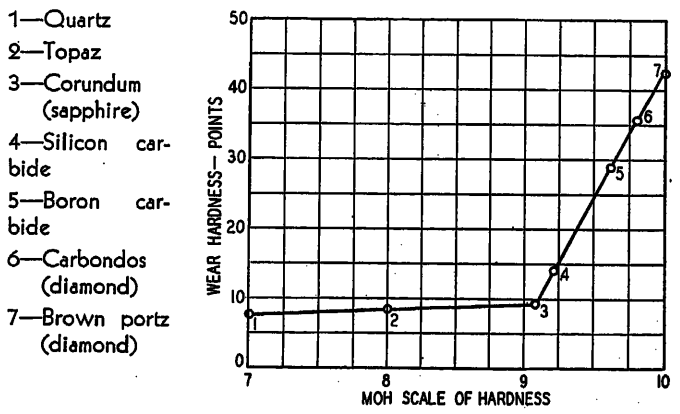

**Fig. 5. Curve showing relation between Moh hardness scale and wear hardness scale**

period showed an average jewel wear area diameter of 0.004 inch for cobalt-tungsten as compared to 0.0084 inch for steel.

## Shock Resistance of Pivot Materials

In order to check the shock resistance of different materials, 2 watt-hour meters rated at 5 amperes, 115 volts were connected in series with a 30-ampere fuse and the load side was short-circuited with a heavy knife switch. An oscillogram was taken to determine the point on the wave at which the switch was closed and the magnitude of the short-circuit current. It was found that a peak value of 1,500 amperes was obtained. Further tests showed that currents under 1,000 amperes were not suffi-

cient to crack jewels or damage the steel pivots used. The 1,500 ampere value was selected as a reasonable one to use as it represents a value that is likely to be obtained in service.

The disk is thrown upward when the short circuit is applied and springs between the damping magnets and the driving element so that energy is stored elastically in the deformed aluminum disk. When the short circuit is removed, the pivot is driven downward like an arrow from a bow and strikes a sharp impact blow upon the jewel.

Figure 8*a* shows the disk, damping magnet, and driving element in the normal position, and figure 8*b* shows the deformed disk under short-circuit conditions. An attempt was made to study the energy of the blow with which the jewel was struck by the pivot by replacing the sapphire jewel with a polished brass plug and observing the depth of the indentation made by the pivot.

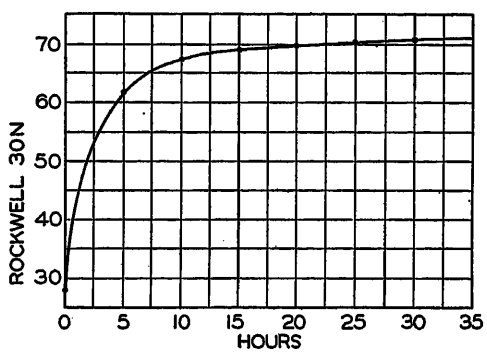

**Fig. 6. Age hardening of cobalt - tungsten pivot material at 650 degrees centigrade**

After one short circuit which was opened within 1/4 cycle after its occurrence, the brass plug showed *seven* indentations. This shows that a condition of oscillation existed after the release of the short circuit, resulting in a multiple hammering of the plug.

The data to plot the curve, shown in figure 4, were obtained with steel pivots and solidly mounted sapphire jewels using short circuits having a peak value of 1,500 amperes. These tests were made, as previously mentioned for the purpose of evaluating the effect of pivot radius on shock-resistance and show conclusively that shock-resistance increases very rapidly with increase in radius.

In making the tests to obtain the data for figure 4, 13 per cent of the jewels were damaged by steel pivots of 0.0185-inch radius. The tests were repeated using 0.0185-inch radius cobalt-tungsten pivots and no jewels were damaged. The cobalt-tungsten pivots are softer than steel pivots and in this test tended to flatten slightly, thereby reducing the stress on the jewel and preventing damage to the jewel surface. The extent of the flattening was not sufficient, however, to measurably increase the friction of the bearing.

## Lubrication

It was shown by Abbott and Goss[1] that the most successful operation of a pivot type bearing is obtained when the bearing is properly lubricated, but the provision of a good lubricant is not a simple matter. The requirements for a lubricant are exacting due to the fact that a small quantity put into the bearing at the time of installation is expected to last for periods up to 10 years. Based on experience and tests on watt-hour meter bearing lubricants over a period of years, the following empirical set of specifications has been developed to serve as a criterion for judging a lubricant for this application:

1. Low evaporation—The evaporation loss shall not exceed 20 per cent in a dry atmosphere at 75 degrees centigrade after 50 days. Free circulation of air shall be provided. The evaporation shall be tested in glass dishes approximately 2 inches in diameter and the depth of oil shall not exceed 1/8 inch or an equivalent ratio of area to volume shall be maintained.

2. Stable viscosity—The viscosity during the evaporation test shall not change more than 10 per cent and no gummy deposits or precipitates shall be formed.

3. Wide temperature range—The viscosity of the oil shall not affect the calibration of a standard watt-hour meter more than 0.10 per cent between +25 and −40 degrees centigrade. The test shall be made with 5 per cent nominal load on the watt-hour meter.

4. High chemical stability—The oxidation or acid forming properties of the oil shall be checked by the following method: 500 cubic-centimeters of oil shall be placed in a 1,000-cubic-centimeter glass beaker which also contains 40 inches of number 18 iron wire and 40 inches of number 18 copper wire. The beaker shall be placed in

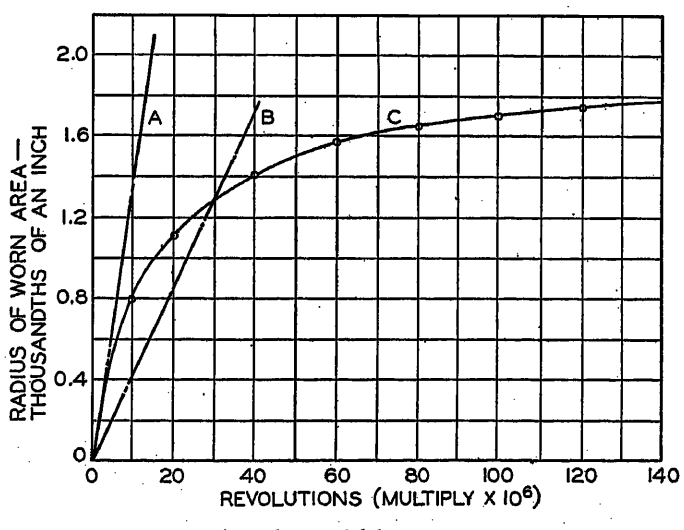

**Fig. 7. Accelerated life test wear curves**

*A*—Standard steel pivot without lubrication; 12 × $10^6$ revolutions for a worn area radius of 0.0015 inch

*B*—Cobalt-tungsten pivot without lubrication; 34 × $10^6$ revolutions for a worn area radius of 0.0015 inch

*C*—Cobalt-tungsten pivot with ideal lubrication

Pivot radius 0.0185 inch

**Table II—Wear in Pivot Material**

| Material | Number of Meters | Number of Revolutions | Mean Diameter of Worn Area, Inches |
|---|---|---|---|
| Steel (1.25 per cent carbon) | 4 | 62.9 × $10^6$ | 0.031 |
| Cobalt-tungsten | 4 | 63.8 × $10^6$ | 0.0113 |

a water bath at 75 degrees centigrade and an excess of free oxygen bubbled through the oil. The initial acidity shall not be over 0.50 per cent and at the end of 500 hours on this test it shall not exceed 1.0 per cent.

5. Low creepage—The oil should have low creepage tendencies.

6. Corrosion protection—The oil should not corrode steel or the other bearing materials used and should also afford good corrosion protection to the pivots.

Over 60 different oils were checked to these specifications during a recent investigation and table III gives the results of a few typical oils.

The literature contains an abundance of material on the properties of different mineral oils, fish oils, animal, and vegetable oils. This information is not, however, of particular value in selecting an oil or the components of an oil to meet the above set of specifications because of the fact that the evaporation requirement is particularly exacting when combined with the low temperature requirement. This subject has been treated by Holtz[7] for the mineral oils. The mineral oils in general are too volatile at the upper temperature (75 degrees centigrade) if they will meet the low temperature viscosity requirements, and too viscous at low temperatures if they will meet the evaporation requirement. There are exceptions, however, as shown by mineral oil *E* in table III.

The fish oil *F* has the unusual property of combining low evaporation with good low temperature performance and meets the specifications very well. The acidity is high, however, and as seen from the table when blended with mineral oil *E* an oil was obtained which fulfilled the requirements satisfactorily. Figure 9 shows the evaporation loss curve for this oil and figure 10 shows the increase in acidity on the oxidation test. Certain inhibitors can be added to oils as shown by Dornte[8] that will materially retard the rate of oxygen absorption in an oil. The chemistry of the reaction of oxygen with oil is complex, but by adding the proper inhibitor, as was done in the case of the blend *A*, the rate of acid formation can be reduced to a very low value.

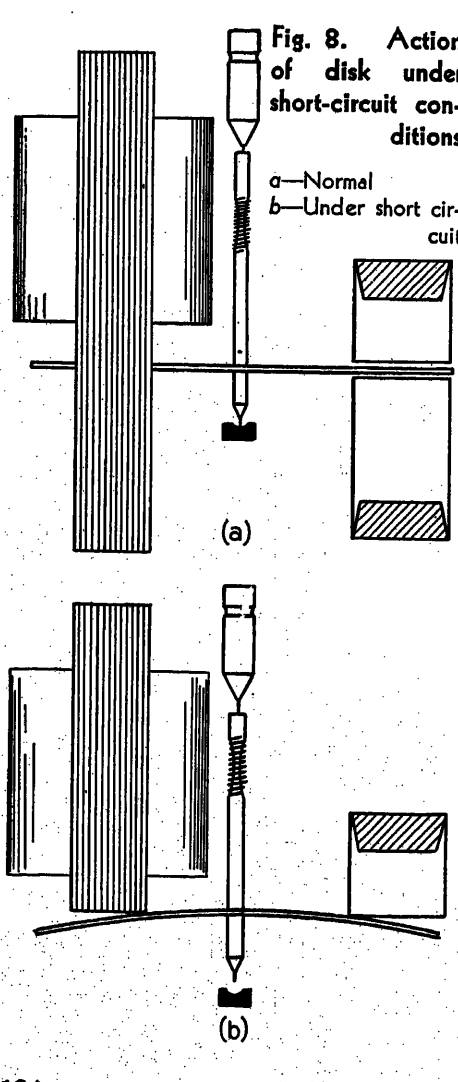

**Fig. 8. Action of disk under short-circuit conditions**

*a*—Normal
*b*—Under short circuit

Table III shows that oil *A* meets all of the specifications by a liberal margin. It represents a good balance between evaporation rate and temperature range so that it can be safely used for the wide temperature range to which outdoor metering subjects the bearing. Ordinary lubricants and many special blends of expensive ingredients will not meet these specifications which are so important to long bearing life. This oil meets the need for a lubricant that can be used in modern watt-hour meter bearings to give the full advantages of reduced wear and long life that good lubrication can produce.

## Top Bearing

Figure 11 shows a typical top bearing for a watt-hour meter. As previously stated, the load this bearing must carry is small and the bearing is subject to little wear for this reason. At the present time a brass washer and steel pivot lubricated with petroleum jelly are the most widely used combination of materials.

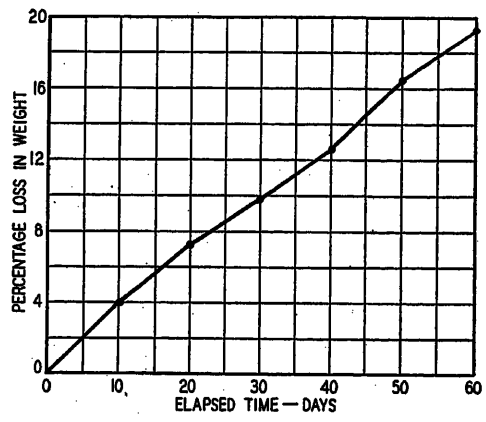

**Fig. 9. Evaporation loss of jewel oil A at 75 degrees centigrade**

Induction-type watt-hour meters require that the clearance between the pivot and washer be kept small in order to provide accurate alignment of the moving element, and to minimize the bearing noise set up by vibration. The addition of the lubricant also serves to reduce this noise as well as to provide the necessary lubrication to the bearing.

This discussion of the top bearing may be summed up by saying that while some improvements may be made in the top bearing by the use of new materials and by improved design, little trouble is experienced at the present time with millions of meters in service.

## Discussion of Typical Bearing Designs

It is evident from the discussion of friction and impact considerations that the radius of curvature for a pivot or ball must be a compromise between initial friction, rate of increase of friction, and impact strength. Figure 12

shows the range within which the radius of curvature for pivots and balls shown in figure 1 falls. These limits have been selected by the different manufacturers of watt-hour meters, based on years of experience, as being a suitable compromise among the various factors for their particular watt-hour meter design.

Too much emphasis should not be placed on the initial or elastic conditions of pivot or ball deformation because it is almost impossible to maintain them due to wear. This was shown by Abbott and Goss[1] for the pivot-type bearing with lubrication and is shown in figure 7 for the pivot-type bearing without lubrication.

Up to this point the design requirements have been considered without reference to any of the particular bearing arrangements shown in figure 1. It will be of value to consider some of the design details together with the advantages and disadvantages of the 3 principal designs.

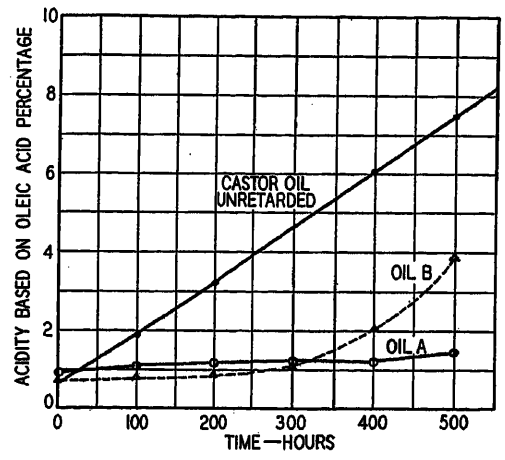

**Fig. 10. Oxidation of oils in stability test**

## Pivot Type Bearing

A typical example of a pivot-type bearing is shown in figure 1*c*. The radius of curvature of the pivot point is 0.0185 inch and the radius of the jewel is 0.035 inch.

The metal guide bearing shown in the figure is to limit the side motion of the pivot and shaft as the load on the meter is increased above a given value. This side motion is due to the combined action of the driving force and the damping force of the meter acting to move the disk out of the meter air gap. Were the side thrust bearing not provided, the meter element shaft would eventually come in contact with the sleeve and the resulting friction would be much greater due to the greatly increased lever arm at which the friction would act. The necessity for such a bearing comes from the wide range over which modern watt-hour meters hold their calibration accuracy and over which they may be used without exceeding their thermal rating. It is possible for a modern watt-hour meter to operate for long periods at 400 per cent to 500 per cent of rated nominal load with good accuracy and no damage to the meter.

*Interchangeability.* In order to insure interchangeability of the pivot and jewel without appreciably affecting the watt-hour meter calibration, it is necessary that the position of the disk in the air gap shall not be materially altered when the bearing is changed. The distribution of the fluxes in the gap is such that both the driving torque and the damping torque vary with the vertical position of the disk in the gap. The speed of the watt-hour meter on a given load will therefore vary with the vertical position of the disk. Figure 13 shows an actual curve taken on a standard make of watt-hour meter rated 5 amperes, 115 volts. It will be noted that as the disk moves down from the top of the air gap, the meter speeds up. For an extreme case this change may be well over 1 per cent.

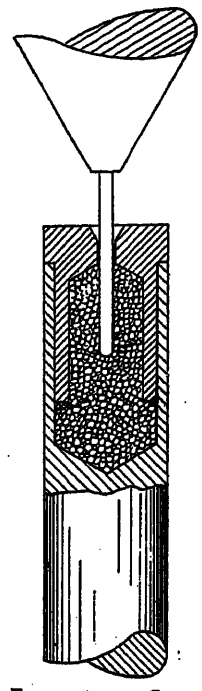

**Fig. 11. Cross section of top bearing**

The control of the position of the disk in the gap necessitates the manufacture of the jewel screw and pivot to within a few one-thousandths of an inch. The sapphire jewel is subject to dimensional variations due to the method of manufacture that makes it necessary to take it into account in the manufacture of the brass screw.

*Lubrication.* The pivot type bearing requires lubrication for the best operation[1] and provision must be made for an adequate supply of the proper lubricant and the retention of this lubricant. The jewel screw shown in figure 1*g* provides a deep reservoir for this purpose.

At low temperatures all oils that are suitable for watt-hour meter bearing lubricants increase in viscosity and

**Table III—Properties of Oils**

| Oil | Composition | (1)* Evaporation Loss, Per Cent | (2)* Viscosity After Evaporation at 75 Deg C | (3)* Viscosity at −40 Deg C | (4)* Percentage Acidity Final | (4)* Percentage Acidity Per Cent of Initial | (5)* Creepage Property | (6)* Corrosion Protection |
|---|---|---|---|---|---|---|---|---|
| *A* | Mineral and fish oil | 16.4 | Unchanged | Satisfactory | 0.09 | 167.0 | Medium | Satisfactory |
| *B* | Castor oil** | 1.0 | Solid | Solid | 0.75 | 3,850.0 | Low | Fair |

* See specifications for details of test method. ** Retarded.

tend to retard the rotation of the moving element. By the proper choice of a lubricant and by minimizing the area of the moving parts (such as the pivot) in contact with the oil, the viscous drag can be reduced to the point where the operation of the watt-hour meter is not affected over a wide range of temperature.

### Ball Type Bearing

Figure 1*d* shows a good example of a bearing using 2 cup jewels and a small ball instead of one cup jewel and a pivot. The jewel radius is the same for this construction as for the pivot construction but the radius of the balls used is approximately 0.030 inch which as shown by figure 12 is the upper limit of radius of curvature for watt-hour meter bearings.

The side thrust for this bearing must of necessity be taken by the shaft and sleeve. It is necessary to make the parts so they will not come in contact until the watt-hour meter is operating under a load sufficiently great to make the effect of the side thrust bearing friction negligible and at the same time not allow the ball to ride out of the jewel cup.

*Lubrication.* This bearing is operated without lubrication as the ball is free to move with the sudden application of load or mechanical vibration and constantly presents new points of contact to the jewel surface. The use of a lubricant in this type of construction is not recommended because it introduces an appreciable viscous drag at low temperatures which slows down the watt-hour meter and is, therefore, objectionable for installations where low temperatures are encountered.

### Cup and Cone Type Bearing

Figure 1*h* shows a modification of the pivot type and the ball type which combines some of the advantages of each. The cone is either metal, or sapphire set into a metal plug. The friction between the ball and cone is greater than between the ball and the lower jewel but still is not great enough to prevent the shifting of the position of the ball with changes in load and with vibration. Added rigidity of the system is obtained by the use of the cone and the construction also makes it possible to take the overload side thrust on a thrust bearing of small radius.

*Lubrication.* This bearing should not be lubricated because of the viscous drag introduced by the oil at low temperatures just as with the ball type with 2 cup jewels. Dependence must be placed on the movement of the ball to distribute the wear over the surface of the ball rather than to rely upon lubrication to reduce the wear to a low value. An alloy ball that will meet the specifications that have been set up for a pivot or ball material should materially increase the life of the bearing over that obtained with a steel ball.

## Field Tests

Based on the material covered under the headings of the component parts of watt-hour meter top and lower bearings, the question naturally arises as to the improvement in bearing life that is to be obtained by carrying out the improvements in construction, materials, and design.

Figure 7 shows the results of accelerated tests on one bearing combination consisting of the jewel screw shown in figure 1*g*, the lubricant oil *A*, and cobalt-tungsten pivots. Figure 7 also shows results for the same combination except without the oil run in comparison with high-carbon-steel pivots. Many accelerated tests of this nature have been run. It is realized, of course, that tests of this nature are not the final method of evaluating any bearing combination and that actual field tests under service conditions offer the final basis for judgment of the true value of a bearing. Hundreds of bearings have been studied that were placed in meters in actual service and the results obtained verify the statements made in this paper. While tests have been for but one and 2 year periods, high-carbon-steel pivots and old designs of jewel screws that did not provide oil reservoirs were run in comparison and served as controls. The indications are that improved lubrication and improved pivot materials have added years to the life of the bearings by reducing wear and maintaining more nearly constant values of friction.

While all tests definitely show that proper lubrication increases the life of bearings, it has also been shown that cobalt-tungsten performs exceptionally well even without oil. Experience may prove that cobalt-tungsten pivots running on sapphire jewels will give entirely satisfactory service without lubrication, but much service data will have to be obtained before this question can be answered.

## Summary

1. It has been shown that the meter bearing problem can be rationalized and simplified by careful analysis and that specific requirements or specifications can be formulated for each component part.

2. Definite limitations on the mechanical design result from the requirements of low initial and sustained friction of the bearing

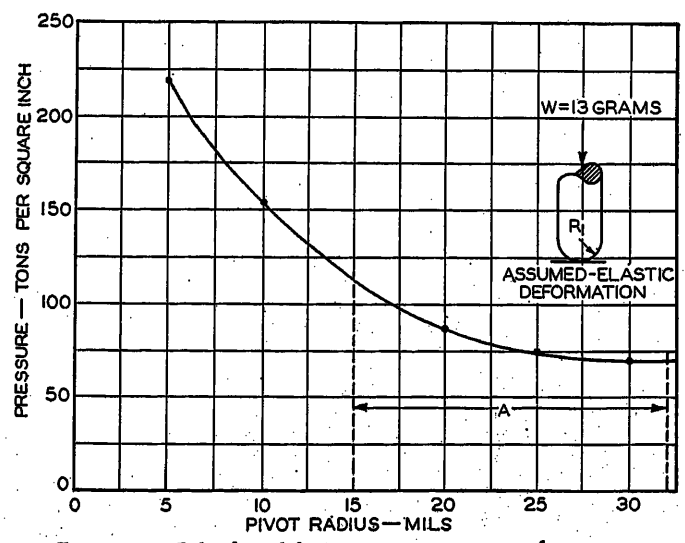

**Fig. 12. Calculated bearing pressure as a function of pivot radius**

*A*—Present range of watt-hour meter bearings

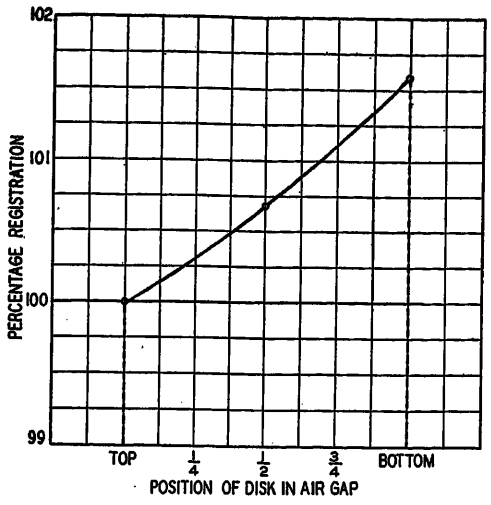

**Fig. 13. Variation of meter calibration as a function of vertical position of the disk in the air gap**

and the shock resistance requirements. Improved materials, therefore, offer the best possibilities for increased bearing life.

3. Although the hardness of sapphire is considerably lower than that of diamond on the new scale of hardness, the high cost and the difficulty of working the latter leave sapphire the best material available for jewel cups.

4. Various alloys offer possibilities of improved bearing life but an alloy of cobalt and tungsten very definitely shows all around superiority to all other materials tested.

5. Research and development work on watt-hour meter bearing oils has resulted in improvements which have made possible a wide temperature-range oil with a low evaporation rate for outdoor meter installations.

6. For pivot bearings, tests indicate that best results are obtained with a jewel screw that maintains a liberal supply of oil in the jewel cup. This is not true for the ball type for which lubrication is not recommended.

7. Improved materials and design may make possible some improvements in watt-hour meter top bearings, but little trouble is experienced with them at the present time.

8. The maximum service for the pivot type bearing is obtained by adopting the 3 improvements mentioned in paragraphs 3 to 5 inclusive of this summary, namely:

(*A*) A jewel screw designed to provide a liberal oil reservoir.

(*B*) Improved oil suitable for a wide temperature range.

(*C*) Cobalt-tungsten pivots which reduce jewel breakage under impact, decrease jewel wear, and reduce abrasion in the event of the loss of the lubricant.

# Trends in Distribution Overcurrent Protection

By G. F. LINCKS
NONMEMBER AIEE

P. E. BENNER
ASSOCIATE AIEE

**The provision of suitable overcurrent protection for distribution systems at low cost is an important problem, for upon the satisfactory solution of that problem depends the continuity of service of a great many consumers of electric energy; consequently, the relations of a public utility company with its customers also depend upon adequate overcurrent protection. This paper presents a discussion of the various trends in overcurrent protection, with the aim of providing for the distribution engineer some basis for selecting the particular protective system best suited to his particular requirements.**

LOW-COST overcurrent protection on distribution systems has commanded the attention of the utility industry. New devices and applications have opened new avenues of thought on this phase of distribution problems. It is proposed to make an impartial presentation of the facts pertaining to the problem of overcurrent protection, from the plug or cartridge fuse on the meter board on the consumer's premises to the co-ordination of the main feeder breaker relays with those on the transmission system. This presentation, by correlating the various trends of thought as they are related to the whole overcurrent protection program, should assist utility engineers in choosing the one best suited to their present and future requirements.

Continuity and quality of service, protection of equipment, and low initial and maintenance costs are often divergent factors governing the application of overcurrent protective apparatus on distribution systems. Where the stressing of one necessitates sacrificing another, it is important to know all the facts so the most efficient balance can be secured. The facts governing such a balance will differ somewhat on urban, suburban, and rural systems. Of first importance is a knowledge of the causes of outages evaluated for different parts of the distribution system in terms of some unit for measuring the service being rendered the consumer.

## Review of the Causes and Evaluation of Outages

Protection of consumer service is of fundamental importance. There is little duplication of equipment on the distribution system for reducing consumer outage, and so the equipment must be used with the greatest possible efficiency. Thus, the protection problem involves the handling of fault conditions more with the idea of minimizing consumer outage rather than from the standpoint of protecting the equipment. In analyzing the effect of troubles with the idea of using an overcurrent protective device to improve the continuity of service, it is necessary to know the duration of the fault, how often it is likely to occur, and the number of consumers affected.

Consumer minutes of outage, which is conventionally used as a measure of continuity is determined from the number of consumers affected by any particular outage and the length of time for which the service is interrupted. The importance of including time is, of course, obvious, although there may be some question as to whether it is correct to say that a 60-minute outage for one consumer is equally undesirable as a one-minute outage for 60 consumers.

When considering consumer outage, attention cannot be confined to the outage of any one particular consumer or group of consumers, but must be given to all the outages of all the consumers. For instance, it might be possible to reduce the outages of a small group of consumers at the expense of increasing the outages for a larger group of consumers. This, of course, would be generally undesirable but nevertheless it can easily happen if one does not have a thorough knowledge of all the factors involved or if one places emphasis on just one part of the system without correlating it with the whole system.

A major factor in the efficient application of protective equipment is the relative percentage of temporary versus permanent outages which occur on that particular part of the system. Temporary outages usually refer to fault conditions which will clear themselves with the interruption of power and before the first or second reclosing of the breaker or fuse cutout, whereas permanent outages are those which require the attention of a line crew. Temporary outages would ordinarily be of less than one minute duration, whereas a study of the records of a number of operating companies shows that faults which require the attention of a line crew last anywhere from several minutes up to several hours and average something like 45 minutes.

## Outage Records

Outage information is an indication of the type of service being rendered. However, to be usable in system design, the outage data should be segregated into those parts of the distribution circuit which might be sectionalized, such as main feeder, branch feeder, distribution transformer, and secondary. Another important segregation should correspond to the nature of the area and the load served. For instance, line outage data on rural

A paper recommended for publication by the AIEE committee on power transmission and distribution. Manuscript submitted October 9, 1936; released for publication November 27, 1936.

G. F. LINCKS is an engineer in the lightning arrester, cutout, and capacitor engineering department of the General Electric Company, Schenectady, N. Y.; P. E. BENNER is an engineer in the central station engineering department of the same company.

1. For all numbered references, see list at end of paper.

feeders should be kept separate from that on suburban or urban feeders.

Line data are usually given in terms of outages per hundred miles per year. Transformer and secondary outages, on the other hand, are given as the per cent of the number of transformer installations or as the number per 100 transformers per year.

An analysis of the outage data of a number of operating companies, some of which is given in table I, shows that the number of outages on primary lines varies from only a few to as high as 70 or 80 per hundred miles per year. The per cent of these faults which are temporary also varies over a wide range. Trees are a very important cause of line outage. Conditions between various localities differ greatly in the possibility to trim or avoid trees, which accounts for the smaller number of outages per hundred miles on many rural lines as compared with urban or suburban feeders on the same system.

Lightning is still of major importance as a cause of distribution-transformer outage due to the large number of older transformers still in service, to the omission of lightning arresters, etc. Fuse blowing and transformer burnouts due to lightning have been greatly reduced by

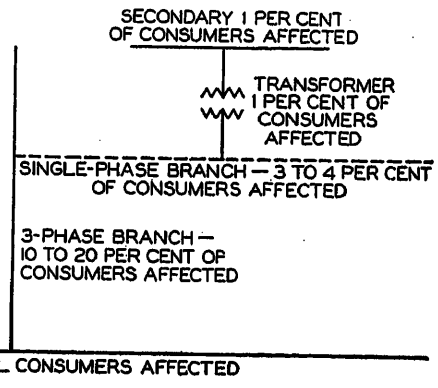

**Fig. 1. Diagram of distribution circuit, showing average percentage of all consumers on the circuit affected by an outage confined to the portion of the line on which the fault occurs**

the interconnection of the lightning arrester grounds with the secondary neutral. This, and the present trend toward connecting the lightning arrester so the discharge currents do not pass through the fuse link, has tended to improve the undesirable situation in which the prevalence of lightning dictated the use of fuse-link ratings larger than might otherwise have been selected.

In analyzing the distribution transformer and secondary outage data from which table I was obtained, it is found that the number of outages accompanied by transformer burnouts is relatively small. For instance, of the distribution transformer and secondary outages tabulated, the transformer burnouts occurred with only 12.5 per cent of the total outages due to lightning (0.256 per 100 transformers average), 6.4 per cent of the total outages due to secondary faults and miscellaneous (0.255 per 100 transformers average), and 30 per cent of the total outages due to overload (0.091 per 100 transformers average). These figures demonstrate the overcurrent protection afforded the distribution transformer by the primary fuse.

As is to be expected, there is a wide variation in the frequency and nature of outages for the various companies which emphasizes the necessity of each company maintaining outage records for its own particular use. If a company attempts to make use of an average value as indicated from a study of the records of other companies, a type of design might result which would not be at all suitable for the particular condition under which the system operates.

## Consumers Affected

The number of consumers affected by a fault accompanied by the functioning of some overcurrent protective device varies from one to all those on a feeder or perhaps even more if the feeder breaker relay is not properly coordinated with devices between it and the source of supply. With the usual type of construction, trouble occurring anywhere from the consumer service fuses to the transformer primary fuses involves all the consumers on the particular transformer. This varies from one consumer in the case of rural areas to over a hundred, and averages from 25 to 40 for the usual type of urban residential construction. The number of transformers on any particular primary branch varies from one or more, in the case of single-phase branches, up to 100 in the case of 3-phase branches. Trouble on branch circuits may, therefore, involve from one up to 1,000 or more consumers. In the case of feeders and branches having a higher percentage of residental consumers, fairly accurate estimates of the actual number of consumers can be obtained by multiplying the peak load in kilowatts by 4. This applies when the kilowatt consumption of the consumers in the area considered averages 600 kw or 700 kw per year.

In studying a distribution system with the idea of reducing the consumer minutes of outage, it is usually important to know the relative importance of troubles on the primary lines, in the distribution transformer, and on the secondary lines; with respect to which causes most of

**Table I—Outage Data for 2,400/4,160 Y Volt Distribution Circuits**

| Company | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | Average |
|---|---|---|---|---|---|---|---|---|---|---|
| Total outages due to line troubles (urban) per 100 miles of line | 29.1 | 13.5 | 41.6 | 53.7 | 20.2 | 13.4 | 40.1 | 29.3 | 2.5 | 27.04 |
| Total outages due to distribution transformer and secondary troubles (per 100 distribution transformers) | 7.2 | 4.1 | 8.7 | 5.6 | 8.1 | 0.9 | 7.8 | 3.0 | 11.6 | 6.3 |
| Total outages due to lightning (per 100 transformers) | 2.02 | 0.86 | 2.53 | 1.34 | 4.05 | 0.298 | 1.67 | 0.09 | 5.57 | 2.05 |
| Total outages due to secondary faults and miscellaneous (per 100 transformers) | 4.54 | 3.08 | 6.0 | 3.64 | 3.48 | 0.612 | 6.11 | 2.70 | 5.68 | 3.98 |
| Total outages due to overloads (per 100 transformers) | 0.065 | 0.16 | 0.17 | 0.62 | 0.57 | 0.0 | 0.02 | 0.21 | 0.35 | 0.304 |

the consumer minutes of outage. Figure 1 shows graphically the probable range in percentage of consumers affected by faults on the various parts of the system for the more generally used types of radial feeders.

Table II, lines 1 and 2 show a study of the ratios of permanent line outages to distribution transformer and secondary outages for the various companies whose outage data are given in table I. The number of transformers per mile is also given in line 3 of table II, so that a direct comparison may be made between them on the same basis as in lines 4 and 5. These point conclusively to the importance of primary line trouble as a cause of consumer minutes of outage. This is confirmed by figure 2 which gives the actual records in percentage of consumer minutes outage for the different parts of two utility companies' systems. The comparisons of lines 4 and 6 show that a reduction of one-half the length of line decreases the effect of permanent line faults in transformer outages to $^1/_4$, whereas lines 5 and 7 show it only decreases the effect of transformer and secondary faults on transformer outages to $^1/_2$.

Therefore branch-line fusing or other sectionalizing of the line to confine the effect of faults to smaller areas, not only attacks the problem at one of the most important causes of consumer minutes outage, but also produces a greater reduction per protective unit installed. The growing interest in the co-ordination of line protection is a natural outcome of an understanding of these facts.

## Time-Current Characteristics

The co-ordination of overcurrent protective apparatus to reduce to a minimum the number of consumer-minutes outage on distribution circuits, is based on the correlation of their time-current characteristics. These are usually plotted as curves so as to show the variations in the shape for different types and ratings of apparatus. This is important as the comparison of one or 2 points may not insure proper co-ordination over the complete range of fault currents that can occur in the section protected. The fault currents will vary with the total impedance of the line, the connected apparatus and the fault.

The total time to clear the circuit is comprised of 2 parts for most protective apparatus: For circuit breakers these parts are (1) the time to complete the electrical cycle of the relay and (2) the time for the breaker to open mechanically and extinguish the arc (see figure 3 $E^{2\prime} - E^{2\prime\prime}$); for fuse links (more especially those used on the primary lines) they are (1) the time to melt the fuse link and (2) the time to extinguish the arc (see figure 3 $B'' - B'''$). Both are essential for the proper co-ordination of protective apparatus. The device farthest out on the line must clear the circuit (total clearing time figure 3 $B'''$, $C'''$, $D'''$) before the fuse link between it and the source of supply melts or the electrical cycle of the relay is completed (figure 3 $E'$, $E^{2\prime}$, $E^{3\prime}$).

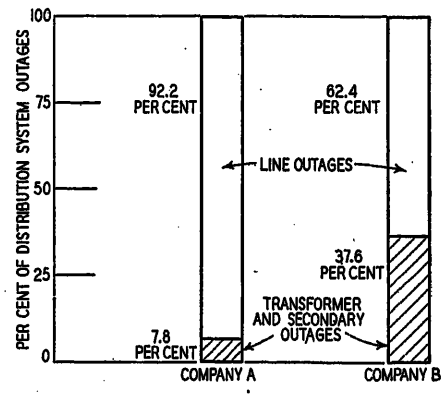

**Fig. 2. Diagrammatic representation of the outage record of 2 companies**

### Circuit-Breaker Relays

The earlier designs of relays of the plunger type functioned almost instantaneously or with a slight time delay where a bellows attachment was provided. The induction relay was developed at a comparatively early date in order to meet operating requirements, necessitating greater time delay to permit a wider range for co-ordination with the current-carrying and current-interrupting characteristics of other apparatus further out on the line. These have been adopted quite universally. The induction relay curves have the inverse time-current characteristic of figure 3 $E'$ or the very inverse time-current characteristic of figure 3 $E^{2\prime}$. The latter provides a sharper knee which is especially valuable at the low time lever settings, where the less inverse curves tend to approach the fuse link curves at the low currents.

Attachments are available for induction relays to permit instantaneous completion of the electrical cycle at any desired current. The use of this attachment allows

**Table II—Comparison of Permanent Primary Line Outages With Distribution Transformer and Secondary Outages**

| | Company | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
|---|---|---|---|---|---|---|---|---|---|---|
| 1 | Permanent line outages (per 100 miles of lines) | 18.65 | 8.3 | 2.54 | 35.0 | 14. | 1.0 | 34. | 1.7 | 4.0 |
| 2 | Distribution transformer and secondary outages (per 100 distribution transformers) | 7.2 | 4.1 | 8.7 | 5.6 | 8.1 | 0.9 | 7.8 | 3. | 11.6 |
| 3 | Transformers per mile | 11.9 | 9.5 | 13.5 | | 10.7 | | 7.9 | | 8.9 |
| 4 | Transformer outages for one mile of line due to permanent line faults | 1.22 | 0.79 | 3.43 | | 1.5 | | 3.58 | | 0.36 |
| 5 | Transformer outages for a one-mile line due to transformer and secondary faults | 0.86 | 0.39 | 1.73 | | 0.87 | | 0.63 | | 1.03 |
| 6 | Transformer outages for a $^1/_2$-mile line due to permanent line faults | 0.305 | 0.20 | 0.83 | | 0.38 | | 0.69 | | 0.09 |
| 7 | Transformer outages for a $^1/_2$-mile line due to transformer and secondary faults | 0.43 | 0.20 | 0.86 | | 0.44 | | 0.31 | | 0.52 |

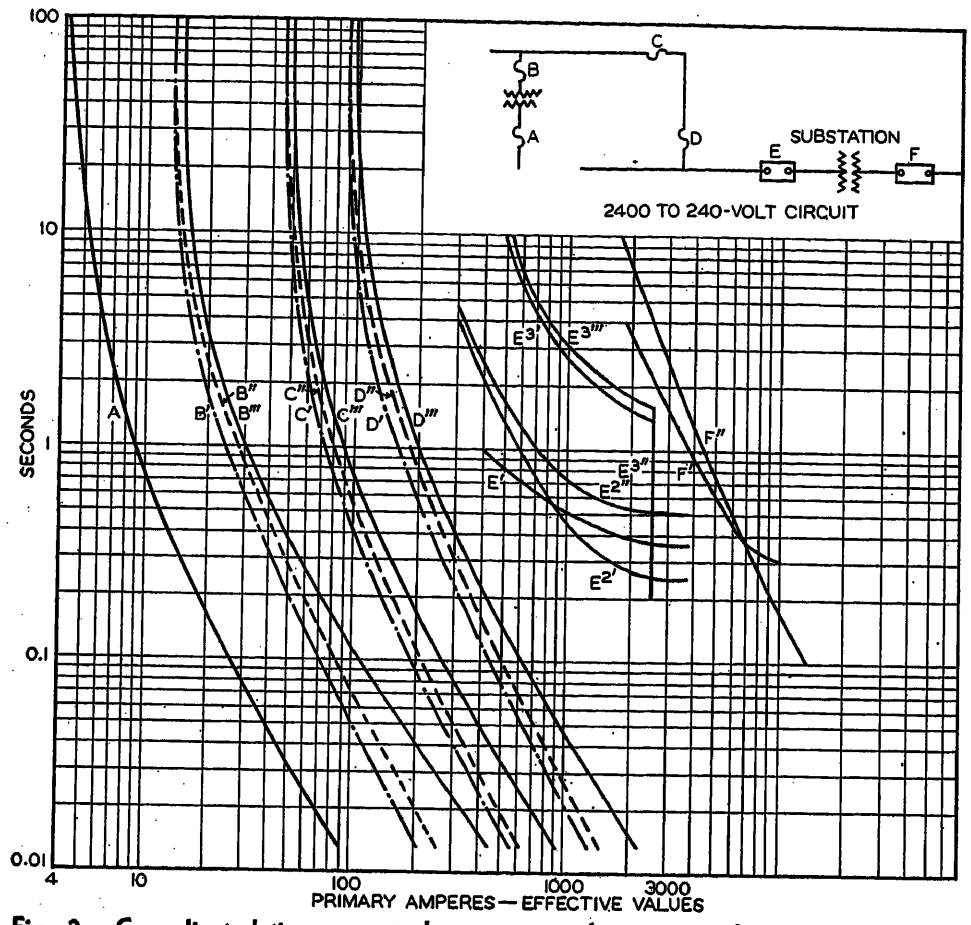

**Fig. 3. Co-ordinated time-current characteristics of protective devices on a typical distribution circuit**

*A*—Household plug or cartridge fuse rated at 30 amperes
*B*—Fuses rated at 10 amperes in primary leads of a distribution transformer

*C*—Branch line sectionalizing fuse rated at 30 amperes
*C', C'', C'''*—Same as *B', B'', and B'''*, respectively
*D*—Branch line sectionalizing fuse rated at 50 amperes
*D', D'', D'''*—Same as *B', B'' and B'''*, respectively
*E*—Feeder oil circuit breaker and relay (minimum pick-up, 200 amperes)
*E'*—Inverse relay (number 1 time lever setting)
$E^{3'}$—Very inverse relay (number 1 time lever setting)
$E^{3''}$—Opening of oil circuit breaker
$E^{3'}$—Very inverse relay (number 10 time lever setting)
$E^{3''}$—Instantaneous attachment on relays function
$E^{3'''}$—Opening of oil circuit breaker
*F*—Protective device on incoming transmission lines
*F'*—Very inverse relay (number 1 time lever setting)
*F''*—Fuse

higher time lever settings (figure 3 $E^{3'}$), which makes possible a greater time-current range for other protective apparatus on the distribution system. The instantaneous pick-up at high currents (figure 3 $E^{3''}$), will prevent distribution system faults from blowing the fuses of figure 3*F''* or operating the relays of figure 3 *F'* on the transmission side of the substation.

### Primary Fuse Cutouts and Fuse Links

As one phase of the marked improvement that has been incorporated in primary fuse cutouts and fuse links[1,2], the time-current characteristic curves for fuse links were made more inverse so as to permit closer co-ordination with the induction relay. Of more recent date, a further improvement figure 4 has resulted from an engineering study that took into consideration the 100 per cent continuous current carrying ability of the fuse links and cutouts, the motor starting demand currents figure 4*A*, the plunger type and the induction relay characteristics figure 4*E* and *D*, and the current-interrupting ability of the fuse cutouts.

### Secondary Fuse Cutouts and Fuse Links

The use of secondary fuse cutouts while not new, has only very recently come into prominence because of the improvement made in the designs available. A large part of this improvement has resulted from making the time-current characteristics of the fuse links identical

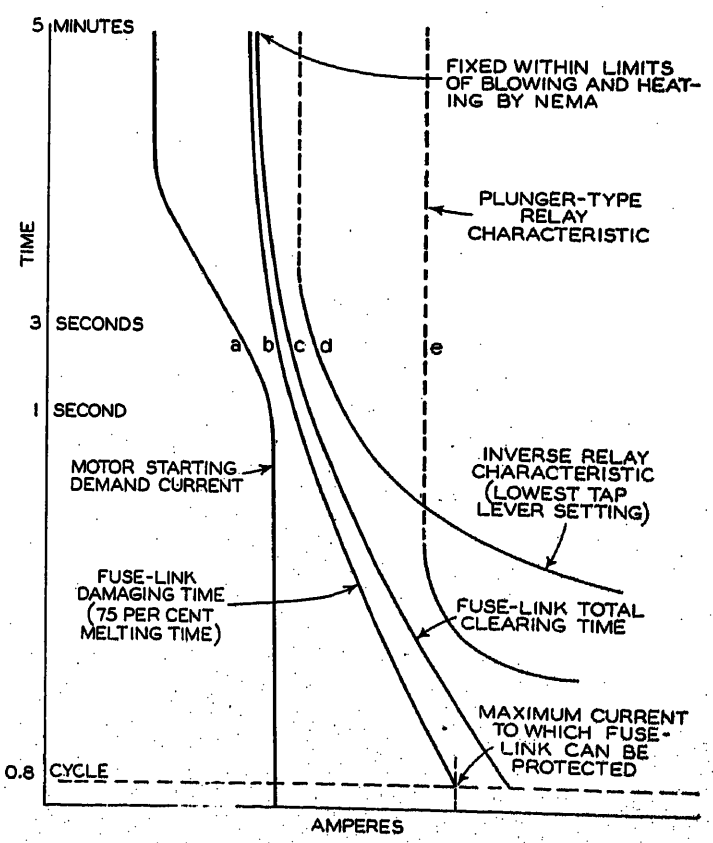

**Fig. 4. Curves showing scientific development of universal cable-type fuse links**

to those for the latest designs of primary fuse links figure 4. This similarity enables a closer co-ordination between the secondary and primary.

### Plug and Cartridge Fuse Characteristics

The household plug and cartridge fuse, commonly used at the meter boards on the consumer's premises, has been a merchandised product that rarely entered into the distribution engineer's problems. The rapid increase in residential loads, especially due to ranges and water heaters, has so raised the ratings of these fuses used with the relatively low kva transformer ratings, that a knowledge of their time-current characteristics has become a vital factor. To date, the different manufacturers of plug or cartridge fuses, of the renewable or nonrenewable type, have complied with the specifications of the National Electric Code and the Fire Underwriters' Laboratories which state:

"*Rating.* Fuses shall be so constructed that with the surrounding atmosphere at a temperature of 24 degrees centigrade they will carry indefinitely 110 per cent current without causing the tubes to char or externally visible soldered connections to melt.

"Temperature and 110 per cent current tests shall be made simultaneously.

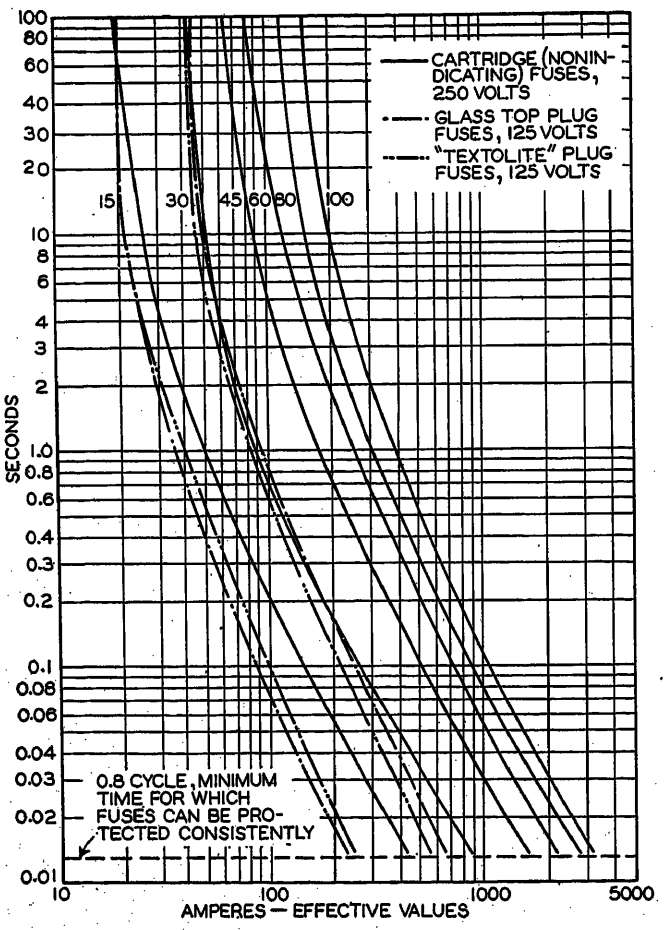
"With a room temperature between 18 and 32 degrees centigrade, fuses starting cold shall blow on 150 per cent current, without causing the tubes to char or externally visible soldered connections to melt, within the times specified below.

| | |
|---|---|
| 0– 30 amperes | 1 minute |
| 31– 60 amperes | 2 minutes |
| 61–100 amperes | 4 minutes |
| 101–200 amperes | 6 minutes |
| 201–400 amperes | 12 minutes |
| 401–600 amperes | 15 minutes |

"In the 150 per cent rating test, only one fuse shall be tested at a time."

Except for these specifications, as quoted, no other published information has been available.

Recent studies have shown a rather wide variation between the curves of fuses of different manufacture.



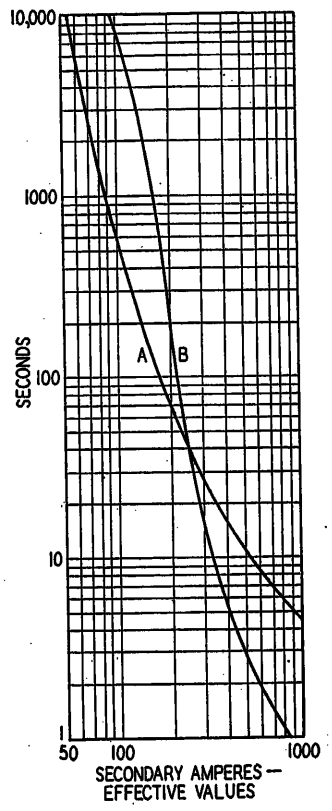


**Fig. 5. Total clearing time-current characteristics of typical plug and cartridge fuses**

Curves are based on tests at normal rated voltage

**Fig. 6. Transformer and internal breaker time-current characteristic curves**

*A*—Recommended time-load curve for a 10-kva transformer

*B*—Secondary breaker curve, with breaker mounted in transformer oil (setting similar to that used in practice)

However, generally these all have an inverse-time-current characteristic, figure 5, quite similar to that of the fuse links and induction relays used on the primary and secondary lines.

## Transformer Time-Load Characteristics

Heretofore transformer protection has been a problem of overvoltage rather than overcurrent. The interconnection of the lightning arrester ground and secondary neutral has so greatly reduced the failures caused by overvoltage, that those caused by overcurrent appear more important. This is accentuated in some places by the desire to increase the average loading of the transformers.

A recommended time-load curve for distribution transformers has been prepared by the AIEE and ASA as a guide (see figure 6*A* plotted for a 10-kva transformer).

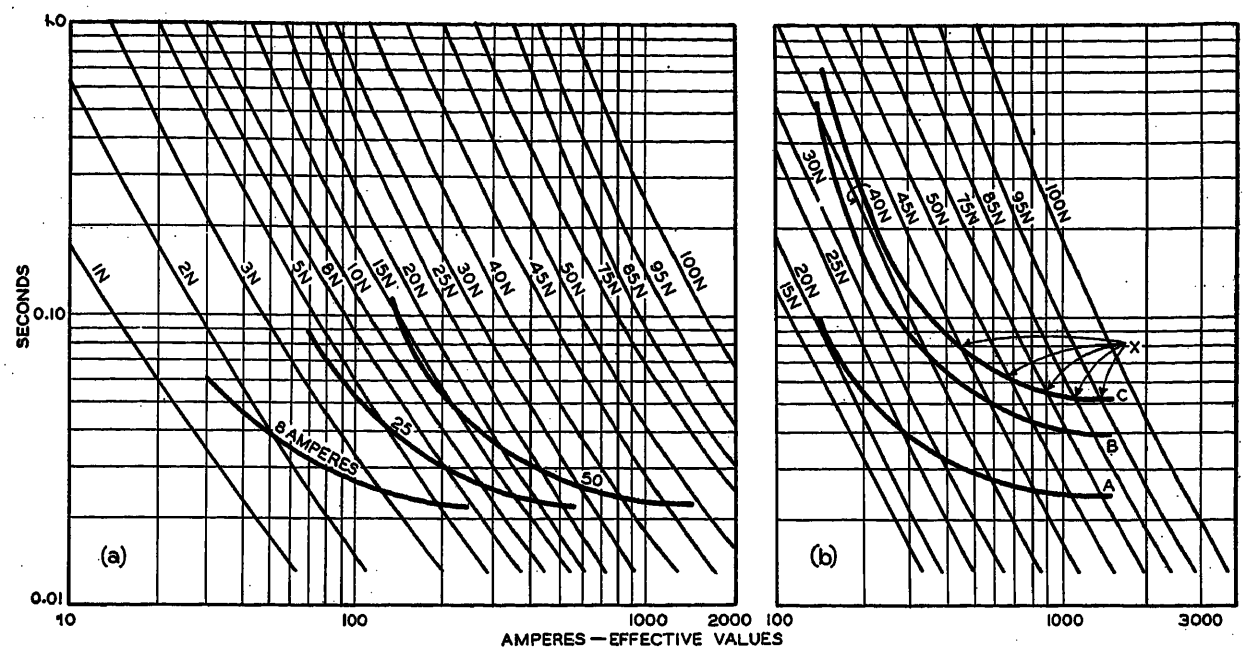

**Fig. 7. Time-current characteristics of recloser and fast-blowing universal cable-type fuse links for enclosed, open, and drop-out cut-outs rated at from 50 to 100 amperes and from 5 to 15 kv**

(*a*)—First opening of recloser and total clearing time for fuse links (fuse link curve must be to left of recloser curve for proper co-ordination)

(*b*)—Curves for 50-ampere recloser and melting time of fuse links

*A*—First opening of a typical recloser

*B*—Equivalent heating of fuse link by current during all operations to lock-out of the recloser, and taking into account the cooling for that part of the cycle during which no current flows

*C*—Equivalent heating, but including a factor for operating variables

This curve has the backing of a large group of utility and manufacturing engineers. In this analysis we are more interested in the shape rather than the exact positioning of this curve with respect to current and time.

The recommended transformer time-load curve (figure 6*A*) has an inverse time-current characteristic. The curve has much less slope, especially at the low-current long-time end, than is provided by the induction relay, the primary and secondary fuse links, or the household plug and cartridge fuses.

## The Low Voltage Breaker

The time-current characteristic curve for the low-voltage breaker recently developed for household application is slightly less inverse than the induction relay and the fuses whose characteristics have to be co-ordinated with it. The breaker characteristics were made to co-ordinate with the fusing of the wire used in buildings so as to afford the maximum fire protection.

### Secondary Breakers in Distribution Transformers

A breaker has been developed for use inside the tank of distribution transformers. It is mounted so as to obtain some of the heating characteristics of the transformer and has a time-current characteristic curve figure 6*B* that approaches the transformer time-load curve at the low-current, long-time end and is more inverse (much faster) at the high-current short-time end. The average slope is less than for induction relays and the fuses.

### Characteristics of Circuit Reclosers

The circuit recloser is a recent development designed to provide low-cost reclosing circuit breaker operation for rural or troublesome branch lines where there are a high percentage of temporary faults. The time-current characteristic curves figure 7*A* for the recloser are similar to the characteristics of plunger-type relays.

Another factor is introduced by the recloser, namely, that of the time to reclose. During the interval after the arc has been extinguished and until the contacts have reclosed, relays connected in series will partially or completely reset to the normal position and fuse links will tend to cool. Thus the resultant effect of the periods when current flows and no current flows must be considered in co-ordinating the recloser with other protective apparatus so as to permit the recloser to lock out before the relay functions or the fuse links are partially melted. The curves figure 7*B* and 7*C* factor the cumulative heating of fuse links.

### The Problem of Co-ordinating the Characteristics

In most cases, existing conditions impose a definite range of time-current characteristics within which all overcurrent protection on the distribution system must be obtained. The curves figure 3 represent the condition in existence on a high percentage of distribution systems in the country. The maximum limit is the highest possible setting of the feeder breaker relay *E* that will permit co-ordination with the relay *F'* or fuse *F''* on the transmission

side of the substation. Quite often the range can be increased by the use of the instantaneous attachment on the induction relays of the feeder breakers set to trip at currents $E^{3}''$ below those which will trip the transmission relay $F'$ or blow the fuse $F''$. In order to confine the effect of faults to the minimum number of consumers, the time-current characteristics of the fuses at the sectionalizing points $C$ and $D$, at the transformer installation $B$, at the meter board on the consumer's premises $A$, and at any other points on the system, have to be squeezed in the range to the left of the feeder breaker relay curve $E$, so that each is co-ordinated with the other. It is frequently found that there is not a sufficiently wide range to the left of the feeder breaker relay curve $E$ to permit the installation of all the protective devices desired on the distribution system. It, therefore, becomes a matter of choosing the ones which will provide the greatest reduction in average consumer minutes outage for the whole system, with, of course, the economics of the particular circuit kept fully in mind.

## The Household Fuse and Breaker

The plug and cartridge fuses located on the meter board of the consumer's premises are becoming a factor to be considered. Their time-current characteristics may determine the lower side of the range available for distribution overcurrent protection. This has become increasingly true where the higher rated household fuses are used for installations supplied through the smaller sizes of distribution transformers. For instance, the 60-ampere cartridge fuse, figure 8$A''$, usually used on services feeding ranges and hot-water heaters requires 2 times the full-load secondary current of a 10-kva transformer (220- to 250-volt winding), 4 times the full load current of a 5-kva transformer, and 7 times the full-load current of a 3-kva transformer to blow within 2 minutes. To co-ordinate the primary fuse links with this 60-ampere household fuse, without any other secondary protective devices in the circuit, necessitates the use of minimum primary fuse-link ratings of approximately 15 amperes for transformers having a 10 to 1 ratio, 5 amperes for transformers with a 20 to 1 ratio, and 3 amperes for transformers having a 30 to 1 ratio, regardless of whether the rating of the transformer is 3, 5, or 10 kva. Figure 8 shows the effect of superimposing the 60-ampere cartridge fuse and the 15-ampere primary fuse link on the curves of figure 7 shaded. As a high percentage of urban distribution circuits use 2,400 to 120 and 240-volt distribution transformers for serving residential loads, this may present an overcurrent protection problem for a great many systems. A factor in this problem is the

$A$—Household plug and cartridge fuses
$A'$—30-ampere rating
$A''$—60-ampere rating
$B$—Fuses in primary leads of distribution transformer
$B^{s}$—$10N$ ampere rating
$B'$—Time-current characteristic curve for 75 per cent of melting time to factor operating and manufacturing variables
$B''$—Melting time-current characteristic curve

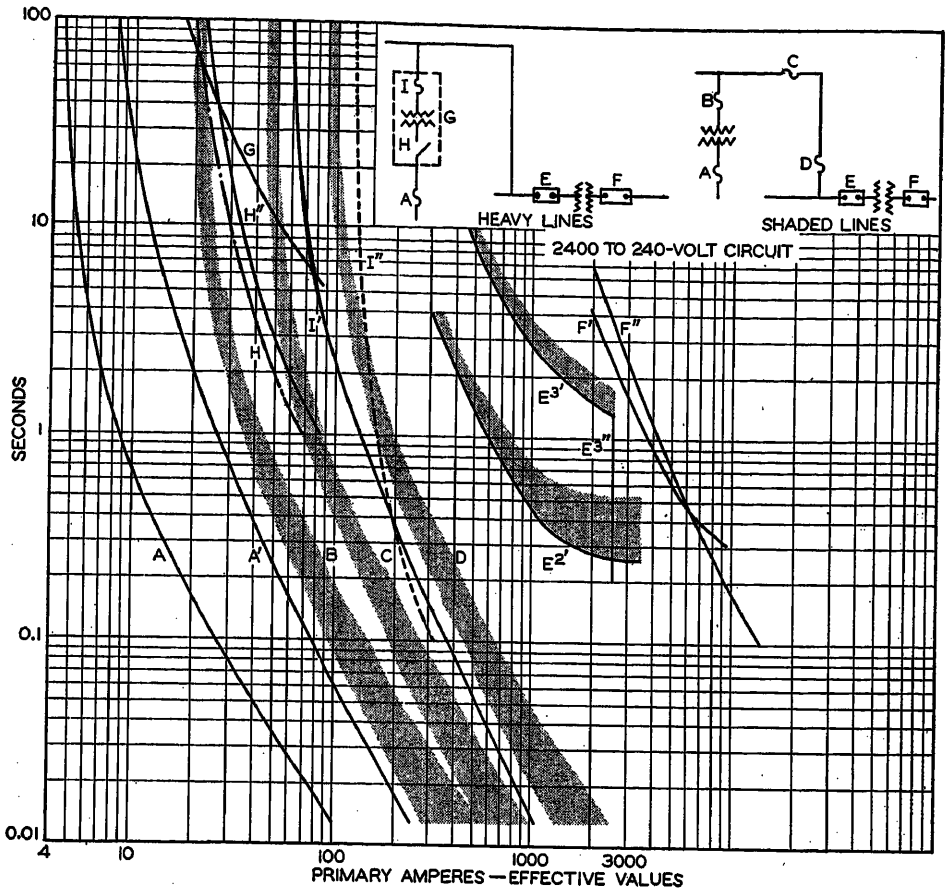

**Fig. 9. Time-current curves for unit-type distribution transformer superimposed on curves of the conventionally co-ordinated system of figure 1, showing comparative use of range available for distribution protection**

probable frequency of faults, occurring, now and later, on the short comparatively new wiring or in the range or water heater fed directly through the 60-ampere fuse. A large majority of the faults should occur on the other house wiring, and should be isolated by lower rated branch fuses, provided these fuses are not short-circuited malicious or otherwise. On the higher-voltage systems, the 60-ampere cartridge fuse or equivalent breaker is not such a limiting factor, except in cases where other secondary protection is introduced into the problem.

## Protection on Secondary Circuits

The protection on secondary circuits from overcurrent faults involves a number of different factors including not only the continuity of service, but the quality and the protection of equipment. Overcurrent protective devices, such as fuses, are installed at the points where the individual service entrances are connected to the main secondary circuit, so as to:

1. Isolate old and faulty installations.
2. Protect against outages from services through buried cable.
3. Isolate services where pennies are inserted behind plug fuses.

The insertion of an overcurrent protective device at the individual service entrance may or may not necessitate using more than a justifiable share of the range available for protection on the whole system. This depends upon several factors. A low rated household plug or cartridge fuse and/or a high transformation ratio makes available a greater range for protection at the service entrances. It will be readily apparent that a protective device such as a fuse, having a time-current characteristic similar in shape to the household fuse and the fuse link on the primary of the transformer permits the closest co-ordination and thus requires the least range for its insertion. If the introduction of a protective device in the service entrance lead necessitates increasing the fusing on the primary of the transformer, an analysis may show the advantages secured for a few consumers have increased the average consumer minutes outage for the whole system.

For example, if the insertion of a secondary fuse cutout in the service leads to confine outages to individual consumers necessitates substituting a $20N$ ampere primary fuse link for the $15N$ ampere rating, figure 8*B*, it cannot be co-ordinated with the $30N$ ampere sectionalizing fuse link, figure 8*C*. Substituting any higher rating for the $30N$ ampere link, in turn, requires the replacing of the $50N$ ampere rating, figure 8*D*, with a larger fuse link which then cannot be co-ordinated with the relay, figure 8*E*. If the relay setting cannot be changed, either the $30N$ or the $50N$ ampere sectionalizing fuse links must be omitted. Then each fault on that portion of the primary line will cause an outage to a larger number of consumers, totaling a great many times those securing

improved service. The average consumer minutes outage for the whole system will, therefore, be increased.

The improved lightning protection afforded by the interconnection of the lightning arrester ground with the secondary neutral has greatly increased the relative importance of overcurrent protection for distribution transformers. Augmenting this relative importance is the desire in some places for higher loading of distribution transformers. New applications of overcurrent protective devices are involved in attempts to meet these changing conditions and requirements. Three major trends in thinking have developed as a result:

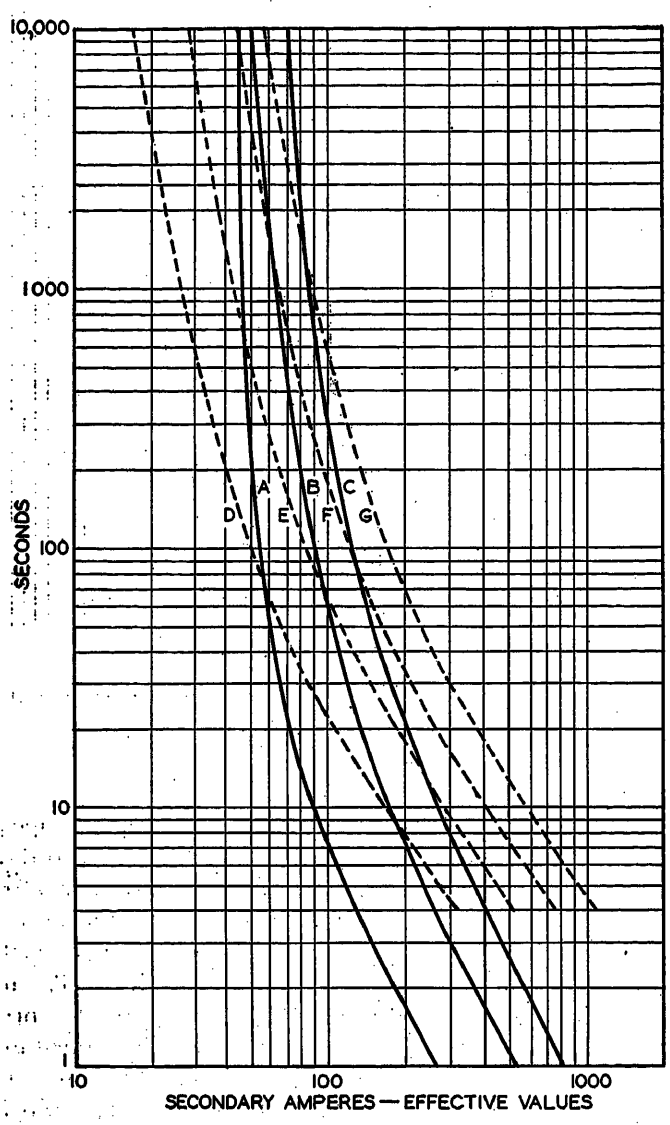

**Fig. 10. Co-ordination of time-current curves for 30-, 45-, and 60-ampere household fuses with those for the time load of 3-, 5-, 7.5-, and 10-kva distribution transformers**

*A*—30-ampere plug or cartridge household fuse
*B*—45-ampere plug or cartridge household fuse
*C*—60-ampere plug or cartridge household fuse
*D*—3-kva transformer time load
*E*—5-kva transformer time load
*F*—7.5-kva transformer time load
*G*—10-kva transformer time load

### 1. Use of Secondary Protection for Higher Loading

Much attention has been and is being given to the use of a secondary protective device supplemented by an overload indicator, to serve as a stop gap against excessive decrease in the life of the transformer so as to permit increased loading at distribution transformers. Such protection must be over the complete range of excessive currents. These vary from long-time, overload currents which are repeated often to the less frequent short-time high short-circuit currents.

In figure 9, the transformer time-load curve *G* is drawn with the corresponding internal secondary breaker *H* and the internal fuse *I* superimposed on the (shaded) curves of figure 8. In studying the effect of time-load curve *G* on the whole protection problem, the important consideration is the flatter slope of the curve, which may make the protective devices curves *H* and *I* co-ordinated with it, occupy too great a portion of the available range for protection on the entire distribution system. If protection is afforded the transformer by a secondary protective device having a time-current characteristic curve identical to or at least closely approximating the transformer time-load curve *G*, the internal primary fuse *I'* or *I''* must be rated much higher than the normal fusing practice *B* so the breaker *H''* will open first and without damage to the fuse *I'* or *I''*. The attendant decrease in the available range may prevent any sectionalizing of the primary lines as indicated in figure 9. The economics of this situation depend wholly upon the degree of protection which can be afforded transformers and the actual number of transformer burnouts saved thereby. Against this must be balanced the increase—or the inability to effect future decreases—in the consumer minutes outage resulting from the utilization of a major portion of the available range for protection on the whole distribution system for protecting the transformer.

For example, consider the degree of protection which can be afforded transformers using as a basis the recommended transformer time-load characteristic curves, figure 10*D*, *E*, *F*, and *G* (for the 3, 5, $7\frac{1}{2}$, and 10-kva ratings, respectively). As shown in figure 10, these curves cross the curves for the household fuses *A*, *B*, and *C* (30-, 45-, and 60-ampere ratings, respectively) due to the dissimilarity in the slopes. Thus any attempt to secure complete protection involves having the secondary protective device interrupt service for all the consumers fed by the transformer for any fault on individual consumer's premises of such magnitude and duration that when plotted on figure 10 the point lies to the left of the fuse curves *A*, *B*, or *C* and to the right of the transformer curves *D*, *E*, *F*, or G.

Complete protection involves a further increase in consumer minutes outage. Any lesser degree of protection means some decrease in the life of the transformer. Therefore, using the recommended transformer time-load curves figure 10 as a basis, it is necessary to strike

a balance between the permissible increase in outages and the degree of protection deemed necessary for the transformer, just as has been done for years in choosing the primary fusing practice.

There is another factor entering the problem; namely, the equipment available and its ability to afford protection to the transformer. Breakers are mounted internally in transformers below the oil level to obtain a portion of the heating characteristic of the transformer. However, curve $C''$, figure 11*a* approaches but does not quite equal the flatter transformer time-load curve $B$, figure 11*a*, at the low current long-time end. The breakers are usually set to trip so the curve $C''$ is well to the right of the transformer time-load curve $B$ at the low current long-time end. Even the overload indicator trips on curve $C'$, to the right of the time-load curve $B$.

The primary and secondary fuse links have more inverse time-current characteristics $D$, $E$, $F$, figure 11*b*, than the transformer curve $B$, figures 11*b* and *c*, and the breaker curve $C''$, figures 11*a* and *c*. Thus in general the primary or secondary fuse link affords a slightly lesser degree of protection to the transformer than the breaker at the low current long-time end as shown by the shaded portion $X$ of figure 11*c*. An exception to this is shown by the shaded portion $Y$, figure 11*c*, indicating a range where the fuse link affords better protection. Comparing the curves $D$ and $F$, figure 11*b* with the curve $E$ shows that the primary and secondary fuse links, respectively, will afford an equal degree of protection to the transformer assuming both halves of the secondary are equally loaded. The secondary fuse link or protective device can be used to afford a greater degree of protection without decreasing service continuity only where it can be co-ordinated with the household fuse and the primary fuse link without increasing the fusing practice on the primary.

### 2. Better Primary Fuse Protection With Increased Transformer Capacity

Some distribution engineers are giving consideration to the economics of affording complete, or very nearly complete, protection to the transformer by installing larger transformers and fusing on the primary at a minimum value which will not cause unnecessary outages from overcurrent surges. They are thinking in terms of having the improved regulation and the saving due to decreased transformer burnouts and the omission of extra protective devices pay the interest on the increased investment for the greater installed transformer capacity.

### 3. Use of Protective Devices and Secondary Banking for Higher Loading

Increasing attention is being given to the protection of the transformer with normal low primary fusing practice and with the banking of transformers to take advantage of the diversity of loads on individual transformers to reduce extremes of loading which also improves the instantaneous regulation.

The protective devices are connected in the secondary lines at sectionalizing points between adjacent transformers, which are tied solidly to these lines. Outages

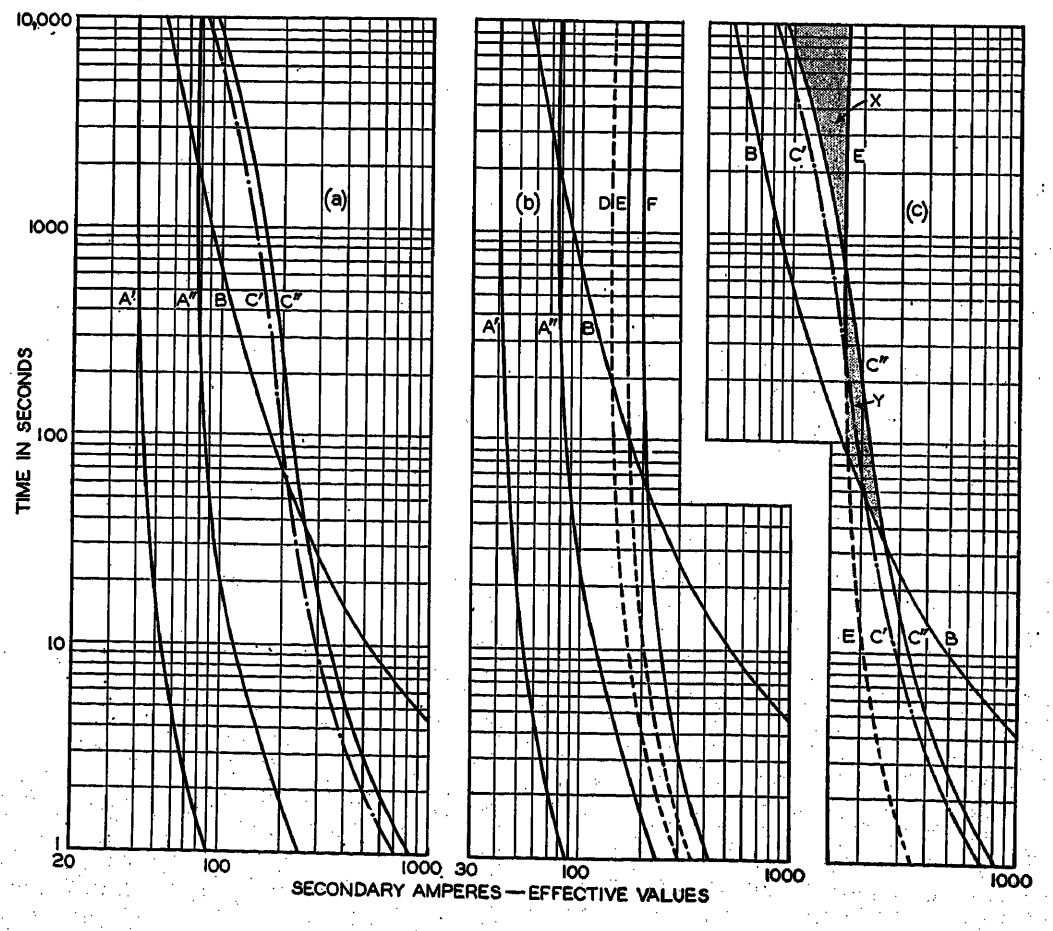

**Fig. 11. Curves showing relative degree of protection afforded distribution transformer by secondary breaker, secondary fuse, or primary fuse on a 2,400 to 240-volt circuit**

*A*—Household plug or cartridge fuse
*A'*—30-ampere rating
*A''*—60-ampere rating
*B*—Recommended transformer characteristic curve
*C*—Secondary breaker and overload indicator
*C'*—Overload indicator lights
*C''*—Breaker opens
*D*—Primary fuse rated at 15 amperes, with no secondary protective device
*E*—Secondary fuse rated at 85 amperes
*X*—Shaded portion showing degree of improved protection afforded by secondary breaker
*Y*—Shaded portion showing degree of improved protection afforded by secondary fuse

from transformer or secondary faults are isolated to the consumers fed by the one transformer. It is not fundamentally important to burn off secondary faults in order to obtain successful operation. The resulting permissible low rating of the secondary and primary protective devices affords generally normal overload protection to the transformer and no decrease in the range available for protection on the primary lines. The co-ordination of the household and secondary fuses can be close since only a maximum of approximately 50 per cent of the current through the household fuse passes through the secondary fuse link.

In some cases the protective devices are placed in the transformer secondary leads and the secondaries of adjacent transformers are tied solidly together to isolate faulty transformers without interrupting service. Faults on the secondary lines or service leads then affect all the consumers on the particular secondary circuit by causing low voltage or the complete loss of service, due to the opening of the secondary protective devices on several or all of the transformers banked on the circuit, known as cascading. The successful operation of banking through protective devices in the transformer leads requires that the majority of the secondary faults clear themselves.

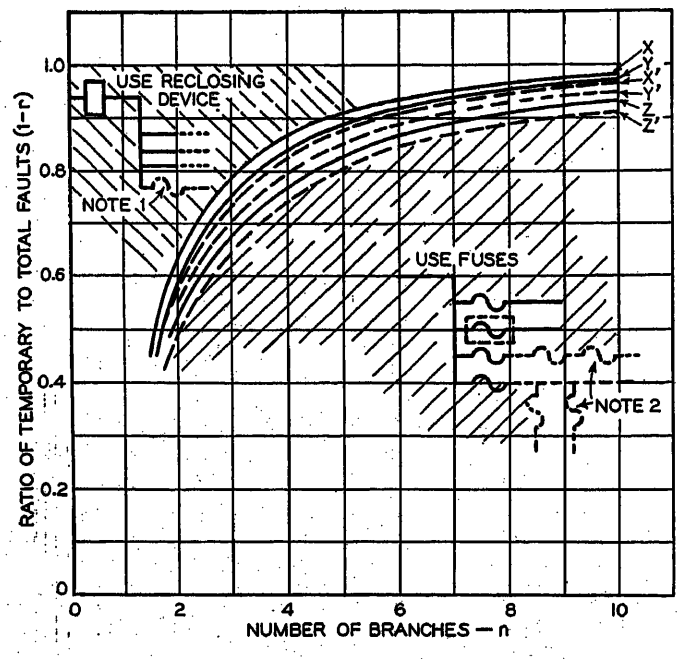

**Fig. 12. Curves showing dividing line above which reclosing equipment, and below which branch line fuses, will reduce consumer minutes of outage for the whole system**

Note 1—Isolating branches on which permanent faults predominate may raise the percentage of temporary faults for the remainder of the system, above the curves

Note 2—Fusing sub-branches or several sectionalizing points will raise the temporary percentage values of the curves

| | X | Y | Z | X' | Y' | Z' |

| Minutes to go to location ($a$) | 30 | 30 | 30 | 60 | 60 | 60 |
| Minutes per branch to locate fault ($b$) | 10 | 5 | 0 | 10 | 5 | 0 |
| Minutes duration of temporary fault ($c$) | 1 | | | | | |

Burning a fault clear, demands that secondary and primary protective devices allow the full use of the transformer thermal capacity which involves all of the problems just discussed as attendant upon the use of secondary protection for the higher loading of individual transformer. A similar compromise must be made between overload protection and service continuity. The higher rating of the protective devices reduces the available range for the protection on the primary lines.

The foregoing consideration of the trends in thinking on solutions for the overcurrent protection of distribution transformers has shown that it evolves into a decision on the relative value of protection to the transformer versus present and future improvements in service continuity for the system as a whole. The success of an operating practice intended to reduce the number of consumers affected by each fault and decrease the length of each outage, centers about the ratings of the fuses required on the primary of the distribution transformers. Schemes for reducing outages due to secondary faults, decreasing transformer burn-outs with increased loading, and improving regulation, should be used with caution if they require increasing the primary fusing practice. Where higher rated fuse links are necessitated in the primary leads of the transformer, the available range is decreased for existing or future protection on the primary lines against the major causes of consumer minutes outage.

## Fusing Transformer Primaries

Among the various trends in thinking, consideration is being given as to whether transformer primaries should be fused with nonrenewable fuses mounted inside the transformer case or with external renewable fuse cut-outs, or whether they should be fused at all.

Nonrenewable fuses, so called "weak links," are mounted inside transformer cases to permit connecting internal gaps on the line side of the fuses and/or to make the transformer and its protective apparatus one unit. Because they are nonrenewable and in blowing will carbonize the insulating oil, the rating of the fuses must be greatly increased, see curves $I'$ or $I''$, figure 9. Internal fuses should blow only in the case of a transformer failure. Fuse blowing otherwise would damage and necessitate the removal of good transformers. The higher primary fusing may decrease the range available for protection on the primary lines as in figure 9, $I'$, $I''$. The lack of a secondary protective device requires the moving of the curves $I'$ and $I''$ still further to the right to prevent unnecessary blowing. This may even prevent proper coordination with the fuses or breaker relay on the primary lines, especially where the fuse ratings or relay settings for line protection are very low on long rural circuits so as to interrupt the flashover of external gaps installed on the transformers for lightning protection. In either case, a probable increase—or prevention of future decrease—in the average consumer minutes outage should be anticipated.

Modern distribution fuse cutouts and renewable fuse links with their background of over 14 years of intensive

*H''*—Equivalent heating of fuse (factors cooling of fuses while recloser is open)
*H'''*—Equivalent heating of fuse, with 25 per cent factor added to permit direct comparison with melting-time curves for fuse *G*
*X*—Maximum current up to which recloser will lock out before fuse link melts

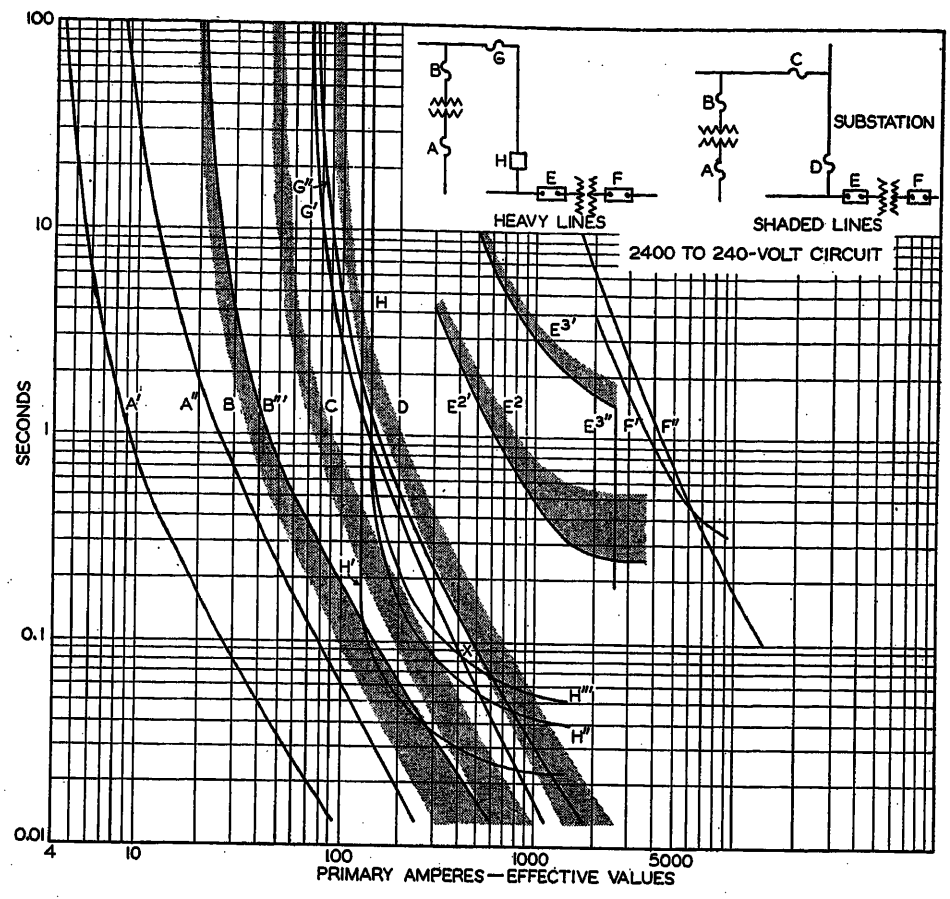

**Fig. 13. Time-current curves for a recloser protecting part of a long line and a fuse cut-out protecting the rest, superimposed on the curves for a conventionally co-ordinated system as shown in figure 3, showing the comparative use of the rangeavail able for distribution protection**

research and engineering development permit the utility engineer to choose the lowest primary fusing practice with assurance of a successful operating record. This cannot be said of some of the earlier designs upon which much of the present-day service data are based. The primary fuse link rating is usually chosen so as to provide a balance between unnecessary fuse blowing and protection afforded the apparatus, and/or proper co-ordination with protective devices on the secondary of the transformer. A fuse cutout provides an easy means for manually disconnecting transformers and for easily and quickly locating those which are damaged.

The prevalence of lightning in some localities makes it desirable to limit the size of transformer primary fuse links to a certain minimum in order to take advantage of the ability of the larger links to more successfully withstand lightning impulses. This is especially true where the lightning arrester is connected on the load side of the fuse cutout. A minimum rating of 10 amperes will generally eliminate the majority of unnecessary fuse blowing and will not ordinarily interfere greatly with proper primary co-ordination. Saving one fuse replacement trip will usually more than pay for the installation of secondary fuses on the smaller sizes of transformers to provide the same overload protection as would be given by the smaller primary fuse link that would normally be used.

The omission of fuses on the primary of distribution transformers is virtually the same as adding miles of exposure to the primary lines. A service interruption to all the consumers on such a line may result from a line fault or a transformer flashover or burnout; or a secondary line fault if no secondary protective device is employed. The cause of each outage must be sought among every one of these possibilities, thus greatly increasing the length of each interruption. The use of secondary fuses or breakers while affording a degree of protection to the transformer, merely removes the secondary line as a possible cause of trouble. Therefore, where primary fuses are omitted, a marked increase in consumer minutes outage can be anticipated over that occurring where protection is afforded the individual transformer by modern fuse cut-outs and renewable fuse links.

## Primary Line Faults

With the fuse link on the primary of distribution transformers kept as small as possible, the effect of faults on

the primary lines can be reduced by the introduction of the properly located protective devices. The choice between fuses and automatic reclosing devices is largely dependent upon the ratio of temporary faults to permanent faults on the whole and each portion of the distribution system. Of course, there is also the question of economics and the importance of loads. Superior service continuity can be secured by the use of fuses at a number of sectionalizing points on the primary lines especially where a fairly high percentage of the faults are permanent. Automatic reclosing equipment will reduce the average consumer minutes outage where temporary faults predominate. This equipment may be a breaker or a recloser which reset themselves after interrupting temporary fault currents, or a reclosing fuse cutout which requires periodic inspection and renewal of blown fuse links.

The dividing line between the percentage of temporary versus permanent faults above which reclosing equipment located either in the station or at branch lines, and below which sectionalizing fuses, will reduce the consumer minutes outage is shown in figure 12. These values were derived using the following formula, with the indicated assumptions as to the times required to restore service.

$r$ = ratio of permanent to total number of faults
$1 - r$ = ratio of temporary to total number of faults
$P$ = faults per branch
$a + nb$ = duration of permanent fault
$a$ = minutes to go to location
$b$ = minutes to locate fault per branch
$n$ = number of branches
$e$ = duration of temporary fault
$N$ = number of consumers per branch

Total consumer minutes outage per year with reclosing device = $nPr\,(a + nb)\,(nN) + Pn\,(1 - r)\,(e)\,(nN)$
Total consumer minutes outage per year with sectionalizing fuses at each branch or sub-branch = $nP\,(a + b)\,N$

$$\text{ratio} = \frac{\text{minutes outage with reclosing device}}{\text{minutes outage with sectionalizing fuse}}$$

$$= \frac{n^2 PN[r\,(a + nb) + e\,(1 - r)]}{nPN\,(a + b)}$$

$$= \frac{n\,(ra + rnb + e - er)}{a + b}$$

The lower cost, nonreclosing fuse cutout can perform a real service for reducing consumer minutes outage both as to the effect and the length of outages. The curves figure 12 show the advantage of connecting fuse cutouts and fuse links in several branch lines. The use of additional fuses at sub-branches or in series at various sectionalizing points, will raise the curves figure 12. For example, with 3 fused branches each having one fused sub-branch, curve $x$ figure 12 will be raised from 79.1 per cent to 84.7 per cent and with 2 sub-branches each to 89.2 per cent. Connecting one and 2 fuses in series with each branch line fuse will raise curve $x$ figure 12 from 79.1 per cent to 84.7 per cent, respectively. In addition to those greater benefits due to the confinement of the effect of faults to fewer consumers, the time to locate the faults will be reduced and the curves figure 12 raised, for example, the 89.2 per cent and 84.7 per cent values given above will be raised to 91.2 per cent and 86.9 per cent, respectively, with a proportionate reduction in time to the length of line affected.

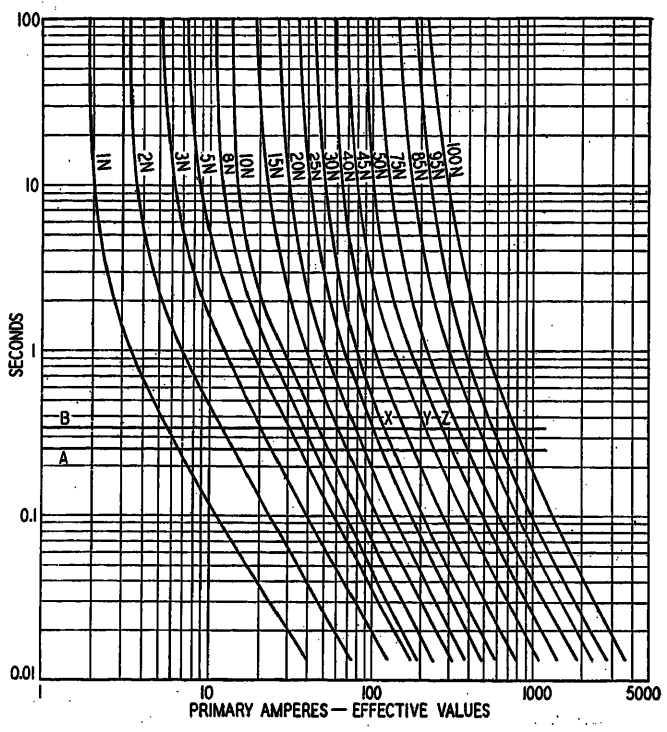

**Fig. 14. Melting time-current characteristic curves for fuse links with lines A and B showing time required to open the feeder breaker, the limiting factor for co-ordinating so that the first opening of the breaker is ahead of the fuse link**

*A*—Time required for instantaneous ground relay and breaker to open
*B*—Factor of 25 per cent added to curve A to permit direct comparison with melting-time curves of fuse links
*X*—Maximum current up to which breaker will clear ahead of 30*N* ampere fuse link
*Y*—Maximum current with 45*N* ampere fuse link
*Z*—Maximum current with 50*N* ampere fuse link

The effectiveness of reclosing fuse cutouts depends on the periodic inspection and replacement of blown fuse links before an outage occurs. If they are not refused until both or all 3 fuse links have blown, their use should tend to raise the curves figure 12 up to which they will improve service continuity. If periodically inspected and a majority of the blown fuse links are replaced before an outage occurs, their performance approximates the reclosing devices indicated on the curves, figure 12.

Both conventional reclosing oil circuit breakers and the lower cost mechanical breakers known as circuit reclosers, are available for use at sectionalizing points. The relay actuating the conventional oil circuit breaker functions with the induction relay characteristics which are similar to those for the modern distribution fuse links, figure 8*B*, *C*, and *D*. Thus the introduction of this equipment permits reasonably close co-ordination with the fuse links at transformer installations and at any desirable sectionalizing point.

The instantaneous plunger type relay characteristics of the circuit recloser figure 13*H'* definitely limit the rating of fuse links which will blow before the first opening

of the recloser, to low values (the fuse link curves which are to the left of the respective recloser curves figure 7*a*). The ratings of practically all internal fuses, or "weak links," are too high to blow soon enough to prevent lockout of the recloser. If the fuses further out on the system are too large to blow before the recloser locks out, a fuse cutout can be connected across the recloser to permit manually by-passing it through a fuse after the recloser locks out. The fuse link in the cutout should be large enough to allow the internal fuses or sectionalizing fuses beyond the recloser to blow first, so as to indicate the location of the fault.

On long lines the recloser can be used for that portion where the fault currents will be greater than the minimum current required to pick up the contact so that it actuates the lockout mechanism. A fuse cutout, installed within this portion, can be fused, figure 13*G*, so as to permit the recloser to lock out on fault currents above the minimum pick-up. The location of the cutout should be such that the maximum fault current available at the point of installation does not exceed the value at which the melting time current curve 13*G'* crosses the recloser curve, figure 13*H'''*, at *X*. Then the fuse cutouts will afford protection for all fault currents below the minimum pick-up of the recloser; in most cases reaching out to the end of a long line. The fuse link can also be co-ordinated with the relay on the main feeder breaker, figure 13*F'* and *F''*.

Automatic reclosing oil circuit breakers are more generally installed at the substation to improve continuity of service to the more important consumers on the main feeder and larger branches. By fusing branches of the circuit where permanent faults predominate, the percentage of temporary faults on the important parts may be raised so the reclosing breakers will reduce the consumer minutes outage for the whole system, note 1, figure 12, as well as for the important loads.

Several large utility companies report an improvement in service continuity resulting from the combination of branch line fusing and automatic reclosing breakers at the substation. Their scheme is applicable on grounded neutral systems where the instantaneous relay, connected to operate on ground and/or neutral currents, can be set to pick up at very low currents for the initial opening of the breaker. A grounding bank can be used to provide the neutral on delta systems. After the first opening, the instantaneous relay locks out and the induction relays, connected in the phase wires are automatically switched on for the subsequent operations to the lockout of the breaker. However, in the case of a permanent fault on a branch line the fuse links and induction relays are coordinated so a time delay is provided and the fuse links clear ahead of the second relay operation. The ground relay is automatically reconnected in the case of a temporary fault or after the fuse disconnects the branch. A practical set-up for the fusing of branch lines in this way automatically differentiates between temporary and permanent faults to neutral and ground.

The successful functioning of such an arrangement depends on the time required for the breaker to open and interrupt the fault current, after the instantaneous ground relay has closed the trip circuit. For example, a relay and breaker requiring a total time of 15 cycles (0.25 second) to clear the circuit, will successfully clear temporary faults up to 125 amperes without damaging a 33*N* ampere branch line sectionalizing fuse link of the design for which the curves figure 14 are plotted. This is indicated by the point *X*, figure 14, where the melting time curve for the fuse link crosses the curve *B* plotted so as to allow a 25 per cent factor for operating and manufacturing variables above line *A* drawn at 0.25 second. Under similar conditions, a 45*N* ampere fuse link will not be damaged up to 205 amperes, and a 50*N* ampere fuse link up to 270 amperes (points *Y* and *Z*, figure 14, respectively). If the short-circuit current available at the point of installation for the sectionalizing fuse cutout exceeds these values, the fuse link may be partially melted. If it is not replaced subsequent melting on load currents may cause arcing which will not clear and will burn the fuse tube of cutouts that provide no mechanical means for separating the burned ends of the fuse link.

One utility company reports that it has been their experience based on observations of actual operating conditions, as well as field tests, that those circuits which are fused with the 30*N* ampere fuse links usually have shorts which range between 100 and 150 amperes, while the circuits on which the 50*N* (60) ampere fuse links are used, run between 200 and 300 amperes. In the cases where it is definitely known a heavy phase short circuit has taken place, it is the operating practice to replace both fuses. From this it would appear practical to secure the combined advantages of automatic reclosing for temporary line-to-ground or line-to-neutral faults and fused sectionalizing for isolating permanent line-to-ground and line-to-neutral and line-to-line faults to small areas. Such a practice should afford a marked decrease in the consumer minutes of outage.

## Summary

In the foregoing an attempt has been made to make an impartial study of the various trends in thinking with respect to the overcurrent protection on distribution systems. This has been done from the standpoint of the effect of each on the service continuity, the protection to apparatus, and the system economy. Major emphasis has been given to service continuity as present-day consumer requirements have increased the utility companies' interest in reducing outages to a minimum. A number of pertinent factors have been brought out which are generally applicable to any such studies that might be made on specific systems. A tabulation of these without doubt, will be of value.

1. Actual operating records on the system in question are essential.
2. The data in such records will be enhanced in value if selected to show the differences,

*a*. On urban, suburban, and rural sections,

*b*. On main feeders, branch feeders, distribution transformers, and secondary lines,

*c*. Between causes of faults such as lightning, short circuits, overloads, etc.,

*d.* Between types of faults, temporary vs. permanent,

*e.* Between modern and old equipment.

3. Such records will show that one permanent fault on the primary lines will cause upward to 100 times as many consumer minutes outage as one fault in a transformer or on the secondary lines, and that generally a greater percentage of faults occur on the primary lines.

4. Secondary protection to continuity and/or apparatus which can be secured without increasing the normal fusing practice on the primary of the distribution transformer (generally 2 or 3 times the full load current of the transformer) will improve service continuity.

5. Conversely, any increasing of the normal primary fusing practice to secure other advantages very likely will increase—or prevent future decreases in—the average consumer minutes outage for the whole system.

6. The use of the external fuse cutout with renewable fuse links enables the use of the lowest possible fusing practice, spoken of as normal. Modern equipment insures an improved service record.

7. The normal fusing practice while termed short-circuit protection, affords a fairly high degree of protection to the transformer as indicated by operating records; such as those where higher internal fusing has been employed with no secondary protection.

8. The use of nonrenewable internal fuses necessitates increasing the primary fusing practice, and without a secondary fuse or breaker affords no protection to the transformer.

9. The omission of fuses on the primary virtually adds miles of exposure to cause and on which to locate, trouble on the primary lines.

10. The ratio of temporary to permanent faults on the whole and various parts of the system governs the benefits in improved continuity of service rendered by fuse cutouts at sectionalizing points and by automatic reclosing equipment.

*a.* Fusing sectionalizing points on the primary lines to confine the effect of outages to small areas will reduce the average consumer minutes outage even with high ratios of temporary to permanent faults (see figure 12).

*b.* Automatic reclosing equipment or reclosers at the substation or in branch lines will reduce the consumer minutes outage where the percentage of temporary faults is high. This percentage in some instances can be improved by fusing branches where permanent faults predominate.

*c.* A practical arrangement for automatically combining sectionalizing fuse and automatic reclosing protection so as to differentiate between temporary and permanent faults will produce the best results.

## A New Service Restorer

(*Continued from page 182*)

Film *B* shows the record of 2 interruptions with 12,000 volts across the terminals, the current being 960 and 880 amperes, respectively. Film *C* shows 4 interruptions (3 reclosures and a final lockout) of 400 amperes at 12,000 volts. Reclosure is immediate after each opening, the average reclosing time from the instant the fault occurs until the device recloses being 31 cycles.

The service restorer was developed primarily for low-capacity low-revenue lines and it is hoped that it will be a real contribution toward the improvement of electric power service by providing an economical and efficient automatic reclosing device for such applications. It should be ideally suited for sectionalizing lines and protecting feeders in rural and suburban districts as well as for use at small isolated industrial and mining properties where a continuous power supply is important.

# Expansion Theorems for Ladder Networks

By MICHEL G. MALTI

S. E. WARSCHAWSKI
NONMEMBER

**The well-known expansion theorem of Heaviside applies to circuits whose current-electromotive force relations may be expressed through differential equations, whereas in some networks such as filters and artificial lines, in which the network consists of a repeated pattern or mesh, the relations give what are known as difference equations. These are equations involving the mesh number of the network. The solutions of such networks are given in this paper in the form of expansion theorems similar to Heaviside's expansion theorem and its extensions.**

THE current-electromotive force relations of filter circuits, artificial lines, and other ladder networks lead to difference equations whose solutions have been given by Pupin,[1] Rüdenberg,[3] Wagner,[4–6] Rogowski,[7,8] Carson,[9–11] Zobel,[11–13] Cauer,[21–23] Alford,[25] and others.[2,14–20,24,26,27] Mathematical work on difference equations has been going on since the days of Newton, Laplace, and Gauss (18th century). Treatises on difference equations have been written by Nörlund,[31] Batchelder,[32] and F. Bleich[29] and E. Melan.[29]

Although Laplace transformations have been used in the treatment of linear difference equations with constant coefficients, particularly by Bochner,[30] the authors do not know of any results which parallel Heaviside's expansion theorem and its extensions for differential equations.[28] The object of this paper is to develop such expressions by the use of Laplace transformations.

## 1. Solution of a Difference Equation

Consider the following linear difference equation of the $n$th order with constant coefficients $a_k$:

$$a_0 f(x) + a_1 f(x+1) + \ldots + a_n f(x+n) = \phi(x) \tag{1}$$

In equation 1, $a_0 \neq 0$, $a_n \neq 0$. This does not detract from the generality of equation 1 because if $a_0 = 0$, then substituting $x$ for $x + 1$ reduces equation 1 to a difference equation of lower order. On the other hand if $a_n = 0$ then again the order of equation 1 is reduced.

Again $\phi(x)$ is a given function which satisfies the following conditions:

1. $\phi(x)$ is of bounded variation in any finite interval
2. $\phi(x) \equiv 0$ for $x < 0$
3. $\phi(x) = [\phi(x+0) + \phi(x-0)]/2$ for every $x$
4. $\int_0^\infty | \phi(x) \epsilon^{-ux} | \, dx$ converges if the real part of $u$ is sufficiently large.

It may be here observed that all functions encountered in engineering practice do satisfy these conditions.

In addition to equation 1 certain boundary conditions must be given. As boundary conditions we shall assume that $f(x)$ is known over the interval $0 \leqq x < n$ and that in this interval $f(x)$ is of bounded variation and $f(x) = [f(x+0) + f(x-0)]/2$. The solution of equation 1 consists in determining $f(x)$ which

1. Satisfies equation 1 for all $x \geqq 0$;
2. Is equal to the given boundary function for $0 \leqq x < n$

Multiply both sides of equation 1 by $\epsilon^{-ux} dx$ and integrate between zero and infinity thus:

$$\sum_{k=0}^{n} \int_0^\infty a_k f(x+k) \epsilon^{-ux} dx = \int_0^\infty \phi(x) \epsilon^{-ux} dx \tag{2}$$

where $u$ is any complex number whose real part is positive and sufficiently large.

Consider a typical term of the sum in equation 2. Let $x + k = y$ then $dx = dy$, $x = y - k$. When $x = 0$, $y = k$ and when $x = \infty$, $y = \infty$. Substitute these relations in the left side of equation 2 and obtain:

$$\sum_{k=0}^{n} a_k \epsilon^{ku} \int_k^\infty f(y) \epsilon^{-uy} dy = \int_0^\infty \phi(x) \epsilon^{-ux} dx \tag{3a}$$

or

$$\sum_{k=0}^{n} a_k \epsilon^{ku} \left[ \int_0^\infty f(x) \epsilon^{-ux} dx - \int_0^k f(x) \epsilon^{-ux} dx \right] = \int_0^\infty \phi(x) \epsilon^{-ux} dx \tag{3b}$$

Since $f(x)$ is known for $0 \leqq x < n$ and since $k \leqq n$, therefore the second integral in each term of the sum to the left of equation 3$b$ is known. Again since $\phi(x)$ is known the integral to the right of equation 3$b$ is also known. Let:

$$\Psi(u) = \sum_{k=0}^{n} a_k \epsilon^{uk} \int_0^k f(x) \epsilon^{-ux} dx \tag{4a}$$

$$\Phi(u) = \int_0^\infty \phi(x) \epsilon^{-ux} dx \tag{4b}$$

Substitute equation 4 in 3$b$ and obtain:

$$\sum_{k=0}^{n} a_k \epsilon^{uk} \int_0^\infty f(x) \epsilon^{-ux} dx = \Phi(u) + \Psi(u) \tag{5a}$$

or

$$\int_0^\infty f(x) \epsilon^{-ux} dx = F(u) \tag{5b}$$

where

$$F(u) = [\Phi(u) + \Psi(u)] \Big/ \sum_{k=0}^{n} a_k \epsilon^{ku} \tag{5c}$$

A paper recommended for publication by the AIEE committee on electrophysics. Manuscript submitted November 6, 1936; released for publication December 1, 1936.

MICHEL G. MALTI is assistant professor of electrical engineering, and S. E. WARSCHAWSKI is a research assistant at Cornell University, Ithaca, N. Y.

1. For all numbered references see list at end of paper.

Equation 5*b* is a well-known integral equation whose solution is:

$$f(x) = \frac{1}{2\pi j}\int_{b-j\infty}^{b+j\infty} F(u)\epsilon^{ux}du \tag{6}$$

where $b$ is a sufficiently large positive number.

Equation 6 is the solution of equation 1. It is given in the form of a complex integral which may be readily evaluated (see section 3).

## 2. Solution of a System of Difference Equations

Consider the following system of linear difference equations of the $n$th order with constant coefficients $a_{lrk}$:

$$\sum_{r=1}^{m}\sum_{k=0}^{m_r} a_{1rk}f_r(x+k) = \phi_1(x) \tag{7a}$$

$$\sum_{r=1}^{m}\sum_{k=0}^{m_r} a_{2rk}f_r(x+k) = \phi_2(x) \tag{7b}$$

.....

$$\sum_{r=1}^{m}\sum_{k=0}^{m_r} a_{mrk}f_r(x+k) = \phi_m(x) \tag{7m}$$

where $\phi_l(x)$ are given functions which satisfy the conditions imposed on $\phi(x)$ in section 1; $f_r(x)$ are unknown functions. As to the boundary conditions we shall assume that $f(x)$ is known over the interval $0 \leqq x < m_r$ and that in this interval $f_r(x)$ is of bounded variation and $f_r(x) = [f_r(x+0) + f_r(x-0)]/2$. The problem is to determine $f_r(x)$ which satisfy the system of difference equations 7 for all $x \geqq 0$ and the boundary conditions for $0 \leqq x < m_r$.

Multiply both sides of each of equations 7 by $\epsilon^{-ux}dx$ and integrate between zero and infinity. Then a typical equation becomes:

$$\sum_{r=1}^{m}\sum_{k=0}^{m_r}\int_0^\infty a_{lrk}f_r(x+k)\epsilon^{-ux}dx = \int_0^\infty \phi_l(x)\epsilon^{-ux}dx \tag{8}$$

where $l = 1, 2, 3, \ldots m$.

Substitute $x + k = y$ in equation 8 and obtain as in equation 3*b*:

$$\sum_{r=1}^{m}\sum_{k=0}^{m_r} a_{lrk}\epsilon^{uk}\left[\int_0^\infty f_r(x)\epsilon^{-ux}dx - \int_0^k f_r(x)\epsilon^{-ux}dx\right] = \int_0^\infty \phi_l(x)\epsilon^{-ux}dx \tag{9}$$

Since $f_r(x)$ is known for $0 \leqq x < m_r$ and since in each inner sum $k \leqq m_r$, therefore the second integral to the left in equation 9 is known. Again, since each $\phi_l(x)$ is known, the integral to the right of equation 9 is also known. Let:

$$\Psi_l(u) = \sum_{r=1}^{m}\sum_{k=0}^{m_r} a_{lrk}\epsilon^{uk}\int_0^k f_r(x)\epsilon^{-ux}dx \tag{10a}$$

$$\Phi_l(u) = \int_0^\infty \phi_l(x)\epsilon^{-ux}dx \tag{10b}$$

Substitute equations 10 in 9 and obtain:

$$\sum_{r=1}^{m}\sum_{k=0}^{m_r} a_{lrk}\epsilon^{uk}\int_0^\infty f_r(x)\epsilon^{-ux}dx = \Phi_l(u) + \Psi_l(u) = M_l(u) \tag{11}$$

Let:

$$\sum_{k=0}^{m_r} a_{lrk}\epsilon^{uk} = A_{lr}(\epsilon^u) \tag{12a}$$

$$\int_0^\infty f_r(x)\epsilon^{-ux}dx = F_r(u) \tag{12b}$$

Substituting equations 12 in equation 11 and remembering that we have $m$ such equations because $l$ assumes all integer valves between 1 and $m$, we have:

$$\sum_{r=1}^{m} A_{1r}(\epsilon^u)F_r(u) = M_1(u) \tag{13a}$$

$$\sum_{r=1}^{m} A_{2r}(\epsilon^u)F_r(u) = M_2(u) \tag{13b}$$

.....

$$\sum_{r=1}^{m} A_{mr}(\epsilon^u)F_r(u) = M_m(u) \tag{13m}$$

Expanding equations 13 we obtain

$$A_{11}(\epsilon^u)F_1(u) + A_{12}(\epsilon^u)F_2(u) + \ldots + A_{1m}(\epsilon^u)F_m(u) = M_1(u) \tag{14a}$$

$$A_{21}(\epsilon^u)F_1(u) + A_{22}(\epsilon^u)F_2(u) + \ldots + A_{2m}(\epsilon^u)F_m(u) = M_2(u) \tag{14b}$$

.....

$$A_{m1}(\epsilon^u)F_1(u) + A_{m2}(\epsilon^u)F_2(u) + \ldots + A_{mm}(\epsilon^u)F_m(u) = M_m(u) \tag{14m}$$

Solving equations 14 simultaneously for $F_r(u)$ we have:

$$F_r(u) = [\Delta_{1r}(\epsilon^u)M_1(u) + \Delta_{2r}(\epsilon^u)M_2(u) + \ldots + \Delta_{mr}(\epsilon^u)M_m(u)]/\Delta(\epsilon^u) \tag{15}$$

where

$$\Delta(\epsilon^u) = \begin{vmatrix} A_{11}(\epsilon^u) & A_{12}(\epsilon^u) & \ldots & A_{1m}(\epsilon^u) \\ A_{21}(\epsilon^u) & A_{22}(\epsilon^u) & \ldots & A_{2m}(\epsilon^u) \\ \ldots & \ldots & \ldots & \ldots \\ A_{m1}(\epsilon^u) & A_{m2}(\epsilon^u) & \ldots & A_{mm}(\epsilon^u) \end{vmatrix} \tag{16}$$

and $\Delta_{pq}(\epsilon^u)$ is the minor of $\Delta$ obtained by omitting the $p$th row and $q$th column and multiplying the determinant so obtained by $(-1)^{(p+q)}$.

Substituting equation 15 in 12*b* we have

$$\int_0^\infty f_r(x)\epsilon^{-ux}dx = F_r(u) = \sum_{l=1}^{m}\Delta_{lr}(\epsilon^u)M_l(u)/\Delta(\epsilon^u) \tag{17}$$

Equation 17 is of the same form as 5*b*. Hence its solution is:

$$f_r(x) = \frac{1}{2\pi j}\int_{b-j\infty}^{b+j\infty} F_r(u)\epsilon^{ux}du \tag{18}$$

## 3. Evaluation of the Integrals of Equations 6 and 18

The complex integrals given in equations 6 and 18 are not usable in their present form. They must be evaluated before the functions $f(x)$ and $f_r(x)$ can be computed in any engineering problem. These integrals have, accord-

ingly been evaluated by us. The actual evaluation is of mathematical interest only. We therefore give here the results.

Referring to the difference equation 1 let:

$$P(\epsilon^u) = \sum_{k=0}^{n} a_k \epsilon^{ku} \tag{19a}$$

$$Q_s(\epsilon^u) = \sum_{k=0}^{n-s} a_{(k+s)} \epsilon^{ku} \tag{19b}$$

If the polynomial $P(\epsilon^u)$ has distinct (unequal) roots $\alpha_k$ then by decomposition into partial fractions we obtain:

$$1/P(\epsilon^u) = \sum_{k=1}^{n} B_k/(\epsilon^u - \alpha_k) \tag{20a}$$

$$Q_s(\epsilon^u)/P(\epsilon^u) = \sum_{k=1}^{n} B_{ks}/(\epsilon^u - \alpha_k) \tag{20b}$$

where

$$B_k = 1/P'(\alpha_k); \qquad B_{ks} = Q_s(\alpha_k)/P'(\alpha_k) \tag{21}$$

On the other hand if the polynomial $P(\epsilon^u)$ has $\lambda$ roots $\alpha_k$, each repeated $n_k$ times, then decomposition into partial fractions gives:

$$1/P(\epsilon^u) = \sum_{k=1}^{\lambda} \sum_{r=1}^{n_k} B_{kr}/(\epsilon^u - \alpha_k)^r \tag{22a}$$

$$Q_s(\epsilon^u)/P(\epsilon^u) = \sum_{k=1}^{\lambda} \sum_{r=1}^{n_k} B_{krs}/(\epsilon^u - \alpha_k)^r \tag{22b}$$

where

$$B_{kr} = [\psi_k^{(n_k-r)}(\alpha_k)]/(n_k - r)! \tag{23a}$$

$$B_{krs} = [\psi_{ks}^{(n_k-r)}(\alpha_k)]/(n_k - r)! \tag{23b}$$

$$\psi_k(\epsilon^u) = [\epsilon^u - \alpha_k]^{n_k}/P(\epsilon^u) \tag{23c}$$

$$\psi_{ks}(\epsilon^u) = Q_s(\epsilon^u)[\epsilon^u - \alpha_k]^{n_k}/P(\epsilon^u) \tag{23d}$$

With these notations the integral equation 6 becomes, for distinct and repeated roots respectively of $P(\epsilon^u)$:

$$f(x) = \sum_{k=1}^{n} B_k \sum_{c=0}^{[x]-1} \alpha_k^c \phi(x - c - 1) + \sum_{s=1}^{n} \sum_{k=1}^{n} B_{ks} \alpha_k^{[x]} f(x - [x] + s - 1) \tag{24a}$$

$$f(x) = \sum_{k=1}^{n} \sum_{r=1}^{n_k} B_{kr} \sum_{c=0}^{[x]-r} \binom{r+c-1}{c} a_k^c \phi(x - r - c) + \sum_{s=1}^{n} \sum_{k=1}^{\lambda} \sum_{r=1}^{n_k} B_{krs} \binom{[x]}{[x]-r+1} \alpha_k^{([x]-r+1)} f(x - [x] + s - 1) \tag{24b}$$

In equations 24:

1. $\binom{a}{b} = 0$ if $b < 0$
2. $x$ is a positive non-integer
3. If $x$ is a positive integer then $f(x) = [f(x + 0) + f(x - 0)]/2$ and $f(0) = f(0 + 0)/2$

Equation 24*a* may be termed Heaviside's expansion theorem for difference equations; while equation 24*b* is

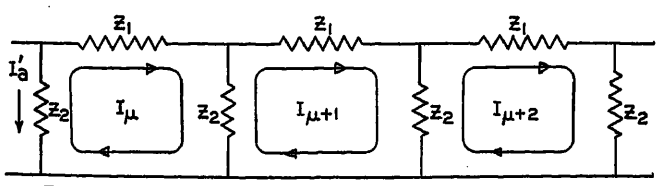

**Fig. 1. Schematic diagram of a ladder network**

the extension of that theorem to the case of repeated roots[28] of $P(\epsilon^u)$.

Next referring to the system of difference equations 7 let:

$$\Delta(\epsilon^u) = \sum_{k=0}^{n} b_k \epsilon^{ku}, \quad \Delta_{lr}(\epsilon^u) = \sum_{\nu=0}^{q_{lr}} b_{lr\nu} \epsilon^{\nu u} \tag{25a}$$

$$Q_{lrps}(\epsilon^u) = \sum_{k=s}^{m_p} a_{lpk} \epsilon^{ku} \Delta_{lr}(\epsilon^u) = \sum_{\nu=0}^{m_p+q_{lr}} \beta_{lrps\nu} \epsilon^{\nu u} \tag{25b}$$

Then the expansion of $1/\Delta(\epsilon^u)$ in partial fractions is given by equations 20*a* and 22*a* respectively where $\Delta(\epsilon^u)$ replaces $P(\epsilon^u)$. With these notations the integral in equation 18 becomes:

$$f_r(x) = \sum_{l=1}^{m} [f_{lra}(x) + f_{lrb}(x)] \tag{26}$$

where

(*a*) *For distinct roots of* $\Delta(\epsilon^u)$

$$f_{lra}(x) = \sum_{\nu=0}^{q_{lr}} b_{lr\nu} \sum_{k=1}^{n} B_k \sum_{c=0}^{\nu+[x]-1} \alpha_k^c \phi_l(\nu + x - c - 1) \tag{27a}$$

$$f_{lrb}(x) = \sum_{p=1}^{m} \sum_{s=1}^{m_p} \sum_{\nu=0}^{m_p+q_{lr}} \beta_{lrps\nu} \sum_{k=1}^{n} B_k \alpha_k^{[x]} f_p(x - [x] + s - 1) \tag{27b}$$

(*b*) *For repeated roots of* $\Delta(\epsilon^u)$

$$f_{lra}(x) = \sum_{\nu=0}^{q_{lr}} b_{lr\nu} \sum_{k=1}^{\lambda} \sum_{r=1}^{n_k} B_{kr} \sum_{c=0}^{\nu+[x]-r} \binom{r+c-1}{c} \times \alpha_k^c \phi_l(\nu + x - r - c) \tag{28a}$$

$$f_{lrb}(x) = \sum_{p=1}^{m} \sum_{s=1}^{m_p} \sum_{\nu=0}^{m_p+q_{lr}} \beta_{lrps\nu} \sum_{k=1}^{\lambda} \sum_{r=1}^{n_k} B_{kr} \times \binom{[x]}{[x]-r+1} \alpha_k^{([x]-r+1)} f_p(x - [x] + s - 1) \tag{28b}$$

In equations 27 and 28:

1. $\binom{a}{b} = 0$ if $b < 0$
2. $x$ is a positive non-integer
3. $\Delta(\epsilon^u)$ has no zero roots

If $\Delta(\epsilon^u)$ has a zero root of the $n_0$th order then $x$ in equations 27 and 28 should be replaced by $x - n_0$ and $\Delta(\epsilon^u)$ in 25, 20*a*, and 22*a* should be replaced by $\Delta_1(\epsilon^u)$ where

$$\Delta(\epsilon^u) = \epsilon^{n_0 u} \Delta_1(\epsilon^u) \tag{29}$$

Equations 26, 27, and 28 correspond to the extensions of Heaviside's expansion theorem[28] to systems of differential equations.

## 4. Application to Ladder Networks

Consider the ladder network figure 1. Writing Kirchhoff's equations for any one element we have:

$$Z_1 I_{\mu+1} + Z_3(I_{\mu+1} - I_{\mu+2}) + Z_3(I_{\mu+1} - I_\mu) = 0 \tag{30a}$$

or

$$Z_3 I_\mu - (Z_1 + 2Z_3) I_{\mu+1} + Z_3 I_{\mu+2} = 0 \tag{30b}$$

Equation 30*b* is a difference equation of the second order similar to equation 1 where:

$$f(x) = I_\mu \text{ for } \mu - 1 < x < \mu \tag{31a}$$

$$a_0 = Z_3, \qquad a_1 = -(Z_1 + 2Z_3), \qquad a_2 = Z_3 = a_0 \tag{31b}$$

$$\phi(x) \equiv 0, \qquad n = 2 \tag{31c}$$

From equations 19 we have

$$P(\epsilon^u) = \sum_{k=0}^{2} a_k \epsilon^{ku} = a_0 + a_1 \epsilon^u + a_2 \epsilon^{2u} \tag{32a}$$

$$Q_1(\epsilon^u) = \sum_{k=0}^{2-1} a_{(k+1)} \epsilon^{ku} = a_1 + a_2 \epsilon^u \tag{32b}$$

$$Q_2(\epsilon^u) = \sum_{k=0}^{0} a_{(k+2)} \epsilon^{ku} = a_2 \tag{32c}$$

The roots of $P(\epsilon^u)$ are:

$$\alpha_1 = \left[-a_1 + \sqrt{a_1^2 - 4a_0a_2}\right]/2a_2; \qquad \alpha_2 = \left[-a_1 - \sqrt{a_1^2 - 4a_0a_2}\right]/2a_2 \tag{33}$$

We shall assume that $\alpha_1 \neq \alpha_2$. It must be also noted that:

$$\alpha_1\alpha_2 = 1 \tag{34}$$

Equations 21 reduce, in this case, to:

$$B_1 = 1/(a_1 + 2a_2\alpha_1) \qquad B_2 = 1/(a_1 + 2a_2\alpha_2) \tag{35a}$$

$$B_{11} = (a_1 + a_2\alpha_1)/(a_1 + 2a_2\alpha_1) \qquad B_{12} = a_2/(a_1 + 2a_2\alpha_1) \tag{35b}$$

$$B_{21} = (a_1 + a_2\alpha_2)/(a_1 + 2a_2\alpha_2) \qquad B_{22} = a_2/(a_1 + 2a_2\alpha_2) \tag{35c}$$

Substituting equations 31 to 35 in 24*a* and remembering that $\phi(x) \equiv 0$ and that (see equation 31*a*) $f(x - [x] + s - 1) = I_s$ and $[x] = \mu - 1$ we have:

$$I_\mu = \sum_{s=1}^{2}\sum_{k=1}^{2} B_{ks}\alpha_k^{(\mu-1)} I_s \tag{36a}$$

$$= (B_{11}I_1 + B_{12}I_2)\alpha_1^{(\mu-1)} + (B_{21}I_1 + B_{22}I_2)\alpha_2^{(\mu-1)} \tag{36b}$$

$$= K_1\epsilon^{\mu \ln \alpha_1} + K_2\epsilon^{\mu \ln \alpha_2} \tag{36c}$$

Equation 36*c* is the form generally encountered in engineering literature.

One more fact might be brought out before leaving this illustrative problem. Quite often the boundary conditions relate not to 2 successive elements but to the 2 ends of a line (say $I_1$ and $I_N$ are given). Such cases could be readily worked out by the use of equation 36*b* or equation 36*c*. Thus in equation 36*b*, substitute $\mu = N$ and solve for $I_2$ thus reducing the problem to the given boundary conditions. On the other hand, if we assume both

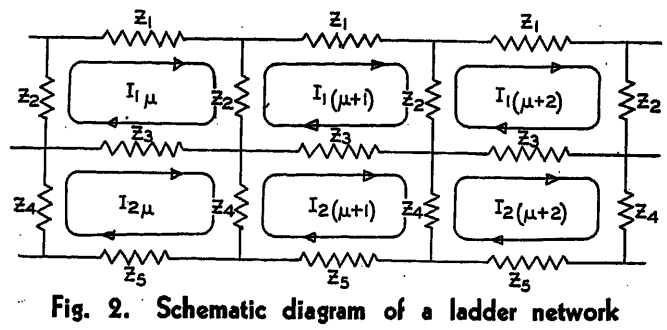

**Fig. 2. Schematic diagram of a ladder network**

$K_1$ and $K_2$ in equation 36*c* to be unknown, then by substituting $\mu = 1$ and $\mu = N$ in equation 36*c* we obtain 2 equations with 2 unknowns. The latter is the classical mode of procedure.

In order to illustrate the use of the solution for systems of difference equations consider the ladder network figure 2. Writing Kirchhoff's equations we have:

$$Z_1 I_{1\,(\mu+1)} + Z_2(I_{1\,(\mu+1)} - I_{1\,(\mu+2)}) + Z_3(I_{1\,(\mu+1)} - I_{2\,(\mu+1)}) + Z_2(I_{1\,(\mu+1)} - I_{1\mu}) = 0 \tag{37a}$$

$$Z_3 I_{2\,(\mu+1)} + Z_4(I_{2\,(\mu+1)} - I_{2\,(\mu+2)}) + Z_3(I_{2\,(\mu+1)} - I_{1\,(\mu+1)}) + Z_4(I_{2\,(\mu+1)} - I_{2\mu}) = 0 \tag{37b}$$

whence:

$$Z_3 I_{1\mu} - (Z_1 + 2Z_2 + Z_3) I_{1(\mu+1)} + Z_2 I_{1\,(\mu+2)} + Z_3 I_{2\,(\mu+1)} = 0 \tag{38a}$$

$$Z_4 I_{2\mu} - (Z_3 + 2Z_4 + Z_5) I_{2\,(\mu+1)} + Z_4 I_{2\,(\mu+2)} + Z_3 I_{1\,(\mu+1)} = 0 \tag{38b}$$

Equations 38 are a system of difference equations of the second order similar to equation 7 where

$$I_{1\mu} = f_1(x) \text{ for } \mu - 1 < x < \mu \tag{39a}$$

$$I_{2\mu} = f_2(x) \text{ for } \mu - 1 < x < \mu \tag{39b}$$

$$\phi_k(x) \equiv 0, \qquad m_1 = m_2 = m = 2 \tag{39c}$$

In order to obtain a clearer insight into the correspondence of equations 38 and the system of difference equations 7 we shall write 7 more explicitly for the case at hand. Thus:

$$a_{110}f_1(x) + a_{111}f_1(x+1) + a_{112}f_1(x+2) + a_{120}f_2(x) + a_{121}f_2(x+1) + a_{122}f_2(x+2) = 0 \tag{40a}$$

$$a_{210}f_1(x) + a_{211}f_1(x+1) + a_{212}f_1(x+2) + a_{220}f_2(x) + a_{221}f_2(x+1) + a_{222}f_2(x+2) = 0 \tag{40b}$$

Comparing equations 40 with equations 38 we have:

$$a_{110} = Z_3 \tag{41a}$$ $$a_{210} = a_{212} = 0 \tag{41a'}$$

$$a_{111} = -(Z_1 + 2Z_2 + Z_3) \tag{41b}$$ $$a_{211} = Z_3 \tag{41b'}$$

$$a_{112} = Z_2 \tag{41c}$$ $$a_{220} = Z_4 \tag{41c'}$$

$$a_{120} = a_{122} = 0 \tag{41d}$$ $$a_{221} = -(Z_3 + 2Z_4 + Z_5) \tag{41d'}$$

$$a_{121} = Z_3 \tag{41e}$$ $$a_{222} = Z_4 \tag{41e'}$$

Referring to equations 12 we have

$$A_{11}(\epsilon^u) = \sum_{k=0}^{2} a_{11k}\epsilon^{ku} = a_{110} + a_{111}\epsilon^u + a_{112}\epsilon^{2u} \tag{42a}$$

$$A_{12}(\epsilon^u) = \sum_{k=0}^{2} a_{12k}\epsilon^{ku} = 0 + a_{121}\epsilon^u + 0 \tag{42b}$$

$$A_{21}(\epsilon^u) = \sum_{k=0}^{2} a_{21k}\epsilon^{ku} = 0 + a_{211}\epsilon^u + 0 \tag{42c}$$

$$A_{22}(\epsilon^u) = \sum_{k=0}^{2} a_{22k}\epsilon^{ku} = a_{220} + a_{221}\epsilon^u + a_{222}\epsilon^{2u} \tag{42d}$$

The determinant $\Delta(\epsilon^u)$ equation 16 is:

$$\Delta(\epsilon^u) = (a_{110} + a_{111}\epsilon^u + a_{112}\epsilon^{2u})(a_{220} + a_{221}\epsilon^u + a_{222}\epsilon^{2u}) - a_{211}a_{121}\epsilon^{2u} \tag{43a}$$

$$= b_0 + b_1\epsilon^u + b_2\epsilon^{2u} + b_3\epsilon^{3u} + b_4\epsilon^{4u} \tag{43b}$$

where:

$$b_0 = a_{110}a_{220} \qquad b_1 = a_{110}a_{221} + a_{220}a_{111} \tag{44a}$$

$$b_2 = a_{110}a_{222} + a_{111}a_{221} + a_{112}a_{220} - a_{211}a_{121} \tag{44b}$$

$$b_3 = a_{111}a_{222} + a_{112}a_{221} \qquad b_4 = a_{112}a_{222} \tag{44c}$$

Moreover:

$$\Delta_{11} = A_{22}, \quad \Delta_{12} = -A_{21}, \quad \Delta_{21} = -A_{12}, \quad \Delta_{22} = A_{11} \tag{45}$$

Finally the values of $\beta_{lr\,ps\nu}$ in equation 25*b* are given in table I.

**Table I—Values of $\beta_{lrps\nu}$**

| lrps | $\nu=0$ | $\nu=1$ | $\nu=2$ | $\nu=3$ | $\nu=4$ |
|---|---|---|---|---|---|
| 1111 | 0 | $a_{220}a_{111}$ | $a_{220}a_{112} + a_{221}a_{111}$ | $a_{221}a_{112} + a_{222}a_{111}$ | $a_{222}a_{112}$ |
| 1112 | 0 | 0 | $a_{220}a_{112}$ | $a_{221}a_{112}$ | $a_{222}a_{112}$ |
| 1121 | 0 | $a_{220}a_{121}$ | $a_{221}a_{121}$ | $a_{222}a_{121}$ | 0 |
| 1122 | 0 | 0 | 0 | 0 | 0 |
| 1211 | 0 | 0 | $-a_{111}a_{211}$ | $-a_{112}a_{211}$ | 0 |
| 1212 | 0 | 0 | 0 | $-a_{112}a_{211}$ | 0 |
| 1221 | 0 | 0 | $-a_{121}a_{211}$ | 0 | 0 |
| 1222 | 0 | 0 | 0 | 0 | 0 |
| 2111 | 0 | 0 | $-a_{121}a_{211}$ | 0 | 0 |
| 2112 | 0 | 0 | 0 | 0 | 0 |
| 2121 | 0 | 0 | $-a_{121}a_{221}$ | $-a_{121}a_{222}$ | 0 |
| 2122 | 0 | 0 | 0 | $-a_{121}a_{222}$ | 0 |
| 2211 | 0 | $a_{110}a_{211}$ | $a_{111}a_{211}$ | $a_{112}a_{211}$ | 0 |
| 2212 | 0 | 0 | 0 | 0 | 0 |
| 2221 | 0 | $a_{110}a_{221}$ | $a_{110}a_{222} + a_{111}a_{221}$ | $a_{111}a_{222} + a_{112}a_{221}$ | $a_{112}a_{222}$ |
| 2222 | 0 | 0 | $a_{110}a_{222}$ | $a_{111}a_{222}$ | $a_{112}a_{222}$ |

Assuming that the roots of $\Delta(\epsilon^u)$ are distinct and equal to $\alpha_1$, $\alpha_2$, $\alpha_3$, $\alpha_4$, and using equation 20*a* where $P(\epsilon^u)$ is replaced by $\Delta(\epsilon^u)$ we have:

$$1/\Delta(\epsilon^u) = \sum_{k=1}^{4} B_k/(\epsilon^u - \alpha_k) \tag{46}$$

where

$$B_k = 1/[b_1 + 2b_2\alpha_k + 3b_3\alpha_k^2 + 4b_4\alpha_k^3], \qquad k = 1, 2, 3, 4 \tag{47}$$

Substituting equations 39 to 47 in 27 and the result in 26 and remembering that $\phi_l(x) \equiv 0$ and that (see equation 39) $f_p(x - [x] + s - 1) = I_{ps}$ and that $[x] = \mu - 1$ we have:

$$I_{\mu r} = \sum_{l=1}^{2}\sum_{p=1}^{2}\sum_{s=1}^{2}\sum_{\nu=0}^{4}\beta_{lr\,ps\nu}\sum_{k=1}^{4}B_k\alpha_k^{\mu-1}I_{ps}, \text{ where } r = 1, 2 \tag{48}$$

This problem could, of course, have been solved by reducing, through elimination, the system of difference equations to 2 difference equations, each of the fourth order, and each involving only one unknown function. The choice between the 2 modes of solution is determined by the nature of the problem. The above example simply illustrates the applicability of our results and could have been solved through elimination.

## 5. Extension to Other Boundary Conditions

Quite often, in physical problems, the boundary conditions are not what we assumed in sections 1 and 2 of this paper. In fact, the boundary conditions are often specified at the beginning and end of a network. It needs but a slight addition to this theory, as indicated in the first illustrative problem, to obtain the solution for any boundary conditions whatever.

Consider equations 24 which are solutions of the difference equation 1. Let, for distinct and repeated roots, respectively:

$$A(x) = \sum_{k=1}^{n} B_k \sum_{c=0}^{[x]-1} \alpha_k^c \phi(x - c - 1) \tag{49a}$$

$$A(x) = \sum_{k=1}^{\lambda}\sum_{r=1}^{n_k} B_{kr} \sum_{c=0}^{[x]-r} \binom{r+c-1}{c} \alpha_k^c \phi(x - r - c) \tag{49b}$$

Let, for distinct and repeated roots, respectively:

$$H_s(x) = \sum_{k=1}^{n} B_{ks}\alpha_k^{[x]} \tag{50a}$$

$$H_s(x) = \sum_{k=1}^{\lambda}\sum_{r=1}^{n_k} B_{krs}\binom{[x]}{[x]-r+1}\alpha_k^{([x]-r+1)} \tag{50b}$$

Then equations 24 may be written in both cases as follows:

$$f(x) = A(x) + \sum_{s=1}^{n} H_s(x) f(x - [x] + s - 1) \tag{51}$$

In equation 51, $A(x)$ and $H_s(x)$ are both known functions. $f(x - [x] + s - 1)$ is the value of $f(x)$ in the interval $s - 1 < x < s$. In our solution $f(x - [x] + s - 1)$ is given for $s = 1, 2, \ldots n$.

It is our object to show that equation 51 gives an explicit solution even when the boundary values are not given for the first $n$ intervals but for any $n$ arbitrary intervals $k_1 - 1 < x < k_1$; $k_2 - 1 < x < k_2$, $\ldots$ $k_n - 1 < x < k_n$.

In the first place it must be observed that $f(x - [x] + s - 1)$ is periodic in one, or:

$$f((x+k) - [x+k] + s - 1) = f(x - [x] + s - 1) \tag{52}$$

Moreover:

$$x = x - [x] + k_r - 1 \text{ if } k_r - 1 < x < k_r \tag{53}$$

Substituting for $x$ its value from equation 53 in 51 for the various intervals where $f(x)$ is known and using the relation 52 we have:

$$f(x - [x] + k_1 - 1) - A(x - [x] + k_1 - 1) = \sum_{s=1}^{n} H_s(x - [x] + k_1 - 1) f(x - [x] + s - 1) \tag{54a}$$

$$f(x-[x]+k_2-1)-A(x-[x]+k_2-1)=\sum_{s=1}^{n}H_s(x-[x]+k_2-1)f(x-[x]+s-1) \quad (54b)$$

.....

$$f(x-[x]+k_n-1)-A(x-[x]+k_n-1)=\sum_{s=1}^{n}H_s(x-[x]+k_n-1)f(x-[x]+s-1) \quad (54n)$$

Equations 54 are $n$ equations with $n$ unknowns, the unknowns being the values of $f(x)$ for the first $n$ intervals, *viz.:*

$$f(x-[x]), \quad f(x-[x]+1), \quad \ldots \quad f(x-[x]+n-1)$$

The solutions of equations 54 give these values of $f(x)$ which can now be substituted back in 24. The process is the same for each $f_r(x)$ in a system of $n$ difference equations.

It should be here remarked that if, as is generally the case, some of the boundary values are given for the first $\beta$-intervals then the number of unknowns and therefore of equations in 54 is reduced to $(n-\beta)$.

## Summary

We have developed 2 expansion theorems applicable to difference equations and to systems of difference equations such as occur in ladder networks. These theorems are given by equations 24, 26, 27, and 28, respectively. The equations presuppose that the boundary conditions are given for the values of $f(x)$ in the first $n$ successive intervals. As, in physical problems, the boundary conditions vary widely, the theorems are adapted to any boundary conditions in section 5 of the paper. Finally 2 problems are worked out in section 4 to illustrate the use of these theorems.

## Notations

$a_k$ = constant coefficient in the difference equation 1
$a_{lrk}$ = constant coefficient in the system of difference equations 7
$A_{lr}$ = see equation 12*a*
$A(x)$ = a function defined by equations 49
$b_k$ = coefficient of the $k$th term of the polynomial $\Delta(\epsilon^u)$
$b_{lr\nu}$ = coefficient of the $\nu$th term in the polynomial $\Delta_{lr}(\epsilon^u)$ see equation 25*a*
$B_k$ = see equation 21
$B_{ks}$ = see equation 21
$B_{kr}$ = see equation 23*a*
$B_{krs}$ = see equation 23*b*
$\binom{a}{b}$ = $\begin{cases} a(a-1)(a-2)(\ldots)(a-b+1)/b! \text{ if } b \geqq 0,\ a \geqq 0 \\ 0 \text{ if } b<0,\ a \geqq 0 \end{cases}$
$c$ = any non-negative integer
$f(x)$ = The unknown function in the difference equation 1. See also equations 6 and 24
$f_r(x)$ = The unknown functions in the system of difference equation 7. See also equations 18, 26, 27 and 28
$f(x+0)$ = $\lim_{\delta \to 0} f(x+\delta)$, $\delta>0$
$f(x-0)$ = $\lim_{\delta \to 0} f(x-\delta)$, $\delta>0$
$f_{lra}(x)$ = see equations 27*a* and 28*a*
$f_{lrb}(x)$ = see equations 27*b* and 28*b*
$F(u)$ = see equations 5
$F_r(u)$ = see equations 12*b* and 15
$H_s(x)$ = a function defined by equations 50
$I_\mu$ = mesh current in the $\mu$th mesh of the ladder network figure 1
$I_{1\mu}$ = mesh current in the first row of the $\mu$th mesh of the ladder network figure 2
$I_{2\mu}$ = mesh current in the second row of the $\mu$th mesh of the ladder network figure 2
$k$ = any positive integer
$K_1, K_2$ = constants defined by equation 36*c*
$l$ = any non-negative integer
$m$ = number of difference equations in the system 7
$m_r$ = order of the difference equation involving $f_r(x)$ in the system of equations 7
$M_1(u)$ = see equation 11
$n$ = order of the difference equation 1
$n_k$ = multiplicity of the root $\alpha_k$ of $P(\epsilon^u)$ (see equation 22*b*) and of $\Delta(\epsilon^u)$
$p$ = any non-negative integer
$P(\epsilon^u)$ = see equation 19*a*
$q$ = any non-negative integer
$q_{lr}$ = the degree of the polynomial $\Delta_{lr}(\epsilon^u)$
$Q_s(\epsilon^u)$ = see equation 19*b*
$Q_{lrps}(\epsilon^u)$ = a polynomial defined by equation 25*b*
$r$ = any non-negative integer
$s$ = any non-negative integer
$t$ = a variable of integration
$u$ = any complex number whose real part is positive
$x$ = independent variable in a difference equation or a system of difference equations
$[x]$ = greatest integer which is equal to or less than $x$
$y$ = a variable of integration
$Z_k$ = an impedance in the ladder networks figures 1 and 2
$\alpha_k$ = roots of the polynomial $P(\epsilon^u)$ or of the polynomial $\Delta(\epsilon^u)$
$\beta_{lrps\nu}$ = coefficient of the $\nu$th term in the polynomial $Q_{lrps}(\epsilon^u)$
$\Delta(\epsilon^u)$ = see equation 16
$\Delta_{lr}(\epsilon^u)$ = the minor of $\Delta(\epsilon^u)$ obtained by omitting row $l$ and column $r$
$\Delta_1(\epsilon^u)$ = a polynomial having no zero roots (see equation 29)
$\epsilon$ = base of napierian logarithms
$\lambda$ = any positive integer
$\mu$ = any non-negative integer
$\nu$ = any non-negative integer
$\phi(x)$ = given function in the difference equation 11
$\phi_l(x)$ = given function in the system of difference equations 7
$\phi(x+0)$ = $\lim_{\delta \to 0} \phi(x+\delta)$, $\delta>0$
$\phi(x-0)$ = $\lim_{\delta \to 0} \phi(x-\delta)$, $\delta>0$
$\Phi(u)$ = see equation 4*b*
$\Phi_l(u)$ = see equation 10*b*
$\psi_k(\epsilon^u)$ = see equation 23*c*
$\psi_{ks}(\epsilon^u)$ = see equation 23*d*
$\Psi(u)$ = see equation 4*a*
$\Psi_l(u)$ = see equation 10*a*

# A New Electrostatic Precipitator

By G. W. PENNEY
ASSOCIATE AIEE

**The cleaning action upon gases of a corona discharge has been known since 1824; however, the technique of electrostatic precipitation has been improved slowly because of the inherent difficulties of the process and the somewhat limited field of its application. With accurately controlled industrial processes and delicate laboratory measurements came the necessary incentive for improving electrostatic precipitation equipment, and recently it has been applied in the field of medicine for the treatment of such maladies as hay fever. The theory of electrostatic precipitation is reviewed briefly in this paper, and a new precipitator is described.**

ELECTROSTATIC precipitation has long been recognized as the outstanding method of removing very fine particles from gases, especially at elevated temperatures.

The cleaning of gases by a corona discharge was observed by Hohlfield in 1824. His experiments were extended by Sir Oliver Lodge who made a working installation in a lead smelter in 1884. In 1906 Dr. Cottrell developed a practical form which has been very successful in handling difficult cleaning problems which could not be accomplished by other cleaning methods. The application of electrostatic precipitation has, however, been limited. The most serious factors limiting the use of electrostatic precipitation are as follows:

1. D-c voltages of from 30,000 to 100,000 and appreciable current are required.
2. The space required is large both for the precipitator proper as well as the high-voltage transformer and rectifier.
3. The corona discharge of the conventional precipitator generates so much ozone that the cleaned air, although free of dust, is too irritating to the nose and throat to be used for ventilation.
4. First cost and maintenance are both high as compared to other types of cleaning equipment.

In considering the field of gas purification, the larger particles (above 10 microns) are readily removed by various means, such as centrifugal devices, simple filters, washers, or by viscous coated devices which depend on impinging the particle onto the coated surface. Somewhat finer particles can be removed by the better grade of filters. However, in many cases the dust particles are only a fraction of a micron in diameter. Such particles approach the resolving power of the ordinary microscope. The diameter of these particles is comparable with the mean free path of air molecules. Such particles defy almost all air cleaning devices except precipitation, although in most cases this could not previously be used for the reasons given.

An analysis of the process of precipitation has pointed the way to the development of a new type of precipitator which reduces the size, voltage, power required, and ozone and compounds of nitrogen generated so that this new device can be applied in fields in which electrostatic precipitation was not previously practical.

## Generation of Ozone

In air, the generation of ozone by a given discharge current depends somewhat upon the geometry of the electrodes. By selecting a favorable design of electrode the generation of ozone per unit of current can be limited to a minimum value. The problem then becomes one of designing the precipitator to clean the air with the minimum discharge current. The analysis given in this paper has resulted in a precipitator which gives a generation of ozone which is small as compared with that found in outdoor air in bright sunlight and at the same time the space, voltage, and power required are small as compared to previous practice.

## Analysis of Electrostatic Precipitation

### The Corona Discharge

The conventional process of electrostatic precipitation uses a wire or system of points at high potential so that there is a corona discharge which carries the dust to the opposite electrode. The forces acting on the particles have been analyzed by R. Ladenburg.[1] The primary effect is an accumulation of charge on each dust particle. The particle is then acted upon by the electrostatic field which carries it toward the electrode of opposite polarity. There is another effect which Ladenburg refers to as the electrostatic wind. This electrostatic wind consists of a movement of air away from discharge points and carries dust toward the collecting electrode. However, the movement of air toward the electrode must also displace air

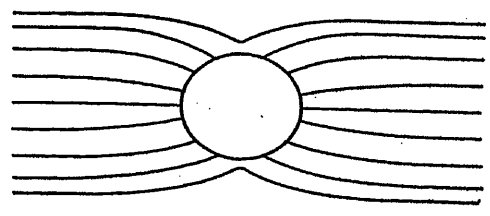

**Fig. 1. Sketch showing how an electrostatic field is distorted by a dust particle**

A paper recommended for publication by the AIEE committee on electrochemistry and electrometallurgy. Manuscript submitted November 6, 1936; released for publication December 2, 1936.

G. W. Penney is manager of the electrophysics division of the research laboratories of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

1. For all numbered references, see list at end of paper.

away from the collecting electrode. The net result increases the precipitation of dust but it appears to be a very inefficient method. In this paper the electrostatic wind is ignored and an attempt made to develop the most efficient device for charging the particles and attracting them out of the air. The resulting device accomplishes results not considered possible in devices where the electrostatic wind is utilized.

### Effect of the Electrostatic Field

The particles are charged in the region of a corona discharge. Here a high local electrostatic field is produced by impressing a high voltage on points or a fine wire. This local voltage gradient is sufficiently high to produce ionization by collision and a self-maintaining discharge. If the point or wire is negative, the positive ions generated in the discharge are attracted to the negative electrode but the electrons are repelled and drift toward the large positive electrode. Probably most of the electrons quickly become attached to air molecules forming negative ions. This space charge forms a high opposing voltage which limits the current and produces a stable discharge.

The electrons or ions drifting through the gas tend to follow the electrostatic lines of flux. Dust particles usually have a dielectric constant greater than one and distort the field tending to concentrate the flux through the particle (figure 1). This drives the drifting charges toward the particle. Any charge on the particle exerts a force tending to repel ions from the particle. The maximum charge which the particle can attain is that at which this repulsive force cancels the effect of the main electrostatic field. Ladenburg's equation expressing the balance of forces acting on an electron just outside the dust particle at this limiting charge is

$$e\left(1+2\frac{k-1}{k+1}\right)E_0-\frac{ne^2}{r^2}=0 \qquad (1)$$

Solving for $n$,

$$n=E_0\left(1+2\frac{k-1}{k+1}\right)\frac{r^2}{e} \qquad (2)$$

This equation gives the maximum number of electrons which can be collected by a dust particle of radius $r$ and dielectric constant $k$ in a field strength $E_0$. Experiments

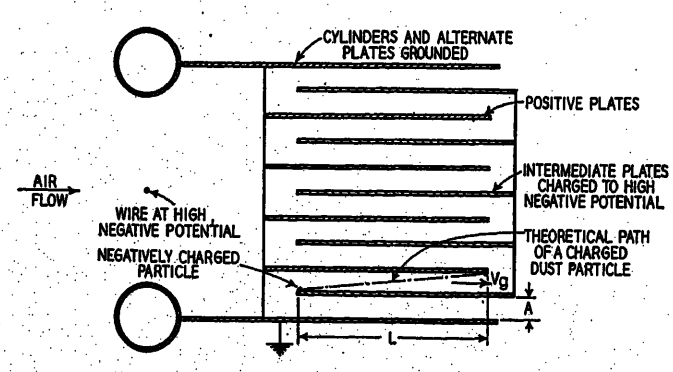

**Fig. 2. Cross section of the ionizing unit and parallel dust-collecting plates of an electrostatic precipitator, showing the path of a dust particle**

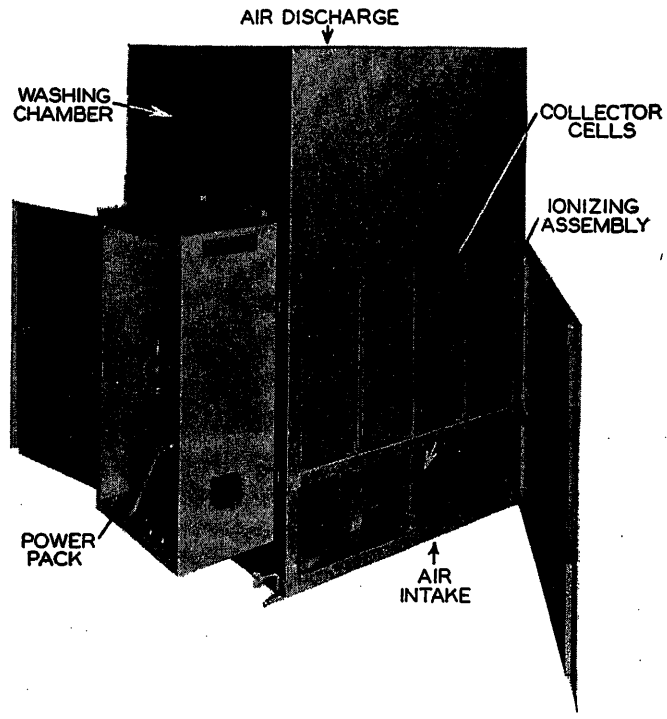

**Fig. 3. An electrostatic precipitator developed for use with a spray booth in a pottery plant**

indicate that this charge is approached in a small fraction of a second as compared to the 2 to 10 seconds ordinarily required for precipitation in conventional practice.

### Effect of Molecular Motion of Electrons or Ions

In addition to the driving force of the electrostatic field the heat or molecular motion of the electrons or ions tends to charge the dust particles. The effect of this heat motion becomes increasingly important as the particle size decreases. Ladenburg considers this effect to be the controlling factor for particles less than $^1/_4$ micron in diameter. When the dust particle is uncharged, the ion will not be repelled but as a charge accumulates on the particle, this charge tends to repel ions so that there will be relatively few ions having sufficient velocity to overcome the repulsive force. This gives a rapid rate of charging the particle as long as the ion velocity required is below the most probable velocity but when the charge on the particle reaches such a value that only a few ions have sufficient energy to reach the dust particle, the charging proceeds very slowly. The mathematical theory is rather long[5,6,7,8] to review here but a few values are given in table I which compares the values of $n$ obtained by this theory with that given by equation 2. The particle will, of course, tend to take the maximum number of charges.

### Separation of Particles From the Gas

In the conventional precipitator the charging of the particles and their separation from the gas was accomplished in one chamber with a discharge taking place throughout the length of travel of the gas. Both experiment and theory indicate that the charging of the particles

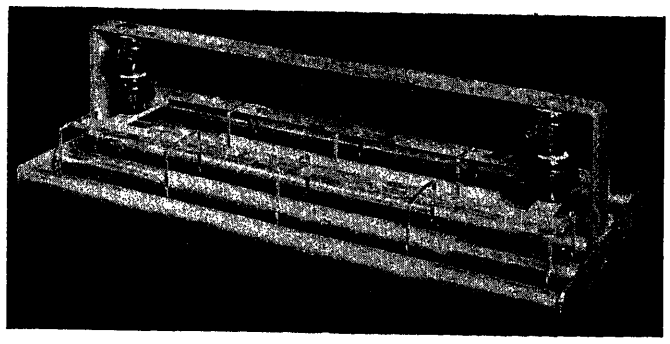

**Fig. 4. The ionizing unit of the precipitator**

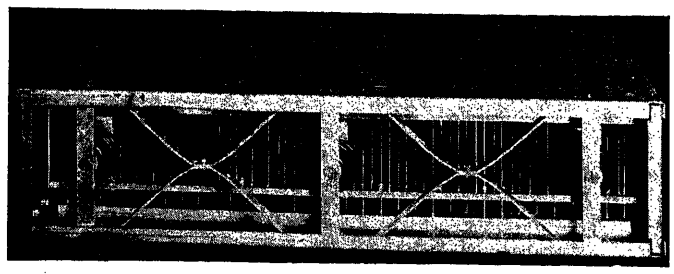

**Fig. 5. Parallel-plate dust-collecting assembly**

takes place very rapidly as compared to their separation from the gas. Furthermore, the charging process inherently requires a nonuniform field while for most efficient separation the field should be uniformly high. It has been found possible to make the process much more efficient by first ionizing the particles and then separating them from the gas in the electrostatic field between parallel charged plates.

Figure 2 is a schematic drawing showing a cross section of a precipitator using an ionizing unit and a separate dust collector consisting of parallel plates, alternate plates being grounded and the remaining plates being connected to a source of high d-c potential.

If we assume any given charge $ne$ on a dust particle, in an electrostatic field, there will be a force $neE_0$ acting to pull the particle toward the opposite electrode. The drift of the particle through the gas is opposed by the viscous resistance of the gas and can be calculated by Stokes' Law.

$$n \cdot e \cdot E = V_d \cdot 6\pi\mu r \tag{3}$$

$$V_d = \frac{ne\ E_0}{6\pi\mu r} \tag{4}$$

The velocity of a given charged particle will then be proportioned to the field strength. The time required to travel the distance $A$ perpendicular to the air is given by

$$t_d = \frac{A}{V_d} = A\,\frac{6\pi\mu r}{n \cdot e \cdot E_0} \tag{5}$$

If we assume such a negatively charged particle moving between 2 parallel electrodes (figure 2) and starting near the negative electrode, the maximum allowable air velocity is that at which the charged particle will just reach the positive electrode before passing out of the region between the plates. The time required to travel the distance $L$ is given by

$$t_g = \frac{L}{V_g} \tag{6}$$

Equating

$$t_d = t_g = \frac{A}{V_d} = \frac{A}{V_g} \tag{7}$$

$$V_g = \frac{LV_d}{A} \tag{8}$$

To secure the maximum capacity, $V_g$ should be as large as possible. It is evident that $V_g$ is inversely proportional to the plate spacing $A$ for a given electrostatic field strength. Over a considerable range of plate spacing the electrostatic field strength can be greater as the plate spacing is decreased, so that the capacity of a given precipitator increases faster than inversely proportional to the plate spacing. The lower limit of plate spacing is usually determined by manufacturing limitations and by space required for the collection of dust.

The arrangement of separate ionization and parallel dust collecting plates has been proposed years ago. But the use of this construction to obtain a more compact and efficient unit for removing low concentrations of dust with a very low generation of ozone and oxides of nitrogen does not appear to have been appreciated.

This discussion has been based on the assumption of streamline flow between parallel electrodes. Actually some turbulence frequently exists but tests have demonstrated that these relations approximate most of the actual conditions and constitute a very valuable guide in the general discussion of precipitation.

### Effect of Particle Size

From equation 2 it is evident that the charge collected by a particle due to the effect of the electrostatic field is proportional to the square of the diameter. While from equation 3 the resistance offered by the air is proportional to the first power of the diameter, the allowable velocity is according to this theory proportional to the diameter of the particle to be removed. As the particle size decreases, the heat motion of the ion gives an additional charge

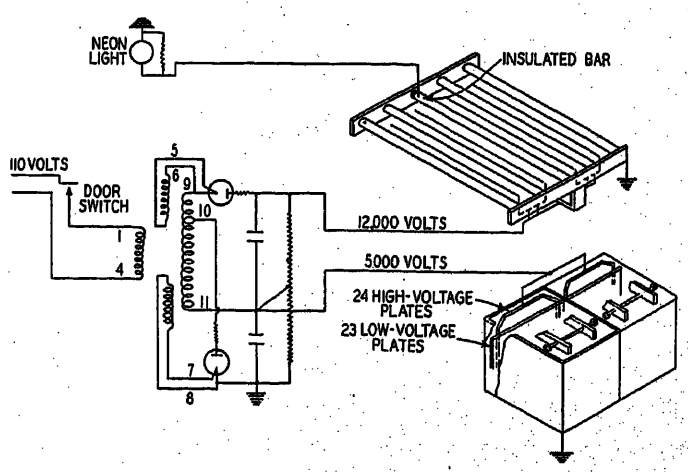

**Fig. 6. Wiring diagram of the precipitator**

above that due to the electrostatic field so that actually the allowable velocity does not decrease directly with the particle size, although the fine particles are more difficult to remove than large particles.

### Retention of Particles on Collecting Electrodes

The electrostatic force exerted by the field on the charged particle acts to carry the particle through the air toward the oppositely charged electrode.

But when the particle touches that electrode if the dust is conducting the charge leaves the particle and a surface charge of opposite sign appears representing the condenser charge of the electrodes. This tends to repel the particle from the electrode. On the other hand, if the particle could be a perfect insulator, at least on the second layer of particles, the charge would remain on the particle and the attraction be maintained. The actual case will be somewhere between these extremes. But in any case we cannot rely on the electrostatic force to hold the particle on the electrode. It must be held by adhesion. Most fine particles normally adhere. In special cases the plates may be coated with oil or other material which will cause particles to adhere, although in this case they adhere so well that cleaning of the plates is very difficult. With some types of dust, it may collect normally but a jar may loosen agglomerations of dust.

**Table I—Theoretical Maximum Charge on a Dust Particle**

| Radius of Particle, Centimeter | Diameter Microns | Dielectric Constant | Maximum Charge Due to Field Equation 2, $E_0 = 5$ | Maximum Charge Due to Heat Motion |
|---|---|---|---|---|
| $1 \times 10^{-3}$ | 20 | 1 | $1.05 \times 10^4$ | |
| $1 \times 10^{-3}$ | 20 | 4 | $2.1 \times 10^4$ | 2,100 |
| $1 \times 10^{-3}$ | 20 | $\infty$ | $3.15 \times 10^4$ | |
| $1 \times 10^{-4}$ | 2 | 1 | 105 | |
| $1 \times 10^{-4}$ | 2 | 4 | 210 | 207 |
| $1 \times 10^{-4}$ | 2 | $\infty$ | 315 | |
| $1 \times 10^{-5}$ | 0.2 | 1 | 1 | |
| $1 \times 10^{-5}$ | 0.2 | 4 | 2 | 19 |
| $1 \times 10^{-5}$ | 0.2 | $\infty$ | 3 | |

Many cases of this type can be solved by using a simple mechanical filter past the precipitator. Such a filter would not remove the dust in its original, finely divided state but when the dust breaks loose from the plates it tends to do so in large pieces or agglomerations which are sufficiently large to be caught by the filter.

## Description of the New Precipitator

Figure 3 shows a photograph of a complete precipitator which was built for removing the glaze from the air exhausted from a spray booth in a pottery plant. The high-voltage power supply unit consisting of transformer, rectifier tubes, and condensers, is mounted in the case at the left of the photograph. The ionizing units are mounted at the lower part of the case and the plate assemblies above. The ionizing unit consists of parallel grounded cylinders with wires carried on insulated supports spaced between the cylinders. The wires are connected to the high-potential power source giving 12 to 14 kilovolts d-c. Figure 4 shows a photograph of an ionizing unit removed from the case.

Some dust collects on the grounded cylinders of the ionizing unit. However, most of the dust is deposited in the dust collection plate assemblies. Figure 5 shows one of these units removed from the case. Alternate plates are grounded, being supported from the case. The remaining or intermediate plates are supported by insulated bars and are charged to a lower voltage than the ionizing units. Figure 6 shows a wiring diagram.

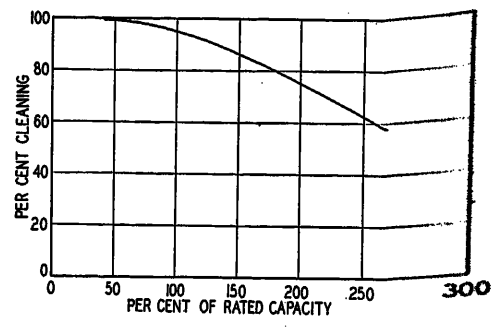

**Fig. 7. Efficiency-volume curve of the precipitator**

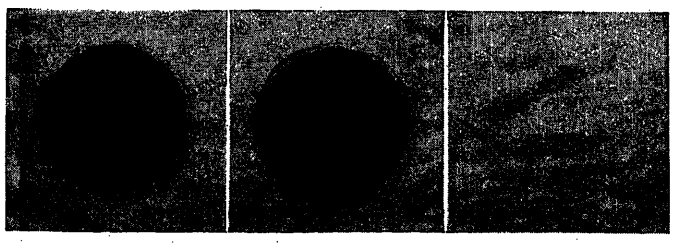
## Efficiency of Precipitation

The equations derived on the basis of maximum charge obtainable would indicate 100 per cent efficiency up to a given critical velocity (equation 8) and a rapid reduction in efficiency above this velocity. In practice, this abrupt transition is not obtained for several reasons. Particles vary greatly in size. All particles of a given size do not obtain the same charge because the dielectric constant varies, the field is not uniform over the ionizing region, the shape of the particles vary, and the equations governing the charging of small particles depend on the probable movement of ions and in the smaller particles the numbers involved are too small to give a uniform result. Figure 7 shows a typical curve obtained by test. This shows that we can increase the efficiency of a given unit to almost any desired value by merely reducing the volume of gas cleaned.

The initial development on this precipitator was for the purpose of removing the dust, mainly black smoke particles, from air particularly in cities where soft coal is burned. In this application we are interested primarily in the tendency of the air to blacken wall paper, draperies, merchandise, etc. This characteristic can be measured by drawing the air to be tested at a measured rate, through a piece of white cloth. Figure 8 is a photograph of 3 such samples taken simultaneously. One shows unfiltered air. The second sample shows air which had passed through a common commercial oil-coated filter. On coarse dusts, tests can be made which will give a weight efficiency of over 99 per cent for this same coated filter, but when tested using these fine smoke particles, the cleaning effect of the coated filter was almost negligible. The third sample shows air which had been passed through an electrostatic precipitator.

Another method of determining efficiency is to count the number of particles suspended in the air before and after passing through the cleaning device, using the Greenburg Impinger[2] recommended by the Bureau of Public Health. A test made using a dust of ground silica rock and counting the particles by this method gave the following results:

1. Unfiltered air—430 × $10^7$ particles per cubic foot.
2. Air filtered through the viscous coated filter—350 × $10^7$ particles per cubic foot or 19 per cent efficiency of cleaning.
3. Air passed through the electrostatic cleaner—2.3 × $10^7$ particles per cubic foot or 99.5 per cent efficiency.



Another method of making such particle counts is the electrostatic dust sampler.[4]

The efficiency of a given unit will vary over wide limits based on the method of test. Usually a weight test gives a high efficiency, since the larger particles are efficiently removed and constitute a large portion of the weight. It is possible on filters for instance, to make tests where the weight efficiency will be above 95 per cent and yet the particle count using the impinger may show an efficiency below 20 per cent. The tests used to obtain the curve of figure 7 were made using a smoke and air mixture and measuring the time required to produce a given blackness of a piece of cloth. A condition giving 95 per cent based on this test would give well over 99 per cent using a weight test.

## Fields of Application

This type of precipitator is particularly adapted to removing light concentrations of fine dust. Some of the principle fields of application are:

1. Removal of industrial dusts which constitute a hazard to health of employees.
2. Air cleaning to protect delicate apparatus or processes.
3. Air cleaning in homes and offices in soft-coal burning cities to reduce cleaning of walls, draperies, etc.
4. Air cleaning for the relief of hay fever and asthma.
5. Air cleaning in stores to reduce damage to merchandise.

A B C

**Fig. 8. Results of passing through cloth filters a volume of 10,000 cubic feet of air cleaned by 3 different methods**

*A*—Uncleaned air
*B*—Mechanically cleaned air
C—Electrostatically cleaned air

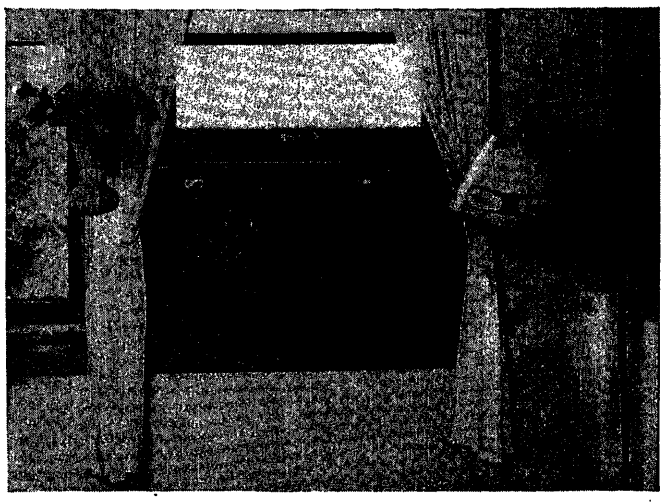


**Fig. 9. A type of electrostatic air cleaner used for the relief of hay fever and asthma**

In the operation of delicate relays such as automatic telephone switching equipment, considerable trouble may be caused by atmospheric dust which is so fine that it is not removed by ordinary means. Precipitators are giving satisfactory results in such service.

Experimental electrostatic air cleaners have been operated in connection with hot air furnaces and have shown a remarkable reduction in household cleaning required in locations where atmospheric pollution is serious.

Hay fever has been recognized as a disease caused by pollen carried by the air. Some types of asthma are also caused by air-borne dust, some of this dust being very fine. Early in the experimental work on the precipitator, 2 hospital rooms were equipped with electrostatic air cleaners. Very satisfactory results were obtained on hay fever and certain asthma cases. This work has been reported by Criep and Green.[3] Since the publication of this paper even more startling results have been obtained in relieving certain asthma cases. Figure 9 shows a picture of a precipitator designed for this service. This unit consists of a fan, ionizing unit, dust collection chamber, and high-voltage power supply consisting of transformer, 2 rectifier tubes and condensers. It is equipped with a small neon light which glows when the unit is operating. The dust collecting element is easily removed for cleaning and is constructed entirely of metal and porcelain so that it can be washed out using an ordinary hose and nozzle. The time required for precipitating the dust (including ionization) is a measure of the size of the unit. In the unit shown in figure 9 the precipitation time is $^1/_5$ second as compared to 2 to 10 in older conventional precipitators.

## Appendix I—Symbols

$\mu$ = viscosity of the gas
$e$ = charge on the electron
$n$ = number of electrons on a dust particle
$E$ = electrostatic field strength in volts per centimeter

# Dielectric Strength of Transformer Insulation

By P. L. BELLASCHI
MEMBER AIEE

W. L. TEAGUE
ASSOCIATE AIEE

**This paper presents a summary of the results of over 2,000 tests on the dielectric strength of transformer oil and insulating material for impulse, switching, and 60-cycle voltages. From these tests the voltage-time characteristics of the 2 insulations tested may be established over the entire range from a fraction of a microsecond to more than one minute.**

THE voltage-time characteristic of insulation is of great importance in engineering and theoretical dielectric problems. A practical case is the early recognition that the time of application of voltage be reduced when testing transformers at industrial frequencies higher than the normal.[1,2] Later when the protection of electrical apparatus against lightning received close attention, naturally insulation was studied in considerable detail in the impulse region which extends from about 100 microseconds to a fraction of a microsecond.[3,4] Recently some data[5,6] have been reported to the AIEE to establish the voltage-time characteristic of insulation over its range up to the order of one minute, but these data are limited in scope. More data are therefore required to establish adequately the voltage-time characteristics of insulation.

The purpose of this paper is to fulfill this need more fully. It presents the data and results of a comprehensive investigation on solid and liquid insulations (0.056- and 0.125-inch fullerboard; 0.25-, 0.50-, and 1.00-inch transformer oil). Some 2,000 tests were made and approximately 750 cathode-ray and magnetic oscillograms recorded. These data permit establishing the voltage-time characteristics of the insulation tested over the entire range from a fraction of a microsecond to beyond one minute. Tests were also made on insulation structures similar to those in large high-voltage electrical apparatus, thus enhancing the usefulness of the investigation. In the paper the technique and test methods developed, always an important factor in fundamental work, are given in detail. These methods can be applied in similar investigations on other insulation materials. Besides the data reported in curve form, other pertinent observations and findings (such as corona, character of breakdown, etc.) are reported, which should be of guidance in the correct interpretation of the mechanism of insulation breakdown.

## Test Methods

The voltages which appear on electrical systems may conveniently be classified according to their duration as impulse, switching, and normal-frequency voltages. Means were therefore provided to produce corresponding testing voltages and to measure the voltage and its duration.

### Impulse Tests

These tests were made with the standard impulse generator set up to produce a nominal $1^1/_2 \times 40$ microsecond wave. Voltage and time were measured with a cathode-ray oscillograph connected across the test piece through a capacitance divider which was calibrated against a resistance divider. The equipment and general procedure conform to the established practice in impulse testing[7-10]. Typical oscillograms of impulse voltages applied to the test piece are shown in figure 8*A*, *B*, and *C*.

### Switching Surge Tests

The circuit in figure 1 was devised for these tests. The surge generator is arranged for a high capacitance ($C_s$ = 0.1 microfarad) and supplies a voltage of 350 kv or less. The generator discharges into a load capacitance of 0.08 microfarad through an inductance of 1.2 henries. The test piece is across the load capacitance. The duration and wave form of the surge across the test piece is fixed by the constants of the circuit and the magnitude can be controlled by the charging voltage applied to the surge generator. A typical oscillogram of the surge voltage employed in these tests is given in figure 8*D*.

capacitance divider as indicated in figure 1. The capacitance divider was calibrated against a resistance divider connected across the load. The resistance divider calibration established that the wave form of the surge applied to the test object was faithfully recorded at the cathode-ray oscillograph with the capacitance divider. The testing set was also calibrated against a 25-centimeter sphere gap and the relation between the output voltage at the load and the charging voltage of the surge generator was established. The 2 methods of voltage measurement checked within 3 per cent.

### Short-Time 60-Cycle Tests

The circuit diagram and test arrangement for the short-time 60-cycle tests are shown in figure 2. The arrangement is such that a voltage of a desired magnitude can be applied for only a short time in the range of 5 to 90 cycles. The voltage was supplied from a 300-kv 150-

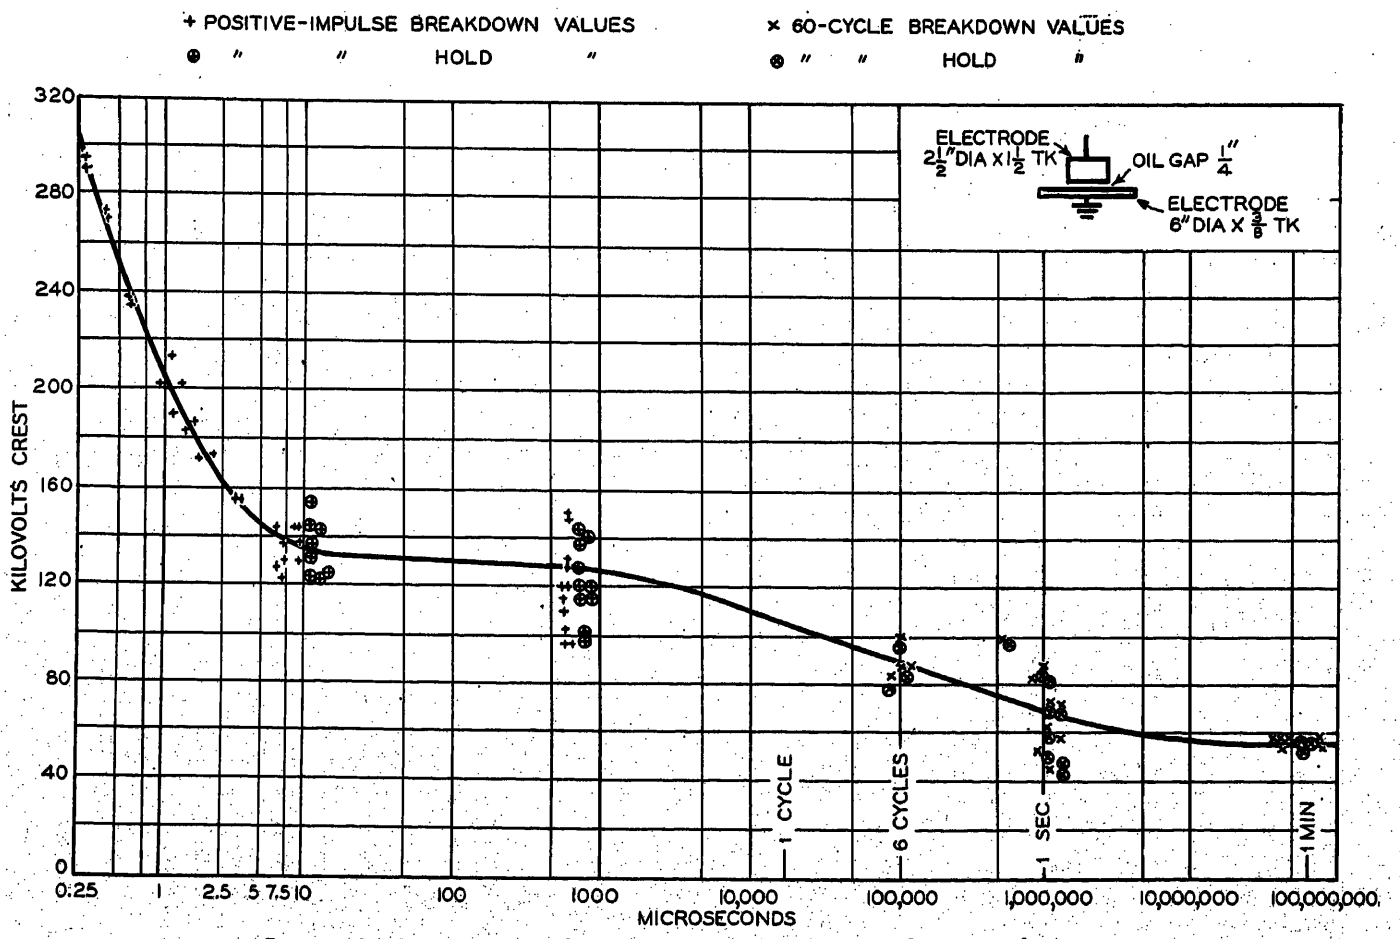

**Fig. 3. Voltage-time breakdown curve for transformer oil, 0.25-inch spacing**

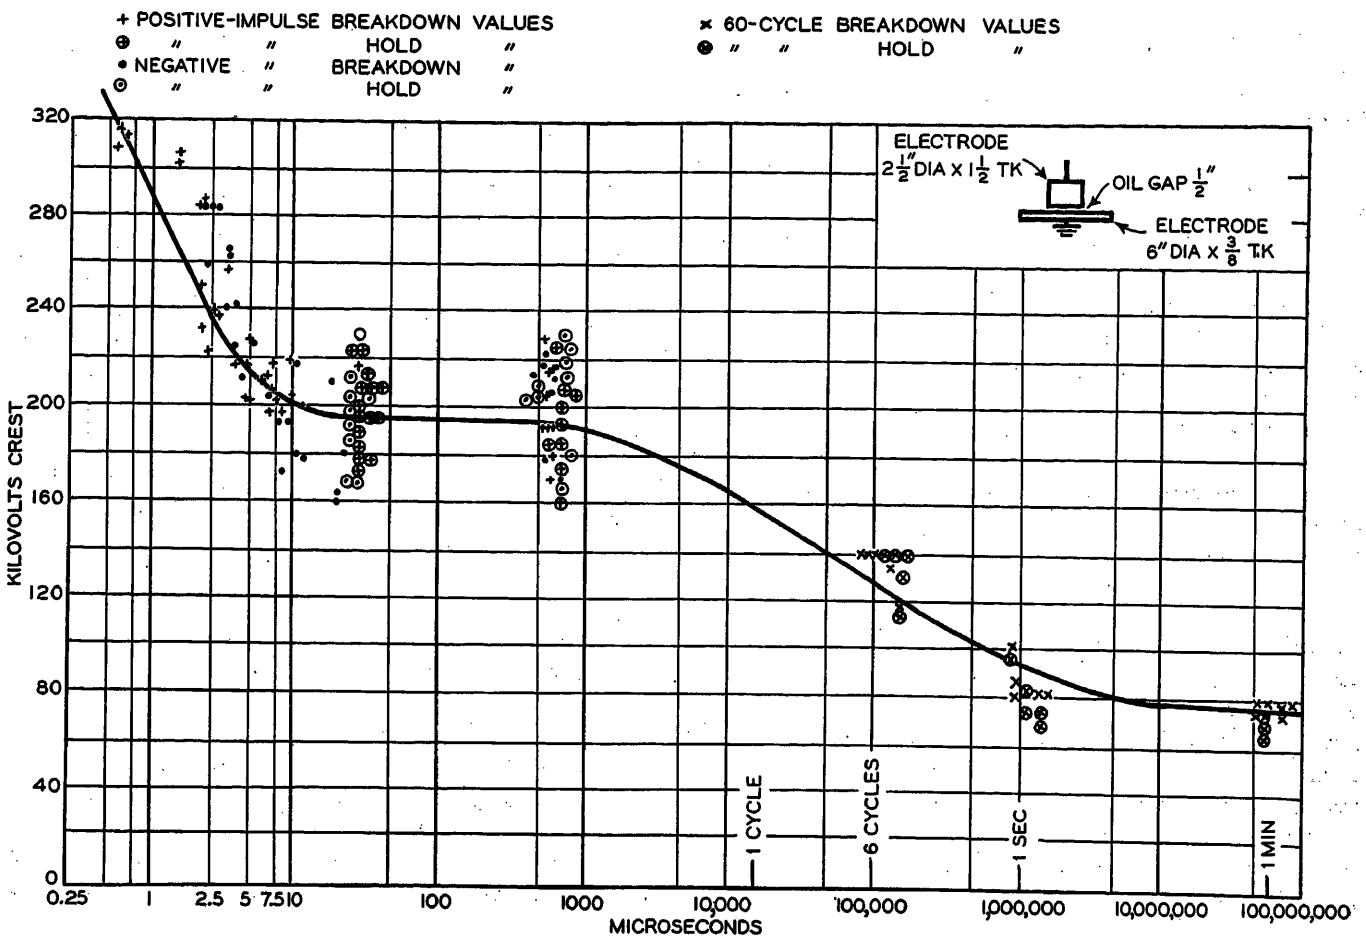

**Fig. 4. Voltage-time breakdown curve for transformer oil, 0.5-inch spacing**

kva testing transformer excited from a step-induction regulator by which the voltage could be adjusted. A load resistance of 132,000 ohms was connected across the testing transformer by means of a large air insulated switch *A*. The test piece was connected directly across this load resistance. The test set was calibrated, measuring the voltage at the test piece with a 25-centimeter sphere gap and the voltage on the voltmeter coil of the testing transformer with the set operating to trip off the voltage in the same way as when making the actual tests.

The method of controlling and measuring the time will be apparent from a brief description of the test procedure and reference to figure 2. The testing transformer is first excited to give the desired voltage. Then the initiating relay, operated by the magnetic oscillograph, energizes the "release magnet" and permits switch *A* to close by gravity, and apply the voltage to the load resistance and the test piece.

The current flowing through the load resistance is stepped up through a 5/50-ampere current transformer and energizes the "time relay". The time relay closes the circuit that energizes the trip-out coil of the circuit breaker in the primary of the regulator and thus the voltage across the test piece is removed. The number of cycles the voltage is applied can be varied by adjusting the timing relay. The time of voltage application is measured by the magnetic oscillograph connected across the secondary of the current transformer. It registers the number of cycles that the current flows through the load resistance and hence the time that the voltage is applied to the test piece. Typical oscillograms of the voltage-time application are shown in figure 8*F* and *G*.

### Long-Time 60-Cycle Tests

The voltage supply for these tests was a 150-kv 75-kva testing transformer excited through an induction regulator for voltage control. The voltage measured at the voltmeter coil of the testing transformer was calibrated against a 25-centimeter sphere gap connected across the test load. The time in these tests was of sufficient duration for direct measurement with an ordinary watch.

## Testing Technique and Data

The fullerboard samples used in the tests were 12 inches by 12 inches for the 0.056-inch thickness and either 12 inches by 12 inches or 24 inches by 24 inches for the 0.125-inch thickness. The fullerboard was thoroughly dried out in a heating oven and oil-impregnated under vacuum similar to the treatment for transformers. In all the tests standard transformer oil was used. The oil was at room temperature, 13 to 22 degrees centigrade, and its strength as tested in the standard AIEE cup was between the limits of 28 to 36 kv (root mean square)

which is well above the accepted value for good oil.

In all tests the line electrode was a 2 1/2 inch diameter, 1 1/2-inch thick polished brass disk with square edges and the grounded electrode was a 6-inch diameter, 3/8-inch thick smooth brass plate. The electrodes were arranged coaxially and supported by a rigid Micarta framework. In the oil tests the electrodes were set and rigidly clamped at the desired separation and in the fullerboard tests they were pressed firmly against the test sample.

All tests were started at 60 to 70 per cent of the expected breakdown value. The voltage was first increased in steps of about 10 per cent and as breakdown was approached the steps were reduced to 2 to 3 per cent. The total number of voltage applications on each sample was from a few up to as many as 25 with an average of about 10. In the impulse tests where the breakdown occurred on the front of the wave (figure 8*A*), the first test resulted in failure. A rest period of 2 minutes or more was allowed between repeated voltage applications on a sample.

The minimum corona voltage was determined starting at a low voltage and increasing it in small increments until corona could just be detected. In the impulse, switching, and short-time 60-cycle tests corona was first detected visually, whereas in the long-time 60-cycle tests it was first detected audibly.

From these tests the voltage-time characteristic curves for transformer oil and oil-impregnated fullerboard are plotted in figures 3, 4, 5, 6, and 7. Both the breakdown and the maximum hold values are given on the curves. The corona values are also shown.

## Discussion of Tests and Data

The breakdown of oil on impulse, switching, and short-time 60-cycle voltages was somewhat erratic. The variation was reduced to an apparent minimum when proper precautions were taken in cleaning the electrodes, in replacing burned oil from between the electrodes with fresh oil, in removing trapped air from the oil, and in beginning the tests at low voltage and increasing it in small steps to failure. Even with these precautions a spread of 20 to 30 per cent is found as shown in figures 3, 4, and 5.

One inherent characteristic of oil is the long time-to-breakdown on impulses, as illustrated in oscillogram figure 8*C*. In some cases the time-to-breakdown was as great as 25 microseconds, as can be seen in figure 4.

No corona could be observed previous to breakdown in any of the tests on oil except there appeared to be a slight amount just preceding breakdown of the 1-inch spacing in the short-time 60-cycle tests. Most of the failures occurred from the edge of the line electrode, though for the 1-inch spacing a considerable proportion was from the face of the line electrode.

Tests with positive and negative impulse and switching voltages were made on the 1/2-inch oil gap. There is no marked difference in breakdown voltage for the 2 polar-

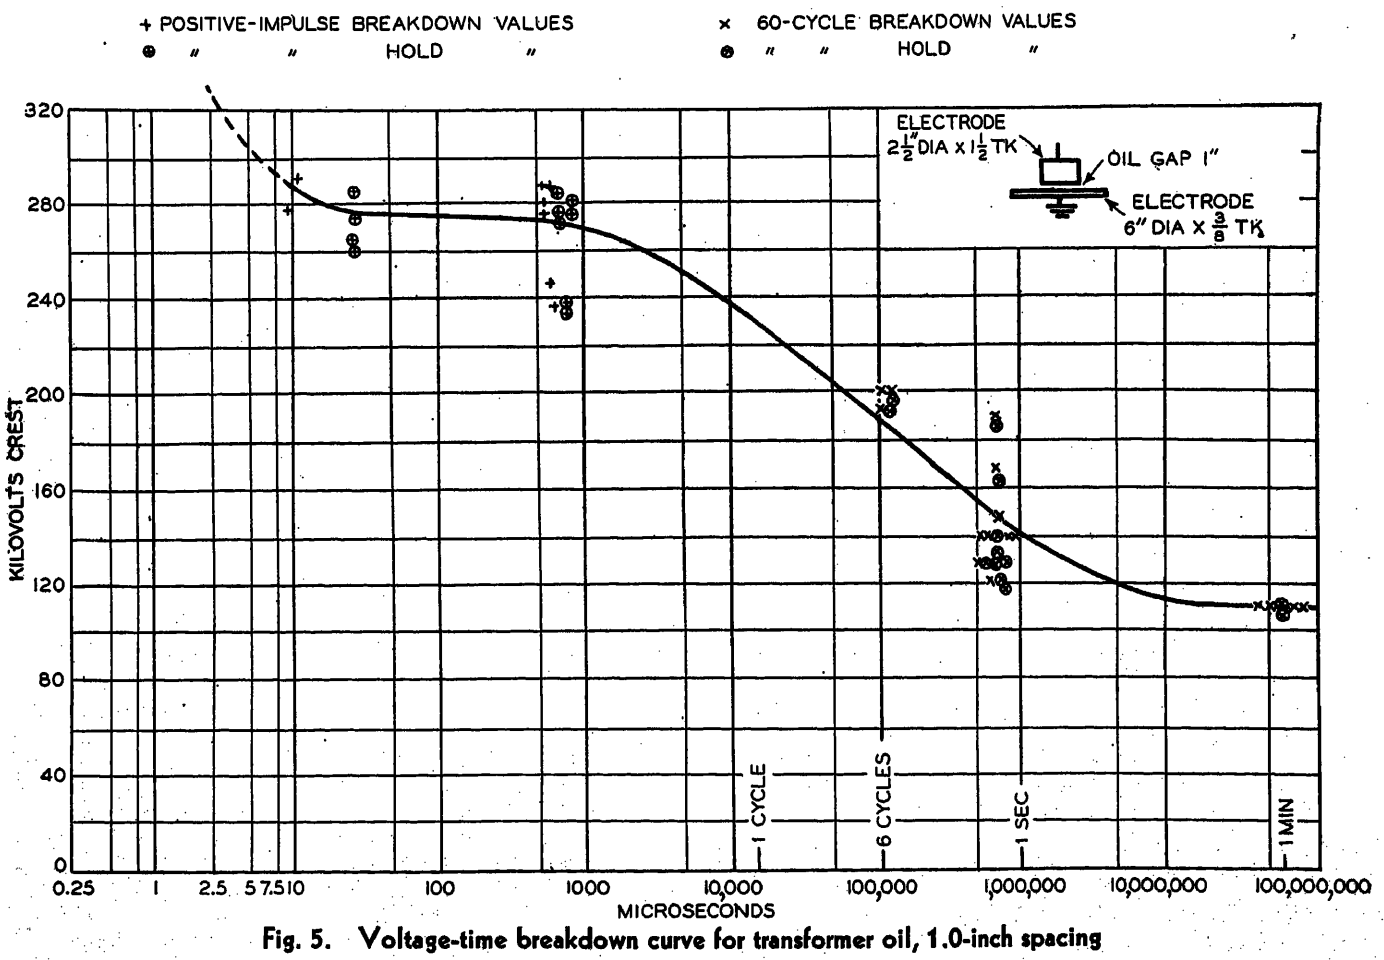

**Fig. 5. Voltage-time breakdown curve for transformer oil, 1.0-inch spacing**

ities, though the negative breakdown values are on the average somewhat greater than the positive. In the short-time 60-cycle tests the polarity of the 60-cycle voltage at failure could be determined from the magnetic oscillograms. Of 22 tests, 15 failed on positive polarity.

The voltage-time characteristic curves for the 1/4-inch, 1/2-inch, and 1-inch oil gaps (figures 3, 4, and 5) are essentially of the same form. They are flat in the region between 10 to 1,000 microseconds, rise rapidly for impulse voltages shorter than 10 microseconds and fall gradually from 1,000 microseconds to one minute. The close similarity of the 3 curves can be seen by comparing the ratios of voltage at any time value to the one-minute voltage (impulse ratio). For example, the impulse ratios for the 1/4-inch, 1/2-inch, and 1-inch oil gaps are respectively 2.4, 2.6, and 2.5 at 40 microseconds. The relation between voltage breakdown ($V$) and oil gap spacings ($d$) for these curves is closely expressed by $\log V = 0.5 \log d$.

The voltage-time characteristic curves of oil-impregnated fullerboard tested in transformer oil are given in figures 6 and 7 for 0.056-inch and 0.125-inch thicknesses respectively. In these tests breakdown was definitely preceded by corona. In the impulse tests the corona voltage for the 2 thicknesses appeared at approximately 45 per cent of breakdown voltage. On increasing the impulse voltage above the corona value visible streamers in increasing length extended from the edge of the line electrode along the surface of the fullerboard reaching a length at breakdown of about 2 1/2 inches for the 0.056-inch fullerboard and 3 1/2 inches for the 0.125-inch fullerboard. These observations of corona were confirmed by the inspection of the marking on the fullerboard after test. The maximum time-to-breakdown in the impulse tests on fullerboard occurred near the crest, figures 6 and 7 and oscillogram figure 8*B*, as compared to the long time breakdown in oil. It is of interest to note that the corona voltages of the 2 thicknesses of fullerboard (60 kv and 95 kv) correspond closely to the estimated breakdown voltage for the same spacing of oil gaps.

An important observation is the nature of breakdown. For the positive polarity impulse tests somewhat more than 80 per cent of failures for the 2 thicknesses of fullerboard were from the face of the line electrode and less than 20 per cent were from the edge. Whereas for the negative polarity tests, which were made on the 0.125-inch fullerboard alone, only 35 per cent of the failures were from the face of the electrode and 65 per cent occurred at the edge. The location of these failures indicates the grading effect of the positive streamers on the edge of the line electrode and also suggests a considerable voltage drop along the length of the streamer from the base to the tip. Apparently negative impulse streamers are of a different character than the positive and do not produce the same grading effect on the edge.

The length of the corona streamers for the switching surges (oscillograms, figures 8*D* and *E*) were considerably

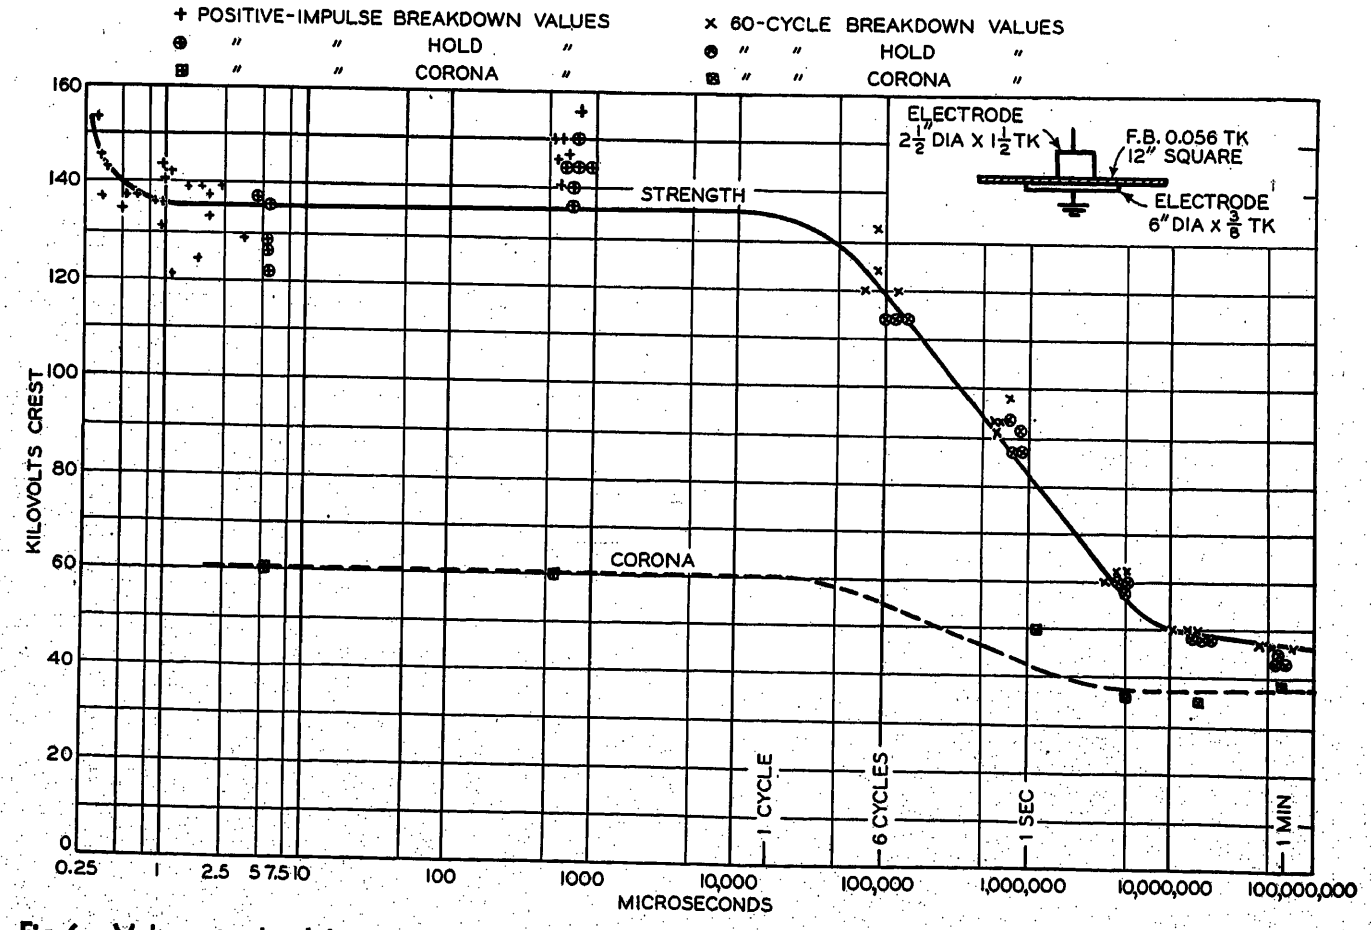

**Fig. 6. Voltage-time breakdown and corona-time curves for 0.056-inch oil-impregnated fullerboard tested in transformer oil**

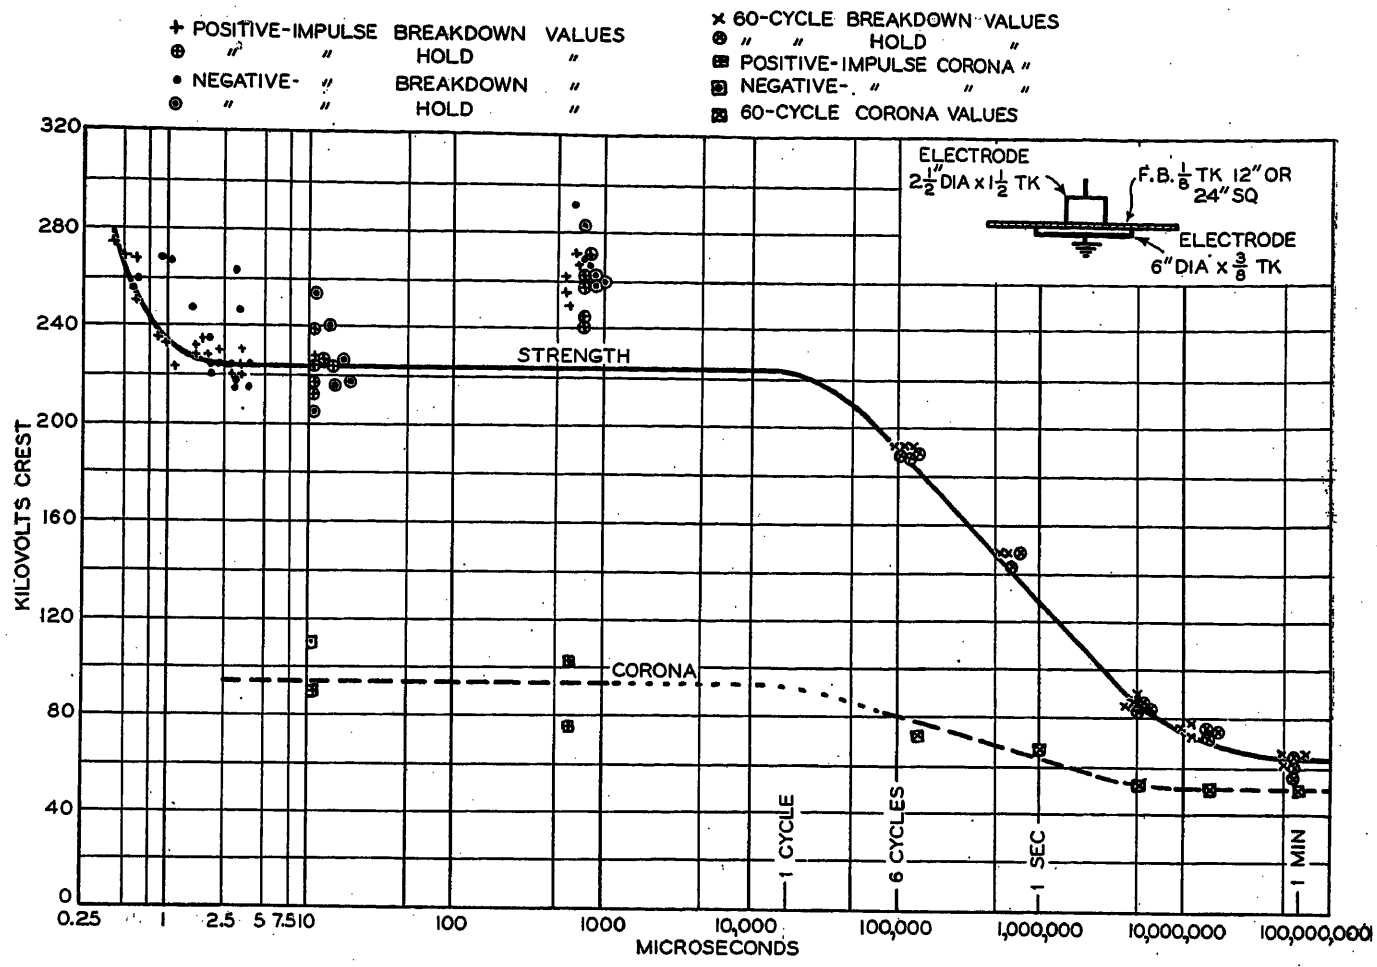

**Fig. 7. Voltage-time breakdown and corona-time curves for 0.125-inch oil-impregnated fullerboard tested in transformer oil**

greater than for the impulse. In fact creepage took place at 160 kv over the edge of the 12-inch by 12-inch samples, 0.125-inch thickness, this making it essential to use 24-inch by 24-inch samples. The location of the breakdown for the positive polarity switching surges was in 55 per cent of the tests from about $^1/_2$ to $1^1/_2$ inches outside the edge of the line electrode. These points of failure were from a streamer. The other 45 per cent of the failures were either from the edge of the electrode or from the face near the edge. These observations for the positive switching surges suggest that due to the relatively long time of application of the voltage the streamers develop into a more conducting path resulting frequently in failure from a streamer rather than from the electrode. The points of failure for the negative polarity were at or near the edge of the electrode, thus indicating again the difference in nature between positive and negative breakdown.

In the short-time 60-cycle tests (oscillograms figure 8*F* and *G*), 12 out of the 13 failures occurred on the positive polarity of the 60-cycle wave. The streamers were about the same length as for the switching surges. One-half of the failures occurred on streamers $^1/_4$ to 1 inch away from the electrode, the others were at the edge. Apparently the nature of breakdown for the short-time 60-cycle tests is of the same general character as that for the positive switching surges. Further evidence on the nature of breakdown is given from the 60-cycle tests applied for durations from 5 seconds to one minute. In 80 per cent of these tests, failure occurred on a streamer $^1/_4$ to 1 inch from the electrode and the other 20 per cent were at the edge. The extent of the visible corona from the electrode was much less pronounced than for short-time 60-cycle switching and impulse voltages, due undoubtedly to the lower breakdown voltage.

The appearance of the breakdown in the fullerboard is illustrated in figure 9. For the impulse voltages the failures are distinctly of a disruptive character with practically no indication of burning. The switching tests produced failures similar in appearance to those of the impulse, although the extent of the rupture was greater due to the larger current. The short-time 60-cycle tests were somewhat disruptive in character and also showed considerable burning. The 5 seconds to one minute 60-cycle failures showed a decided burned effect.

An important observation of the fullerboard tests was in connection with the surface marking on the test sample. Even though as many as 25 repeated impulse or switching surge voltages were applied to a sample up to breakdown, entailing profuse corona discharges, yet the amount of damage was extremely small and appeared to be confined to the surface layer.

The form of the voltage-time characteristic for the 2 thicknesses of fullerboard (figures 6 and 7) is of the same

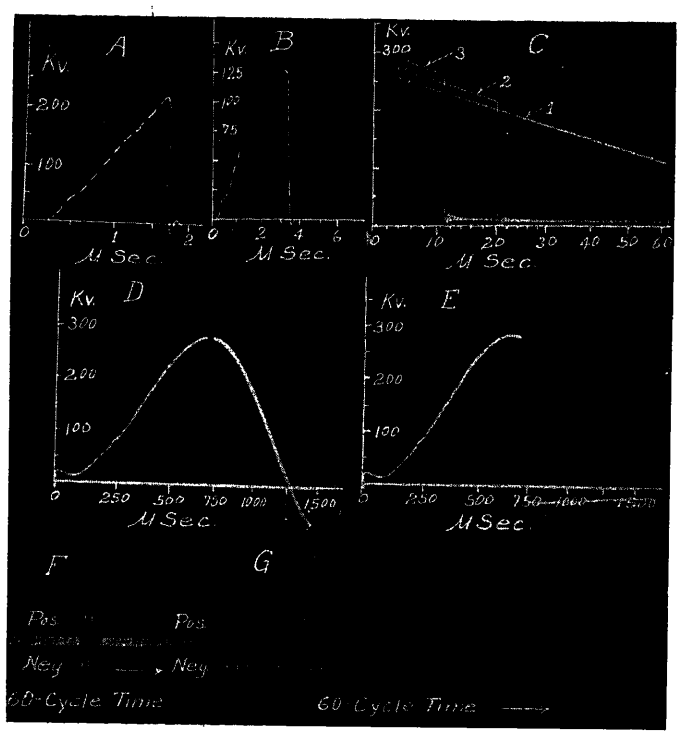

**Fig. 8. Typical oscillograms**

*A*—Impulse tests, 1/8-inch thick fullerboard
*B*—Impulse tests, 0.056-inch thick fullerboard
*C*—Impulse tests, 1.0-inch oil gap
*D*—Switching surge tests, 1.0-inch oil gap
*E*—Switching surge tests, 1.0-inch oil gap
*F*—Short-time 60-cycle tests, 0.25-inch oil gap
*G*—Short-time 60-cycle tests, 1.0-inch oil gap

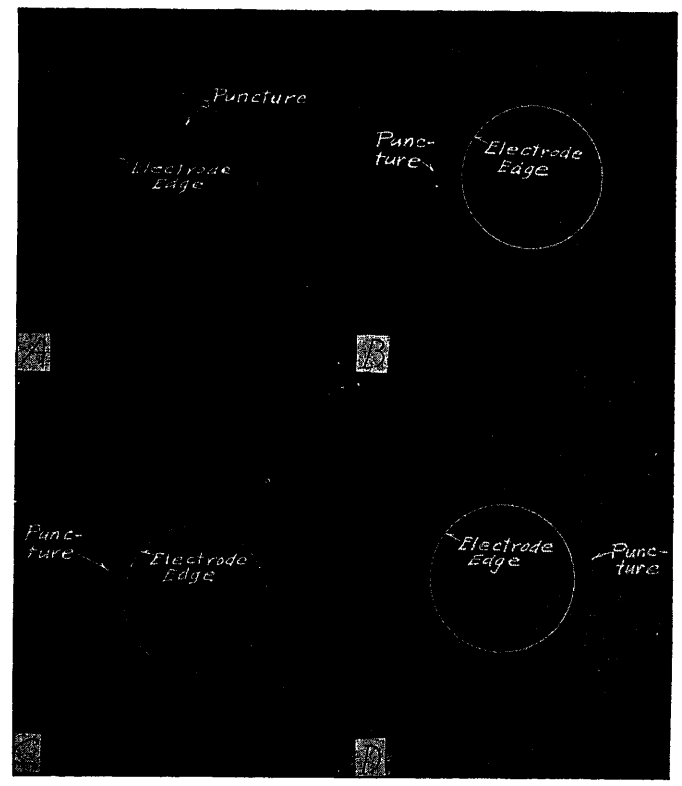

**Fig. 9. Typical fullerboard failures**

*A*—Impulse tests, 0.056-inch thick fullerboard
*B*—Switching surge tests, 0.056-inch thick fullerboard
*C*—Short-time 60-cycle tests, 0.056-inch thick fullerboard
*D*—One-minute 60-cycle tests, 0.056-inch thick fullerboard

type. As compared to the characteristic of oil however, the fullerboard characteristic is flat for a greater range of time in the impulse and switching surge regions. The fullerboard curves are flat from 2 to 10,000 microseconds, rise for shorter times than 2 microseconds, and fall quite rapidly from 10,000 microseconds to one minute. The corona curves are of similar shape. The data points are quite consistent from 6 cycles to one minute. In the switching surge region the spread in the points is about 20 per cent, which is the same as in the impulse region, but the values are higher than for the long impulses, apparently due to a better grading effect.

The impulse ratio for the 2 thicknesses of fullerboard is of the same order for the entire range of time and at 2 microseconds the average is 3.1.

The relation between voltage strength ($V$) and thickness over the greater range of the 2 curves for fullerboard is expressed by $\log V = 0.6$ to $0.7 \log d$.

## Combined Solid and Liquid Insulation

To further extend the investigation, tests were made on a barrier structure of 2 0.056-inch thick, 36-inch by 36-inch fullerboard sheets and 3 1/8-inch oil ducts arranged alternately. A 4-inch disk and a plate were used for the line and the ground electrodes, respectively. Impulse tests were made by applying 100 repeated applications at each voltage setting up to failure. The one-minute 60-cycle breakdown strength was also established. The average test values were 300, 300, 280, and 130 kv for 0.35 microsecond, 2.5 microseconds, full 40 microseconds, and one-minute 60-cycle test (crest), respectively. These results show an average impulse ratio of 2.2. These tests for a large number of repeated impulses confirm the constant strength over the impulse region even down to the very short times, as previously established.[4] For the longer times these values indicate the same form of voltage-time characteristic as shown for the fullerboard and oil alone.

Though this barrier and the fullerboard and oil alone are elements of electrical apparatus insulation, they do not conform to the best design structure used in practice. Therefore 2 power transformers, a 132 kv core-type and a 132 kv shell-type were tested, as shown in figure 10. The impulse tests from 1 microsecond and less were made with a 24-inch rod gap chopping the wave on the front.[11] From about 2.5-microsecond duration to the 40-microsecond full wave the tests were made in the same manner as in the recommended practice[12,13] using a test rod gap. Switching surges limited by a 38 1/4-inch co-ordinating rod gap were made on the core-type transformer and in a few of the tests the gap actually flashed over. Furthermore this transformer had previously been used in the switching surge tests in the set-up of figure 1 and had been subjected to more than 500 of these tests from 350 kv and less.

The standard one-minute 60-cycle test had also been made.

The dotted line at 860 kv (391 × 2.2) shows the maximum permissible impulse test level corresponding to the standard AIEE 60-cycle test.[3,4] It will be seen that the tests above this line in region *E* encroach on the margin of the insulation impulse strength. The tests in region *D* verify the adequate impulse strength levels of the transformers. The tests in region *C* represent AIEE recommended impulse tests.[12,13] The highest switching tests are indicated at *B*. These tests on the transformer are amply indicative that the voltage-time characteristic of this and other apparatus of the kind is similar in shape to that for the oil and fullerboard. These large numbers of tests over the entire time range, from a fraction of a microsecond to a minute, indicate that impulse and 60-cycle tests are sufficient to establish the adequacy of a transformer design for practically all conditions of service.

## Conclusions

1. In the oil tests corona and breakdown apparently occurred simultaneously.

2. The impulse ratio at the full impulse wave for the oil tested is approximately 2.5. The average strength of the oil is practically constant from 15 to 1,000 microseconds.

3. In the fullerboard tests even though profuse corona preceded breakdown, no appreciable damage could be observed on the insulation.

4. The strength of fullerboard is practically constant from 2 to 16,000 microseconds. Over this range the impulse ratio is close to 3.1.

5. In the fullerboard tests a distinct difference was found in the nature of breakdown between the positive and the negative polarity as indicated by the corona streamers, the failures and the 60-cycle tests.

6. The character of the breakdown for the impulse, switching, short-time 60-cycle, and long-time 60-cycle voltages was progressively from a distinct disruptive character to a burning effect.

7. The strength of fullerboard and oil is essentially the same for switching surges as for impulse voltages at the full 40-microsecond wave. This characteristic and the tests on the transformers indicate that 60-cycle and impulse tests are proof of the adequacy of design for practical service conditions.

# Development of a Modern Watt-Hour Meter

By I. F. KINNARD
MEMBER AIEE

H. E. TREKELL
ASSOCIATE AIEE

**A comprehensive discussion of the factors affecting the performance of a watt-hour meter is presented in this paper, and the general discussion is applied to a description of the development of a new type of domestic watt-hour meter. Design and performance data on the new meter also are presented.**

THE a-c watt-hour meter has undergone many stages of development and improvement since the first ac-dc meter designed by Thomson in 1889 and the first induction watt-hour meter by Shallenberger in 1894. Meters have grown smaller, they have become much more accurate under varying load conditions, and their cost has been reduced. There has been a definite tendency to increase the current range over which a meter will operate successfully. Another important improvement has been the minimizing of errors due to variations in ambient temperature. Both of these features are of particular significance when considered from the standpoint of modern metering conditions.

Watt-hour meters as they exist today have built up a deserved reputation for accuracy and reliability and at first thought it might appear that further attempts to improve performance might be unwarranted, if not impossible. When carefully analyzed, however, it is evident that the "long range accuracy" that has been built into recent meters has really been an attempt to reach closer to the ideal, which would be a single meter capable of measuring all currents encountered in a given class of installations. Such a meter would simplify the problem of providing for future growth of load on an installation and at the same time adequately take care of the very small loads that are frequently of importance. It would eliminate the uncertainty of choosing the correct current rating for a given job, because there would be only one meter to use—one meter for all domestic loads. Such an arrangement would obviously be advantageous, particularly from the standpoint of reduction in inventory expense of complete meters and parts.

More general mounting of meters out-of-doors in locations where extreme high and low temperatures were encountered presented new problems. One of these was to provide higher accuracy over wider temperature ranges than heretofore.

There appeared, therefore, sufficient justification to warrant a complete analysis of the fundamentals of watt-hour meter design with the objective of discovering means of providing these and other desirable improvements.

## Factors Affecting Meter Performance

At the outset, the basic design problems with an induction watt-hour meter are: first, to provide sufficient torque with a minimum of friction so that the effects of friction are minimized; second, to minimize the damping effects of the a-c fluxes in order that the performance will be good at abnormal voltages and at heavy loads; third, to decrease the inherent lagging angle and the potential circuit watts loss in order that wave form, frequency, low power factor, and class II temperature errors will be minimized. The induction meter is inherently accurate but it is these details that are the main causes of any inaccuracy. A good design must incorporate a consideration of all these factors.

### Analysis of Element Driving and Damping Torques

To analyze the inherent effects of the a-c fluxes in the driving element of a watt-hour meter, it is well to consider how these fluxes determine the element driving and damping torques. At normal conditions of load—that is, rated frequency and voltage, unity power factor, and nominal-load current, there will be established definite values of flux, and the driving torque at this point is commonly known as the nominal or full-load torque. For this condition, it may be assumed that the effective potential flux crossing the disk lags the applied voltage by 90 electrical degrees and that the useful current flux is in phase with the load current. For this condition, Jimbo[1] has shown that the load torque is equal to

$$T = 4\pi \frac{stf}{g} G_d \phi_e' \phi_i' \cos\theta \, 10^{-8} \qquad (1)$$

where

$T$ = load torque in gram-millimeters
$s$ = conductivity of disk in mhos per centimeter cube
$t$ = thickness of disk in centimeters
$f$ = frequency in cycles per second
$g$ = gravitational constant
$G_d$ = driving constant
$\phi_e'$ = useful potential flux in maxwells, effective values
$\phi_i'$ = useful current flux in maxwells, effective values
$\theta$ = phase angle between voltage and current

$G_d$ is a dimensionless constant which is determined by pole shapes and displacements, their position relative to the disk, and the size of the disk. For any design, $G_d$ may be readily estimated by methods of Jimbo or by methods proposed by Morton.[2] This driving constant is a direct measure of the effectiveness of any design in producing torque from given amounts of flux.

A paper recommended for publication by the AIEE committee on instruments and measurements. Manuscript submitted October 30, 1936; released for publication December 8, 1936.

I. F. KINNARD is executive engineer in charge of the engineering department of the West Lynn works, General Electric Company, Lynn, Mass. H. E. TREKELL is meter development engineer for the same company.

1. For all numbered references, see list at end of paper.

The current and potential fluxes not only produce a driving torque but each also provides a damping torque which in the case of the current flux is the major cause of heavy-load droop, and in the case of the potential flux is the major cause of meter voltage errors. These damping torques are expressed as follows:

$$T_i = \frac{st\omega}{g} G_i (\phi_i')^2 10^{-8} \quad (2)$$

$$T_e = \frac{st\omega}{g} G_e (\phi_e')^2 10^{-8} \quad (3)$$

where

$T_i$ = current flux damping torque in gram-millimeters
$T_e$ = potential flux damping torque in gram-millimeters
$\omega$ = speed of disk in radians per second
$G_i$ = current damping constant
$G_e$ = potential damping constant

These damping constants are also dimensionless and depend upon the inherent meter design. The designer's problem is to provide the useful potential and current fluxes from appropriate windings, so designing the magnetic structure that the driving constant $G_d$ is as large as possible and the damping constants $G_i$ and $G_e$ are as small as possible. By knowing these constants, the inherent qualities of any element are largely established although there are other features that must be considered. For instance, the structure which gives desirable driving and damping constants may not be at all practical in that it may be difficult to efficiently provide the required magnitude of a-c fluxes.

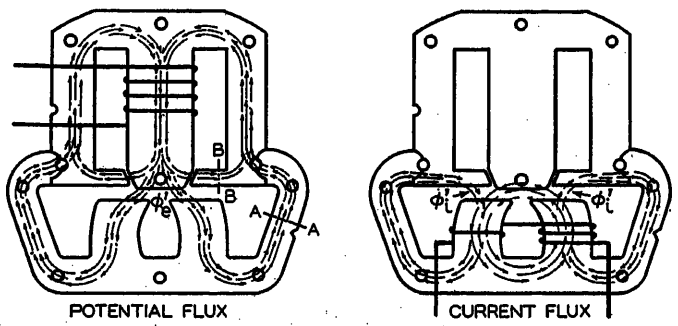

**Fig. 1. Distribution of potential and current fluxes in a watt-hour meter**

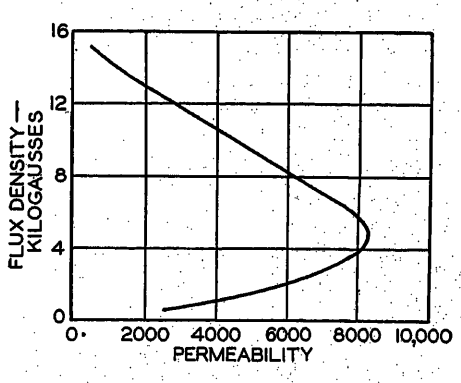

**Fig. 2. Permeability curve for silicon steel**

Equations 1, 2, and 3 have further value for they show that:

1. The a-c damping torques in a meter are proportional to the meter speed so it is desirable to make the nominal speed as small as possible. This is accomplished by the use of a high-strength control magnet.

2. For small current damping, the ratio $\phi_i'/\phi_e'$ should be small and for small potential damping the inverse is true. The final choice depends upon the errors and the relative ease of correcting for them in the design.

3. For given amounts of flux, the driving torque is proportional to frequency so that for the higher frequency ratings the damping effects of the a-c fluxes are relatively smaller. The damping torques do not depend upon the rated frequency.

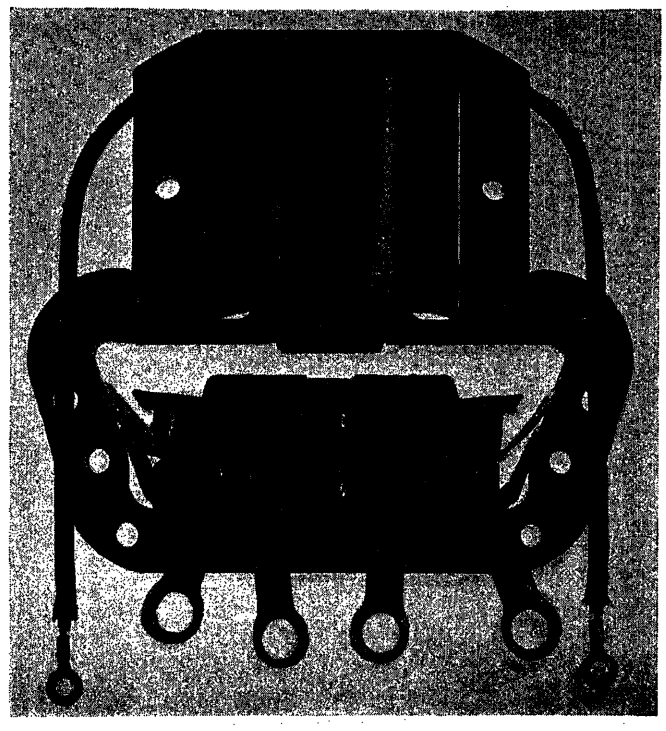

**Fig. 3. Element assembly of a new 3-wire domestic watt-hour meter**

High-conductivity aluminum is used for the disk because of the superior torque to weight ratio that results.

## The Voltage Curve

Since commercial power systems usually hold voltage within 10 per cent, it is necessary that a meter be correct for only a rather limited voltage range. Because of this and since the error is easily corrected in the design, the useful potential flux in modern watt-hour meters is usually 4 or 5 times as large as the useful current flux at nominal load. This practice gives less current damping torque, improving the heavy load registration curve. A common method in use today to correct for the voltage damping torque or voltage error is to proportion the magnetic structure so that the useful potential flux increases more rapidly than the applied voltage. This has been accomplished[8] without resorting to saturation. In this

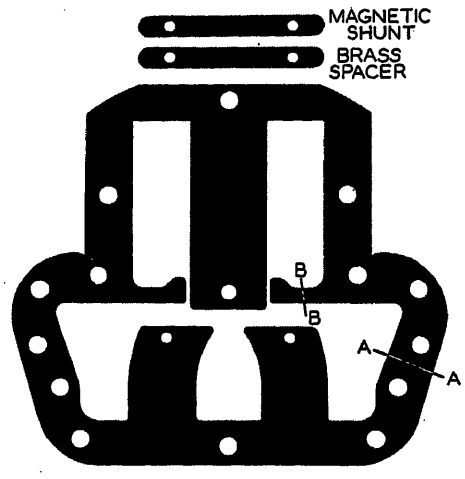

**Fig. 4. The type of lamination used for all sizes of watt - hour meters**

scheme, the useful potential flux through sections *A*—*A*, figure 1, works below the point of maximum permeability in the iron and is operated in parallel with the shunt path at section *B*—*B* which works above the point of maximum permeability.

## The Load Curve

The factors which determine the shape of the speed-load or meter-accuracy curve, some of which have been previously published,[4] may be divided into 2 classes: (1) those that are significant in affecting the light load performance and (2) those that have the most influence on heavy load performance. These factors include:

1. Ratio of friction to load torque.
2. Variation of iron permeability.
3. Variation of torque due to anticreep holes.

These factors affect light-load performance.

4. Damping effect of current flux.
5. Torque due to load current alone.

These factors affect heavy-load performance.

These 5 factors are the inherent factors in any meter that determine the load curve. A sixth factor which is a powerful tool to correct for error is load compensation which will be considered later in this paper.

*Friction.* Friction largely determines the reliability of sustained performance and its presence is the principal reason for a high driving torque which minimizes the effect of the friction torque. Friction is essentially constant in value at light loads where it is significant and provides a constant retarding torque which, unless compensated, will cause a drooping characteristic in the registration curve as light load is approached from nominal load. In a meter, this retarding torque is balanced by the light-load adjustment torque. At normal voltage, the 2 torques cancel and the shape of the load curve is not affected. It is very desirable to keep the total friction

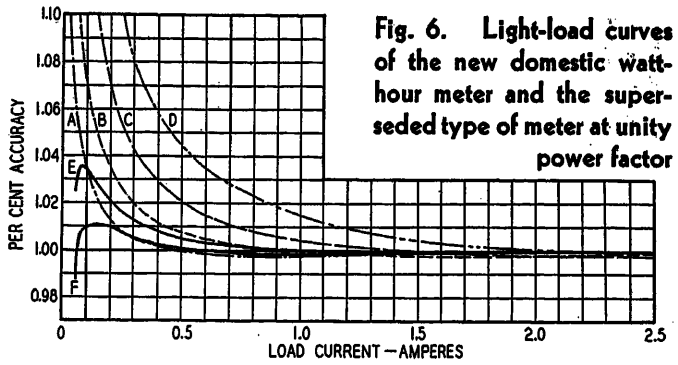

**Fig. 6. Light-load curves of the new domestic watt-hour meter and the superseded type of meter at unity power factor**

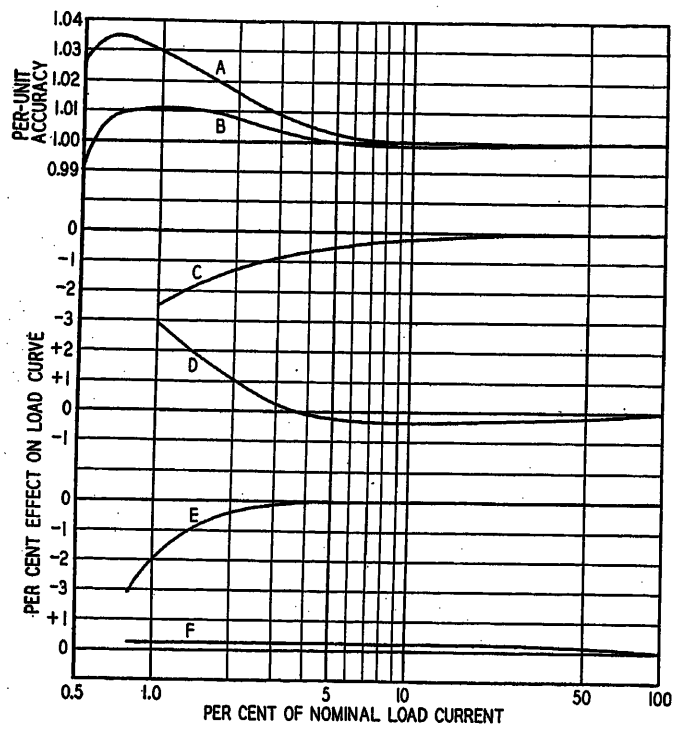
*F*—Current damping

torque low in order to decrease variations and to reduce the compensation required. With latest improvements in bearing design which have been described recently,[5] the total bearing and register friction as measured[6] is approximately 0.013 gram-millimeter. With a nominal load torque of 52 gram-millimeters, the friction represents only 0.25 per cent of the torque at 10 per cent nominal load. In the earlier days of the metering art, friction was a greater limitation, and the introduction of high-torque meters was a significant advance. Further refinements in bearings which give long life and low friction have reduced the effect of friction until other factors at light load are equally or more important.

*Iron Permeability.* With iron in the element magnetic circuit, the current flux is usually more than proportional to the load current. This is due to the fact that in most designs the current flux magnetic circuit operates below the point of maximum permeability. The effect on the load curve is often confused with friction since the effect of the permeability change is also a drooping characteristic as light load is approached, unless it is corrected by means



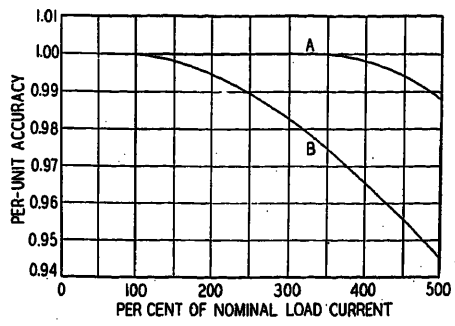


**Fig. 8. Components of light-load curve with load compensation at unity power factor**

*D*—Iron
*E*—Anticreep holes
*F*—Current damping

of the light-load compensation. Usually the compensation required at 10 per cent nominal load, the usual calibration point, is more than that required at smaller loads so the net result is a rising load curve below 10 per cent nominal load. The effect of the iron can be minimized by the proper choice of magnetic sections, the use of high-

*A*—Compensated
*B*—Uncompensated

permeability iron, and by using a large main air gap with a large number of ampere-turns in the current coils.

*Anticreep Holes.* The anticreep holes in the disk reacting with the potential flux cause a small locking torque which must be overcome by load torque due to both current and potential flux before the meter will start. It is in this manner that the anticreep holes keep the disk from rotating when there is no load current flowing even though the light-load compensation torque has an average positive value. At loads just above starting, the meter speed varies due to the anticreep holes and the variation causes the average meter speed to be lower than it would be without the holes. This influence is present to a significant extent only at loads below 5 per cent of nominal rating. It may be considered beneficial because it he ps to correct for the effect of iron permeability variation.

*Current Flux Damping Torque.* The presence of the current flux damping torque has been explained with the analysis of the element driving and damping torques. The current flux damping torque is the largest cause of heavy load errors. For any design, this error is approximately proportional to the square of the load current since the current damping torque increases as $(\phi_i'^2)$ and $\omega$ whereas the load torque is proportional to $\phi_i'$. Meter speed $\omega$ is proportional to $\phi_i'$ neglecting the meter error. There has been much progress in design to decrease this inherent error. In early meters, the error at 400 per cent nominal load amounted to as much as 12 per cent, thus limiting the load range for acceptable accuracy within 150 per cent of nominal rating. This error at 400 per cent nominal load had been reduced to less than 2.7 per cent by the year 1927.[6] This was accomplished by designing a meter element to make the best known possible use of the a-c fluxes as regards driving and damping torques, by using a high useful potential flux and a low useful current flux, and by using a strong permanent magnet and a low meter speed. This design gave very good performance without the use of heavy load compensation, giving satisfactory operation up to 300 per cent nominal load and still retaining good operation at light loads.

*Current Torque.* It is well known by designers and has been experimentally determined that when there is an unbalance in the current flux magnetic circuit caused by having more turns on one current pole than on the other, there will be a driving torque generated in the disk due to the current flux alone. By making the proper pole have the greater number of turns, this torque will be

forward and will tend to correct for heavy load droop. This effect may amount to as much as 1 per cent at 400 per cent nominal load with a 2 to 1 unbalance. This torque is present at all power factors so that it is proportionately more effective at the lower power factors. This feature is usually not desirable, particularly when heavy load compensation is used. In this case, the compensation is designed to be satisfactory at unity power factor so that with the current circuit unbalance the compensation will be too great at lower power factors and the meter will run fast.

### Potential and Current Flux Circuits

The design of the current flux circuit is determined largely by the ampere-turns desired, the ratings in which a line of meters must be manufactured, and the space limitations. Provision must be made to include sufficient section so that temperature rise will be small, and the coils must be insulated for abnormal voltages. These features, with a consideration of the driving and damping constants, establish the current pole shapes and the current coil designs.

The potential coil and core must provide useful flux at a phase angle not far from quadrature with the applied voltage. The design problem is to provide sufficient sections so that the watts loss is low. Furthermore, the ratio of resistance to reactance must be as small as possible. This is helped by using a coil of small mean length of turn and a good space factor. The number of potential coil turns should be low, calling for potential air gaps of small reluctance. This takes loss from the copper and places it in the iron where it is not so effective in determining the inherent lagging angle.

### Temperature Errors

The causes of temperature errors have been considered by Kinnard and Faus.[7] These errors are divided into 2 classes, depending upon their influence on the meter. These 2 classes are:

*Class* I. Those errors which affect all loads alike and which are equivalent to a change in magnet strength.

*Class* II. Those errors caused by a change in phase angle between the useful potential and current fluxes. These errors appear only at lower power factors.

The common method of class I temperature compensation is that described in the paper referred to, in which a material having a negative permeability-temperature characteristic is used to shunt some of the permanent magnet flux. With increases in temperature, the shunt is less effective and the magnet damping strength is held within desired limits. Much research has been undertaken since 1925 to extend the range of compensation to wider temperature differences.

Class II errors should first be minimized by designing with a small inherent lagging angle. The error can be reduced by using lag plates and lag coils of low resistivity-temperature coefficient materials. A common method of compensation, described by Brooks,[8] is to overlag the useful potential flux with a low-coefficient material and then correspondingly lag the useful current flux with a high-coefficient material. With the proper balance, the phase angle will remain unchanged with change in temperature. This method has its disadvantages because it introduces additional watts loss and in some cases makes the low power factor operation poor. A more successful method of class II compensation is described later in this paper.

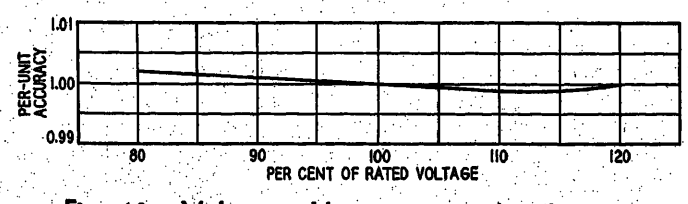

**Fig. 10. Voltage calibration curve for the new domestic watt-hour meter**

## Consideration of a Specific Design

### Inherent Accuracy

The real criterion of any meter is its performance, but the reasons for all characteristic curves are related with the above factors affecting meter performance. A fundamental method of comparison and analysis is to prepare a table listing the major design constants for any design. The choice of any design is then very straightforward, for the various factors can be weighed in their true sense. In developing the meter described below, many samples were tested and analyzed. All designs were compared by listing the characteristic constants as

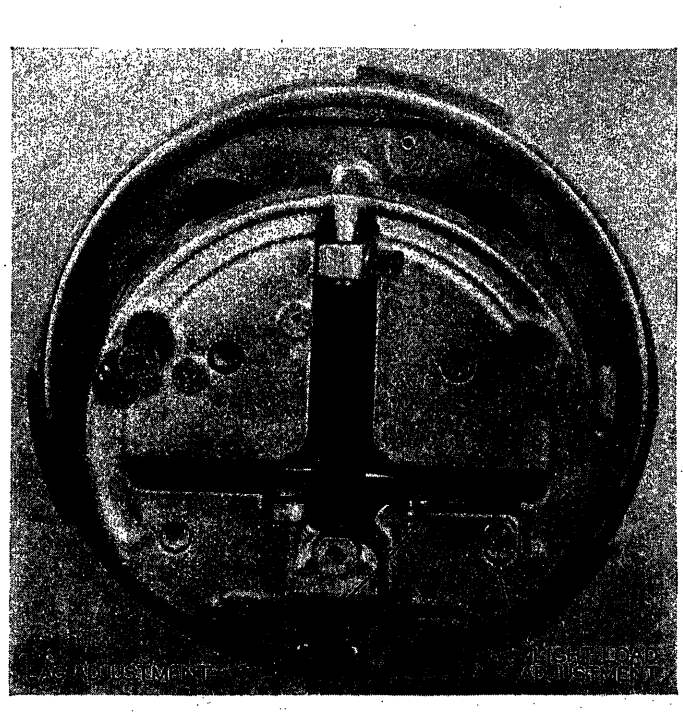

**Fig. 11. Interior view of the new domestic watt-hour meter, showing the light-load and lag adjustments mounted on the frame**

shown in table I, which in this instance includes only the data for the design finally chosen.

Table I shows the inherent errors of the latest design to be small without compensation. It was found that better and more consistent operation was obtained by thus reducing inherent errors and applying a minimum amount of compensation.

Sufficient amounts of flux and a large driving constant result in a high torque-to-weight ratio. It was necessary to keep the watts loss down to a reasonable value in deciding on flux values.

The slow meter speed and the small damping constants $G_i$ and $G_e$ result in small inherent errors for abnormal

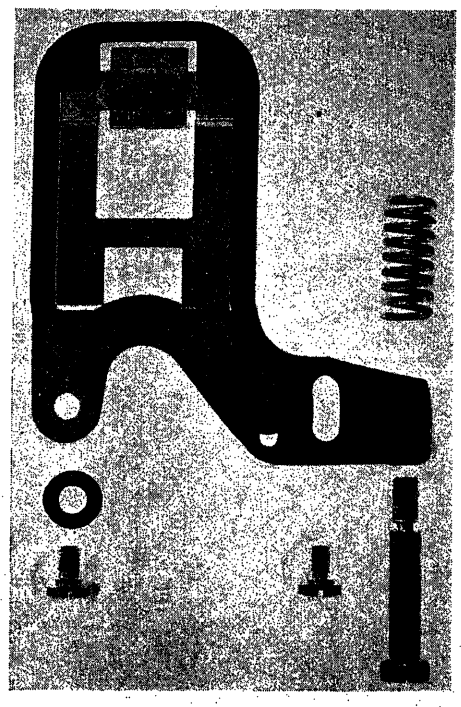

**Fig. 12. Lag plate and support, showing class II temperature-compensating device**

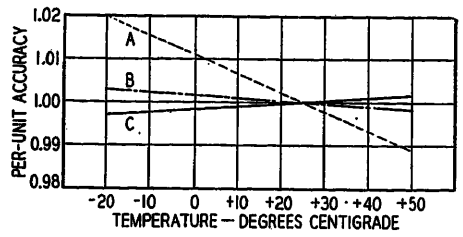

voltages and heavy loads. Improved compensations then result in negligible resultant errors due to voltage and temperature variations and permit a much longer load range than before possible.

The choice of current circuit ampere-turns is limited on the low side by the required flux and necessary air gap; it is limited on the high side by the same factors, also heating and volt-ampere burden. The number within this range found to be most suitable for all ratings was 100. This number makes it possible to use an equal number of turns on each current pole on one iron structure for all ratings, 2-wire and 3-wire. This insures most consistent performance and simplifies manufacture and stocking due to having only one iron structure, magnet strength, and adjustment mechanism with which to deal.

## Ratings

Figure 3 shows the complete assembled element. Form-wound current coils are used and are readily placed on the current poles. Figure 4 shows the laminations and the load shunt and spacer which are securely attached to the

**Fig. 13. Temperature calibration curve for the new domestic watt-hour meter**

*C*—With temperature compensation at unity power factor

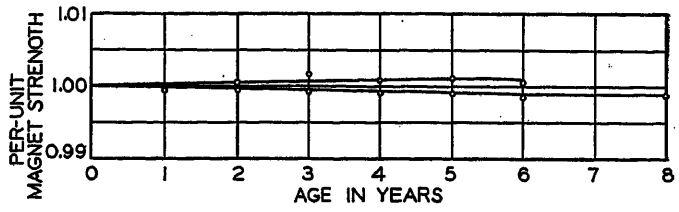

**Fig. 14. Typical aging curves for the magnet used in the new watt-hour meter**

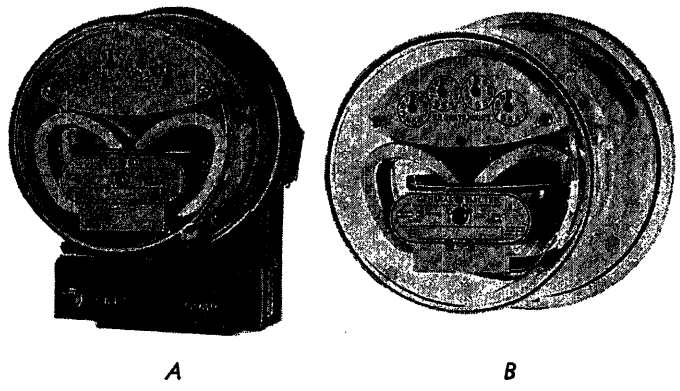
current laminations and also serve to hold the current coils in place. Using this iron structure, 3 self-contained sizes are suggested: a long-range domestic meter, a long-range commercial meter, and a low-capacity meter.

The domestic meter is proposed for modern home loads, including the latest advances in lighting, appliances, cooking, refrigeration, and air conditioning. At the same time, this meter should measure small loads such as clocks and night lights. A 2-wire 115-volt meter of this type will start at 4 watts and will measure accurately loads up to 6,000 watts.



The commercial meter is intended to handle heavier loads. This meter will start at 16 watts and will measure loads accurately up to 150 amperes.

The low-capacity meter is proposed for use where small loads are of primary importance and provision for higher loads is not required.

It will be interesting to compare the performance of the domestic meter just described with existing meters rated 5, 10, 15, and 25 amperes, respectively. This is shown in figures 5 and 6 where meter accuracy is plotted as a function of load current. At heavy currents up to 60 amperes, the accuracy of the domestic meter is superior to that of any of the 3 lower ratings of the existing meter and about equal to that of the 25-ampere rating. At light loads, its accuracy is definitely superior to the 10-, 15-, and 25-ampere ratings. When the domestic meter is calibrated at 5 per cent nominal load, its performance is superior to the existing 5-ampere meter except from the standpoint of starting watts. Even when calibrated at 10 per cent nominal load, the performance is comparable.

Because of this long load range, the number of essential self-contained ratings required is reduced from 5 to 2. These 2 ratings, together with the proposed low-capacity meter, are shown in table II with the nominal and maximum

current ratings, the watt-hour constant, and the balanced current coil turns. The nominal rating corresponds to what has been known in the past as the full-load or name-plate rating. With improved heavy-load performance, the nominal rating represents only a calibration and reference point. The maximum rating is determined by accuracy and heating limitations so that it does have real significance. All 3 ratings have the same speed and

A B

**Fig. 15. Types of the new watt-hour meter**

*A*—Type *A* bottom-connected meter
*B*—Type *S* socket meter

torque obtained by the use of 100 ampere-turns in the current circuit at nominal load.

The domestic meter has a watt-hour constant of 1.5. This provides a good compromise between the 2 basic meter speed systems in general use today. Assuming all meters concerned to be 100 per cent accurate, a given even number of revolutions of this domestic meter corresponds to integral numbers of revolutions of all watt-hour meter standards now in production. Other possible constants do not have this desirable feature.

### The Load Curve

The load shunt not only compensates for heavy load droop but also improves the performance at light loads. Figure 7 shows the light-load curve and the relative values of all the factors comprising it when no compensation is used. These curves are plotted on a semilogarithmic scale in order to expand the extremely light load portions. As described previously the curve rises at light loads due to the effect of the iron.

When the load shunt is applied, figure 8, the droop due to the iron is reduced because the shunt was designed so that its permeability decreases with decrease in load from the nominal rating. This reduces the light-load compensation necessary for correct calibration and the resulting load curve is accurate to lower values.

At heavy loads, compensation for the droop is accomplished as a result of the load shunt approaching saturation so that the current flux is more than proportional to load current. Figure 9 shows the compensated and uncompensated heavy-load curves at unity power factor. The use of balanced ampere-turns on the current poles and the particular design of load shunt result in equivalent performance at low power factors.

**Table I—Analysis Chart of a Watt-Hour Meter**

| Quantity* | Symbol | Unit | Value |
|---|---|---|---|
| Rated voltage | $V$ | volts | 115 |
| Nominal current | $I$ | amperes | 12.5 |
| Frequency | $f$ | cycles per second | 60 |
| Watt-hour per revolution | $K$ | | 1.5 |
| Speed at nominal load | $\omega$ | radians per second | 1.672 |
| Disk diameter | $D$ | inches | 3.5 |
| Disk thickness | $t$ | inches | 0.027 |
| Disk thickness | $t$ | centimeters | 0.0686 |
| Disk weight | $W$ | grams | 13.3 |
| Torque at nominal load | $T$ | gram-millimeters | 52.5 |
| Torque-to-weight ratio | $T/W$ | | 3.95 |

† Goss[9] has shown friction to vary as $(W)^{4/3}$.

** $R = 100\,\frac{15\,T_i/T}{1 + 15\,T_i/T}$

‡ $S = 100\left(\frac{(1.2)^2 T_e}{1.2T} - \frac{T_e}{T}\right) = 44.4\frac{T_e}{T}$

**Table II—Self-Contained Ratings**

| Meter | Nominal Rating, Amperes | Maximum Rating, K (115 Amperes Volts) | Turns on Current Poles: Right | Left | Total | Nominal Ampere-Turns |
|---|---|---|---|---|---|---|
| Commercial | 50 | 150 | 6.0 | 1 | 1 | 2 | 100 |
| Domestic | 12.5 | 60 | 1.5 | 4 | 4 | 8 | 100 |
| Low capacity | 5 | 20 | 0.6 | 10 | 10 | 20 | 100 |

### The Voltage Curve

The inherent voltage error at 120 per cent of rated voltage is shown in table I to be 0.98 per cent. As previously described, this error can be compensated for effectively by the use of the proper sections at *B*—*B* and *A*—*A* in the magnetic circuit (figure 4). The resulting voltage curve obtained is shown in figure 10. It was found possible to reduce the actual error to less than 0.2 per cent for 40 per cent voltage range.

### Light-Load and Lag Adjustment

The most straightforward and effective method of providing light-load and lag adjustment in this design was found to be modification of a mechanism already in general use, as shown in figures 11 and 12. The lag

plate is supported in the proper position by a bracket made of high-resistivity alloy. For light-load adjustment, this support is rotated by the light-load adjusting screw. A spring mounted on this screw between the lag plate support and the frame prevents backlash. The lag adjustment is accomplished by moving the lag plate radially with respect to the disk.

### Temperature Compensation

Class II temperature compensation is accomplished by a novel method proposed by Faus.[10] The lag plate is made with a small core linking it, composed of a material having a negative permeability-temperature characteristic similar to that used for magnet compensation. This core imposes an impedance in the lag circuit which becomes less effective with increases in temperature so that the lag plate becomes more effective. In this manner, the necessary increase in lagging is obtained to compensate for the shift in flux angles. Figure 13 shows the resulting temperature curves with both class I and class II compensation. Improvements in characteristics of the temperature-sensitive material has made possible more effective compensation of class I errors.

### Control Magnet

The control or damping magnet is of standard construction that has been used for many years. It is designed to give a high braking torque, making possible the slow meter speed which is so desirable for improved accuracy and a long load range. Magnets of this form are unusually stable. Figure 14 shows typical aging curves on 2 groups of magnets over periods of 6 and 8 years, respectively. At no time does the strength vary more than 0.2 per cent from the initial value.

## Summary

1. It is shown that fundamental analysis of meter theory can be used effectively in meter design and provides a basis of accurate comparison of inherent characteristics.
2. Emphasis is laid on the importance of minimizing the inherent errors, thereby reducing the magnitude of the required compensations. This results in improved accuracy and more consistent performance.
3. Slow meter speeds are desirable from the standpoint of higher accuracies and greater suitability for operation over a long load range.
4. The meter described with long range performance reduces the number of ratings required. It also provides for growth of load without sacrificing light load accuracy.
5. An improved temperature compensation is described which insures accurate registration under conditions of extreme temperature variations.
6. With improved performance, "full load" has lost its significance and should be replaced by a "nominal" and "maximum" rating. Nominal rating aids in comparisons and in calibration, but a maximum rating, corresponding to both accuracy and thermal limits, is the real criterion of a meter's capacity.

# Synchronous Machines With Solid Cylindrical Rotor

(*Continued from page 58*)

By equation 22, assuming that $e_r$ also varies as $e^{pt}$, we obtain the rotor-coil equation:

$$RI_r = e_r + Zk\int_0^e A_1 \cos ax\, E_r(x)dx = e_r - \frac{Kp\left[I_r A_1^2 \cosh ag + \frac{3}{2}A_1B_1(De^{-j\gamma} + D'e^{j\gamma})\right]}{a(q\cosh ag + \sinh ag)} \quad (52)$$

where

$$q = \frac{\beta}{\mu a}\left[p + \left(\frac{a}{\beta}\right)^2\right]^{\frac{1}{2}},\ K = 2\pi 10^{-9} Z l k$$

Similarly by equation 24, the voltage equation of stator coil $a$ is

$$r_s I_a = e_a + Zk\int_0^l B_1 \cos ax_1 E_s(x_1)dx_1 = Ce^{j\omega t} + C'e^{-j\omega t} + e_0 - \frac{K}{a(q\cosh ag + \sinh ag)}\left\{\frac{1}{2}I_r A_1 B_1[(p + j\omega)e^{j(\omega t+\gamma)} + (p - j\omega)e^{-j(\omega t+\gamma)}] + \frac{3}{2}B_1^2[D(p + j\omega)e^{j\omega t} + D'(p - j\omega)e^{-j\omega t}][\cosh ag + q\sinh ag]\right\} = r_s(De^{j\omega t} + D'e^{-j\omega t} + i_0) \quad (53)$$

Equation 53 is seen to be composed of 3 components, constant terms, terms containing $e^{j\omega t}$ as a factor, and terms containing $e^{-j\omega t}$ as a factor. By combining this equation with 2 similar equations for coils $b$ and $c$ it may be separated into its 3 component equations. Thus from equations 49 and 53 are formed the 4 final equations 30 given in the body of the paper.

# A New Service Restorer

By E. F. SIXTUS ASSOCIATE  W. R. NODDER NONMEMBER

**Equipment capable of restoring service automatically after temporary interruptions on transmission and distribution systems has been developed to a high degree of effectiveness; however, most of such equipment is suitable only for systems of high capacity, and comparatively little attention has been given to systems of low and intermediate capacities. An automatic service restorer, designed primarily for use on systems of low capacity, is described in this paper, and some data on its operating characteristics are presented.**

IN RECENT years there has been an increasing demand on the part of operating companies for equipment capable of automatically restoring service after interruptions due to momentary or self-clearing faults on transmission and distribution systems. Where protective equipment of high interrupting capacity is involved, this demand has been met by the use of the conventional oil circuit breaker in conjunction with protective relays and an adjustable timing relay to control the reclosing cycle. This equipment has been developed to such an extent that immediate reclosing breakers, capable of reclosing so quickly that in most cases service will be restored before synchronous motors can fall out of step, are now available for use on systems as high as 115,000 volts.

Up to the present time little has been done to extend the line of automatic reclosing breakers to the lower capacities, due mainly to the fact that the cost of such equipment could not be justified in the low-revenue field where it would be applied. The 7,500-volt breaker with an interrupting capacity of 50,000 kva has so far set the lower limit at which the conventional reclosing equipment has been economically feasible for outdoor service.

A study of outages on rural distribution systems has shown that from 75 to 90 per cent of the faults are momentary and self-clearing, but will blow a fuse and thereby cause a long power outage. It is evident, therefore, that a low-capacity automatic-reclosing breaker, if used in place of fuses, would result in a great improvement in service. Reclosing fuses have, of course, been available but they cannot be expected to give service equivalent to an enclosed high-speed reclosing breaker.

To be completely successful a breaker to fill this low-capacity requirement must have certain very definite characteristics:

1. It must be low in cost—considerably lower than the conventional reclosing breakers now on the market. It must be simple to install, to keep the labor and cost of installation at a minimum.
2. It must be simple to operate, so that it can be opened, closed or reset by an inexperienced person and thus save trained power company employees from making long trips to isolated installations.
3. It must be suitable for outdoor service and for pole mounting.
4. It must provide dependable overload and short circuit protection under all weather conditions with very little maintenance.
5. It should provide at least 3 automatic reclosures with the first reclosure immediate if so desired.
6. It should be multipole with all poles opening simultaneously to prevent single phase operation of three phase equipment.
7. It should trip on extremely low currents, about 10 amperes minimum, to provide dependable overload protection for lightly loaded lines.

After giving careful consideration to the above requirements it was decided that conventional designs must be discarded and it was on this basis that the type *AP*-1 automatic service restorer illustrated in figure 1 was developed.

One of the first problems to be solved in the design of the device was that of securing power to provide 3 automatic reclosures. Two types of control were considered; one where the operating power is derived from a relatively inexhaustible source such as an auxiliary battery and charger unit, or the line voltage or current itself; and the other where the actuating power is derived from an exhaustible source such as a spring.

If an inexhaustible power supply were used it would be necessary for an attendant to visit the switch every time it locked open for the purpose of resetting the lockout mechanism. Assuming that 75 per cent of the shorts are self clearing, the device would lock out and require the service of an attendant after every 4 short circuits.

With an exhaustible power supply, such as a spring that could be wound to provide sufficient energy for 4 openings and 3 reclosures, the attendant would be required to reset the lockout mechanism after every lockout as above and in addition would be required to restore the energy in the spring after every 4 shorts which were cleared, because the spring would be completely unwound. This would result, let us assume, in the attendant making twice as many trips to a device with a spring type of power supply as to one with an inexhaustible power supply. It is possible, of course, that a carrier current control could be used in lieu of an attendant to reset the lockout mechanism, although such an arrangement does not seem economically advisable at present.

The inexhaustible power supply could be provided by:

1. The use of a potential transformer placed in the tank of the device and connected to a small motor arranged to rewind an operating spring and keep it wound at all times.
2. The use of some sort of capacitance device in place of the potential transformer to supply energy to the rewinding motor. The out-

A paper recommended for publication by the AIEE committee on protective devices. Manuscript submitted October 29, 1936; released for publication November 20, 1936.

E. F. SIXTUS is vice-president in charge of sales, Pacific Electric Mfg. Corporation, San Francisco, Calif. W. R. NODDER is an engineer for the same company.

put of such a device would necessarily be small but rewinding could be accomplished over a relatively long period of time, as the spring could be designed to provide enough energy for 4 openings without rewinding.

3. The use of a falling weight heavy enough to provide energy for a large number of operations, possibly 20 or 30.

4. Using the short-circuit current, which causes the device to trip, to store sufficient energy for the next closing and opening operation.

In the design of the type *AP*-1 the first 2 methods listed above were discarded because they added materially to the cost of the device, and it was felt that the increased expense would not be justified in the majority of installations. The third alternative, that of using the falling weight was considered impractical and was not used because of the probable unfavorable reception such construction would receive from prospective users of the device. The fourth idea, that of using the short-circuit current to provide energy for closing and reopening the circuit, was not considered favorable because of the high current required to trip a device of this kind; a low tripping current being one of the requisites of the design.

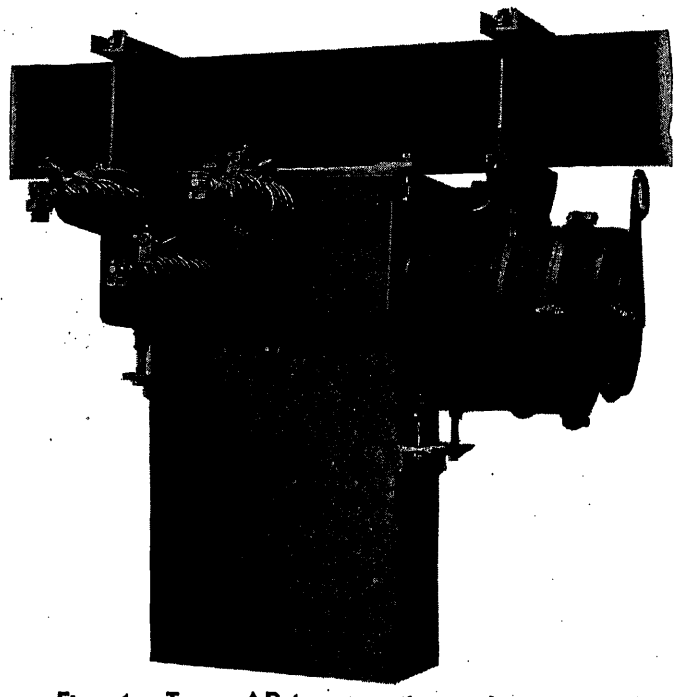

**Fig. 1. Type AP-1 automatic service restorer, 7,500/12,500 Y volts**

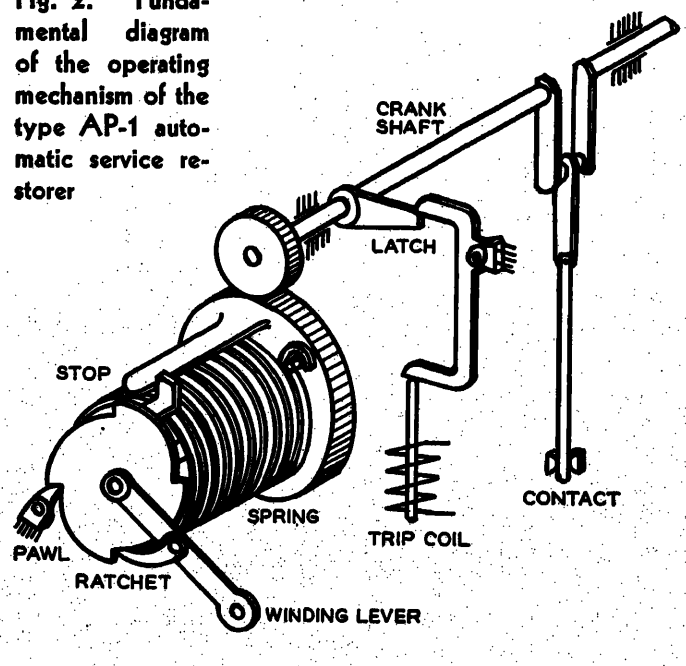

**Fig. 2. Fundamental diagram of the operating mechanism of the type AP-1 automatic service restorer**

In view of the disadvantages of the inexhaustible power supply as applied to this particular device, the *AP*-1 was designed to use, as an operating mechanism, a manually wound spring which when fully wound, would store enough energy to give 3 closing and 4 opening operations. A helical twist spring was selected because its unidirectional motion was most easily adapted to the reciprocating motion of the switch blades. In actual construction one end of the spring is connected to a rewinding lever and the other, through a 4-to-1 reduction gear, to a crankshaft to which the blades are connected. See figure 2. The 4-to-1 reduction gear is used so that a $^1/_4$ turn on the rewinding lever will rewind the spring sufficiently for one reclosing cycle and a dial has been added to indicate to what extent the spring is wound. A stop is provided to hold the contacts in the open position upon completion of the last opening stroke.

The crankshaft is fitted with a latch plate engaging a latch to hold the breaker closed with the spring wound. This latch, which is actuated by a series trip coil in each pole, is released on overload permitting the contacts to open at high speed under the action of the helical spring. There being no latch to hold the switch open, it recloses and remains closed until the latch is again released by one of the trip coils, except in the case of the last opening when it locks in the open position.

In order to provide a timing mechanism to control the reclosing interval a special dashpot was developed. Upon attempting to determine the reclosing interval to use it was found that prospective users required different reclosing cycles. Some required an immediate first reclosure and others 3 reclosures at equal time intervals. In order to give the device as wide an application as possible the dashpot was designed so that it could be set to provide either 3 reclosures at an adjustable time interval, or one immediate reclosure with 2 additional reclosures at an adjustable time interval. In each case the reclosing interval is adjustable from 1 to 10 seconds.

The design of the arc-rupturing chamber for such a low interrupting capacity

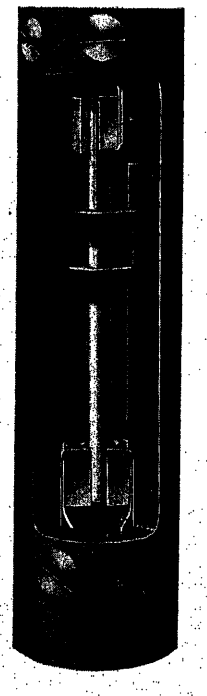

**Fig. 3. Cross-sectional view of expulsion contact chamber of the automatic service restorer**

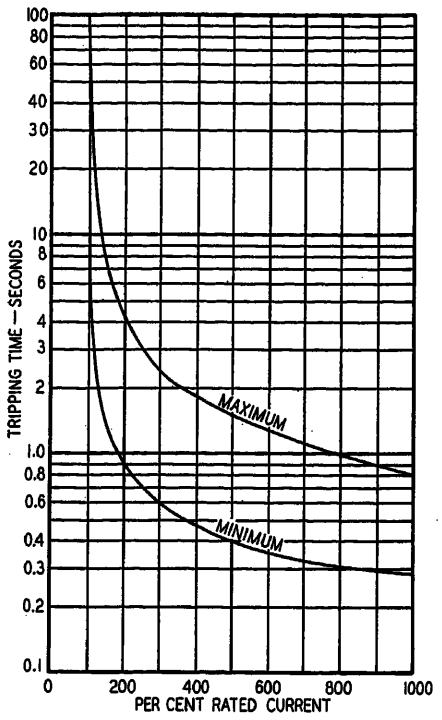

**Fig. 4. Time-current curves of delayed trip attachment**

device presented no problem, as previous papers have demonstrated the ability of the expulsion chamber contact to easily interrupt currents both greater and smaller than those required in this instance. The contact design used is shown in cross section in figure 3. It consists essentially of a moving blade engaging with high-pressure full-floating stationary contacts and separating at high speed in an enclosed chamber provided with baffles and vents to secure the most efficient arc extinguishing action.

The continuous current rating of the service restorer was set at 100 amperes in order to include the full current range normally covered by fuses. It was felt inadvisable to provide for larger currents because of the desire to keep the dimensions as small as possible and because investigation indicated that a 100-ampere capacity would be ample for most applications.

Consideration was, of course, given in the design to the need for co-ordinating the series trip coils with the blowing characteristics of fuses and the time current characteristics of oil circuit breaker relays. Trip coils for instantaneous and inverse time delay action have been developed. Instantaneous coils are provided with current adjustments so that they can be adjusted to operate at either 100, 150, or 200 per cent of the coil rating. Time-delay coils are provided with current and time adjustments, the characteristics of which are shown in figure 4.

Extensive tests were performed on the service restorer to verify its assigned interrupting rating of 1,200 amperes at 12,500 volts. Typical results are shown in figure 5.

Film *A* shows the performance during 2 interruptions of 1,780 amperes with 2,600 volts across the terminals. The total fault time in the first case is 7.0 cycles and in the second 7.4 cycles.

# Impulse-Generator Voltage Charts for Selecting Circuit Constants

By J. L. THOMASON
ASSOCIATE AIEE

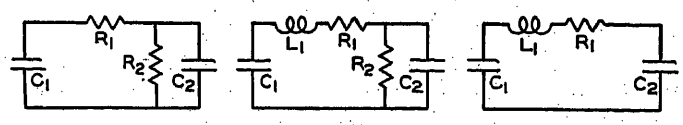
**It is suggested in this paper that impulse generator voltage waves for commercial testing may be compared not only on the basis of wave shape but also on the basis of relations between circuit constants. The charts and graphs included are intended to show how desirable this is, and they may be used to facilitate both front-of-wave and full-wave testing.**

PREVIOUSLY published articles[1-6] have indicated the need of an accurate method of comparing impulse voltage waves, and although it has already been recommended[1] that impulse voltage waves be designated by the "2 point" method, that is, 1.5x40, a considerable range for wave shape variation is possible even if it is specified that the wave is smooth. It seems desirable therefore in those cases where more accurate determination of wave shape is required to specify the generator circuit constants and to compare the wave shapes on some definite basis such as on a basis of ratios between the different circuit constants as presented here.

There are numerous impulse-generator circuits, each having its merits, which will produce desirable voltage test waves. However, to escape the use of a multiplicity of circuits it seems desirable to use one or 2 circuits. Then the small differences and oddities in waves produced by the different circuits can be eliminated, theoretically at least, in comparing test results.

## Circuits Analyzed

In this paper only 2 impulse-generator circuits are considered, figures 1 and 2. Such circuits of the impulse generator are well enough known and are in such common use that they need only a brief explanation. Referring[7] to figure 2, $C_1$ is the generator capacitance, $L_1$ is the total series inductance, $R_1$ is the total series resistance, $R_2$ is the shunt resistance, and $C_2$ is the total load capacitance. These constants are basic in the impulse generator circuit, and although in an actual generator they may be distributed and have mutual effects on each other, for the purpose of this paper they alone are considered. This circuit of figure 2 is recommended as basic by the International Electrochemical Commission.[6]



In the first circuit, figure 1, the inductance is considered negligible.

In the second circuit, figure 2, the inductance is considered and in the calculations is made of such value that neglecting $R_2$ as in figure 3 the series resistance $R_1$ will just damp out oscillations. That is, the critical resistance is $R_1^2 = 4L_1/C$, or transposing, $L_1 = R_1^2C/4$, where $C = (C_1C_2)/(C_1 + C_2)$. By using this relation the oscillations are negligible (less than one per cent) at the crest. Thus using this relation between various circuit constants, the impulse generator applies to the test piece a voltage wave which has 3 desirable characteristics, considering that each is dependent upon the others:

1. A practically smooth wave
2. A minimum wave front
3. A maximum crest voltage

## Relationship Between Circuit Constants

In analyzing the circuits, the relationship of the constants is considered also from the point of practical importance. The available capacitance of the generator is frequently a limiting factor both theoretically and economically, and when oscillograms are taken the shunt resistance may frequently be the divider resistance only, so both $C_1$ and $R_2$ are limiting factors. In making the tests the relation of the load to the generator capacitance, $C_2/C_1$, as well as the relation of the series resistance to the shunt resistance, $R_1/R_2$, must be considered if the proper voltage and wave shape are to be applied to the test piece.

**Figs. 1–3. Schematic diagrams of impulse generator circuits**

## Calculated Charts

With these relationships in mind the characteristics of the voltage test waves applied to a capacitance load were calculated for a wide range of circuit constants in the 2 circuits and the characteristics were so expressed in the calculated charts, charts I and II. In chart I the impulse generator circuit of figure 1 is considered in which the inductance is made equal to zero. At the top of the chart $K_2$ shows the ratio between the load and generator ca-

A paper recommended for publication by the AIEE committee on instruments and measurements. Manuscript submitted October 26, 1936; released for publication December 4, 1936.

J. L. THOMASON is electrical engineer and gas plant supervisor, General Electric Company, Pittsfield, Mass.

OC indicates an infinite value.

pacitances. At the left of the chart $K_1$ shows the ratio between the series and shunt resistances.

For any particular values, for instance, $K_1 = 0.04$ and $K_2 = 0.20$, line *F* gives the wave front divided by $C_1R_2$. Thus *F*, or here 0.0342, times $C_1R_2$ equals the wave front. Likewise *D*, or here 0.896, times $C_1R_2$ gives the duration of the wave. As before explained[1] the wave front is the time from zero to crest and the wave duration is the time from zero to half crest on the tail of the wave.

Line *C* expresses as a ratio the crest magnitude of the test wave in terms of the initial voltage charge on the generator. For the example given, $C = 0.789$ which means that the voltage on the test piece will be 78.9 per cent of the initial voltage on the impulse generator.

Line *R* is the ratio between the wave front and duration. For the example, $R = 0.0381$. For a 1.5x40 wave $R = 0.0375$.

Lines *a* and *b* give the values of the 2 exponents of the

equation expressing the test wave. See appendix I. The values are expressed in terms of $C_1R_2$, that is, $a = m \times C_1R_2$ and $b = n \times C_1R_2$.

In chart II the inductance is considered and has the value previously determined, $L_1 = R_1^2C/4$. The symbols have meanings similar to those in chart I and there is added the term $w$ which equals $\omega \times C_1R_2$, as shown in appendix II. In chart II there are 3 values of $w$, indicated by asterisks, which denote that the roots are real numbers and that these waves are perfectly smooth.

## Curves and Illustrative Example

From these 2 charts a set of curves is plotted in figure 4. In figures 4*a*, 4*b*, and 4*c*, $L_1 = 0$ and in figures 4*A*, 4*B*, and 4*C*, $L_1 = R_1^2C/4$ where $C = (C_1C_2)/(C_1 + C_2)$.

These curves show (1) that with widely different values of circuit constants the same wave front, wave shape, and crest can be obtained, and (2) that wave shape is to a considerable extent a function of ratios between circuit constants.

Figure 5 shows the relation between $L_1$, $R_1$, and $C$ and is an aid in making tests and calculations.

For purposes of mathematical interest numerous curves could be drawn to show the relation between $a$, $b$, and $w$ and the wave characteristics but these curves will be omitted here for the sake of brevity. However, the data are presented in the charts for such use.

As an example of how to use these charts and curves suppose a 1.5x40 wave is desired where $C_1 = 0.005$ microfarad and $C_2 = 0.001$ microfarad. In circuit I neglect the inductance and in circuit II consider that the inductance has a value determined from figure 5. Then constant by constant,

| Constant | Circuit I | Circuit II | Remarks |
|---|---|---|---|
| $K_2$ | 0.2 | 0.2 | $K_2 = C_2/C_1$ |
| $K_1$ | 0.04 | 0.06 | Figures 4*b* and 4*B* |
| $F$ | 0.035 | 0.034 | Figures 4*a* and 4*A* |
| $R_2$ | 8,600 | 8,800 | Front = $FC_1R_2$ |
| $R_1$ | 340 | 530 | $K_1 = R_1/R_2$ |
| $L_1$ | 0 | 58 | Figure 5 |

The procedure is to first determine from figures 4*b* and 4*B* the values of $K_1$. Then determine from figures 4*a* and 4*A* the values of $F$. The values of $R_2$ and $R_1$ can then be quickly calculated and the value of $L_1$ can be obtained from figure 5. In case the stipulated values of inductance cannot be obtained, the values of the circuit constants will have to be estimated on a straight line basis.[7] Thus in circuit II hereinbefore if $L_1 = 40$ microhenries, make $R_2 = 8{,}700$ and $R_1 = 460$.

## Front-of-Wave Testing and Example

Charts I and II and figure 4 show how easy it is even with widely varying circuit constants to make front-of-wave tests approximating the same rate of voltage rise. The main stipulation is to have the waves for the different circuits reach the same crest voltage at the same time.

For the smooth wave characteristics shown in figure 4, the first thing to do is to choose circuit constants giving the same wave fronts (same $C_1R_2$ values in figures 4*a* and 4*A*) and the second thing to do is to choose the proper charging voltages on the generators to give the same crest voltages on the test pieces. The refining stipulation would be to have in all circuits, if possible, equal values of $L_1$, $K_1$, and $K_2$.

As an example, suppose figure 2 with series inductance was used to get a long wave for test purposes and that $C_1 = 0.02$ microfarad, $C_2 = 0.001$ microfarad, $R_1 = 4{,}000$, $R_2 = 10{,}000$, and the crest voltage = 1,500 kv. Therefore $K_1 = 0.4$, $K_2 = 0.05$, and from figure 4*A*, $F = 0.053$. Suppose that only series resistance as in figure 1 was available for securing the same rate of voltage rise, given $C_1 = 0.008$ microfarad, and as before $C_2 = 0.001$ microfarad. Since the wave fronts must be equal $(FC_1R_2)_1 = (FC_1R_2)_2 = 10.6$ microseconds, and $R_{22} = (0.053 \times 0.02 \times 10{,}000)/(0.053 \times 0.008) = 25{,}000$. As $K_2 = 0.001/0.008 = 0.125$ and $F = 0.053$, $K_1$ must equal 0.12 from

* The asterisks indicate that the roots are real.
OC indicates an infinite value.

figure 4*a* and $R_1 = 3{,}000$. The charged voltage on the second generator must be from figure 4*c*, 1,500/0.77 = 1,950 kv.

In constructing an impulse generator for wave-front testing, adjunct load capacitances as well as series resistances and inductances could be used for increasing the wave front.

By using the data presented here the slope of the wave-

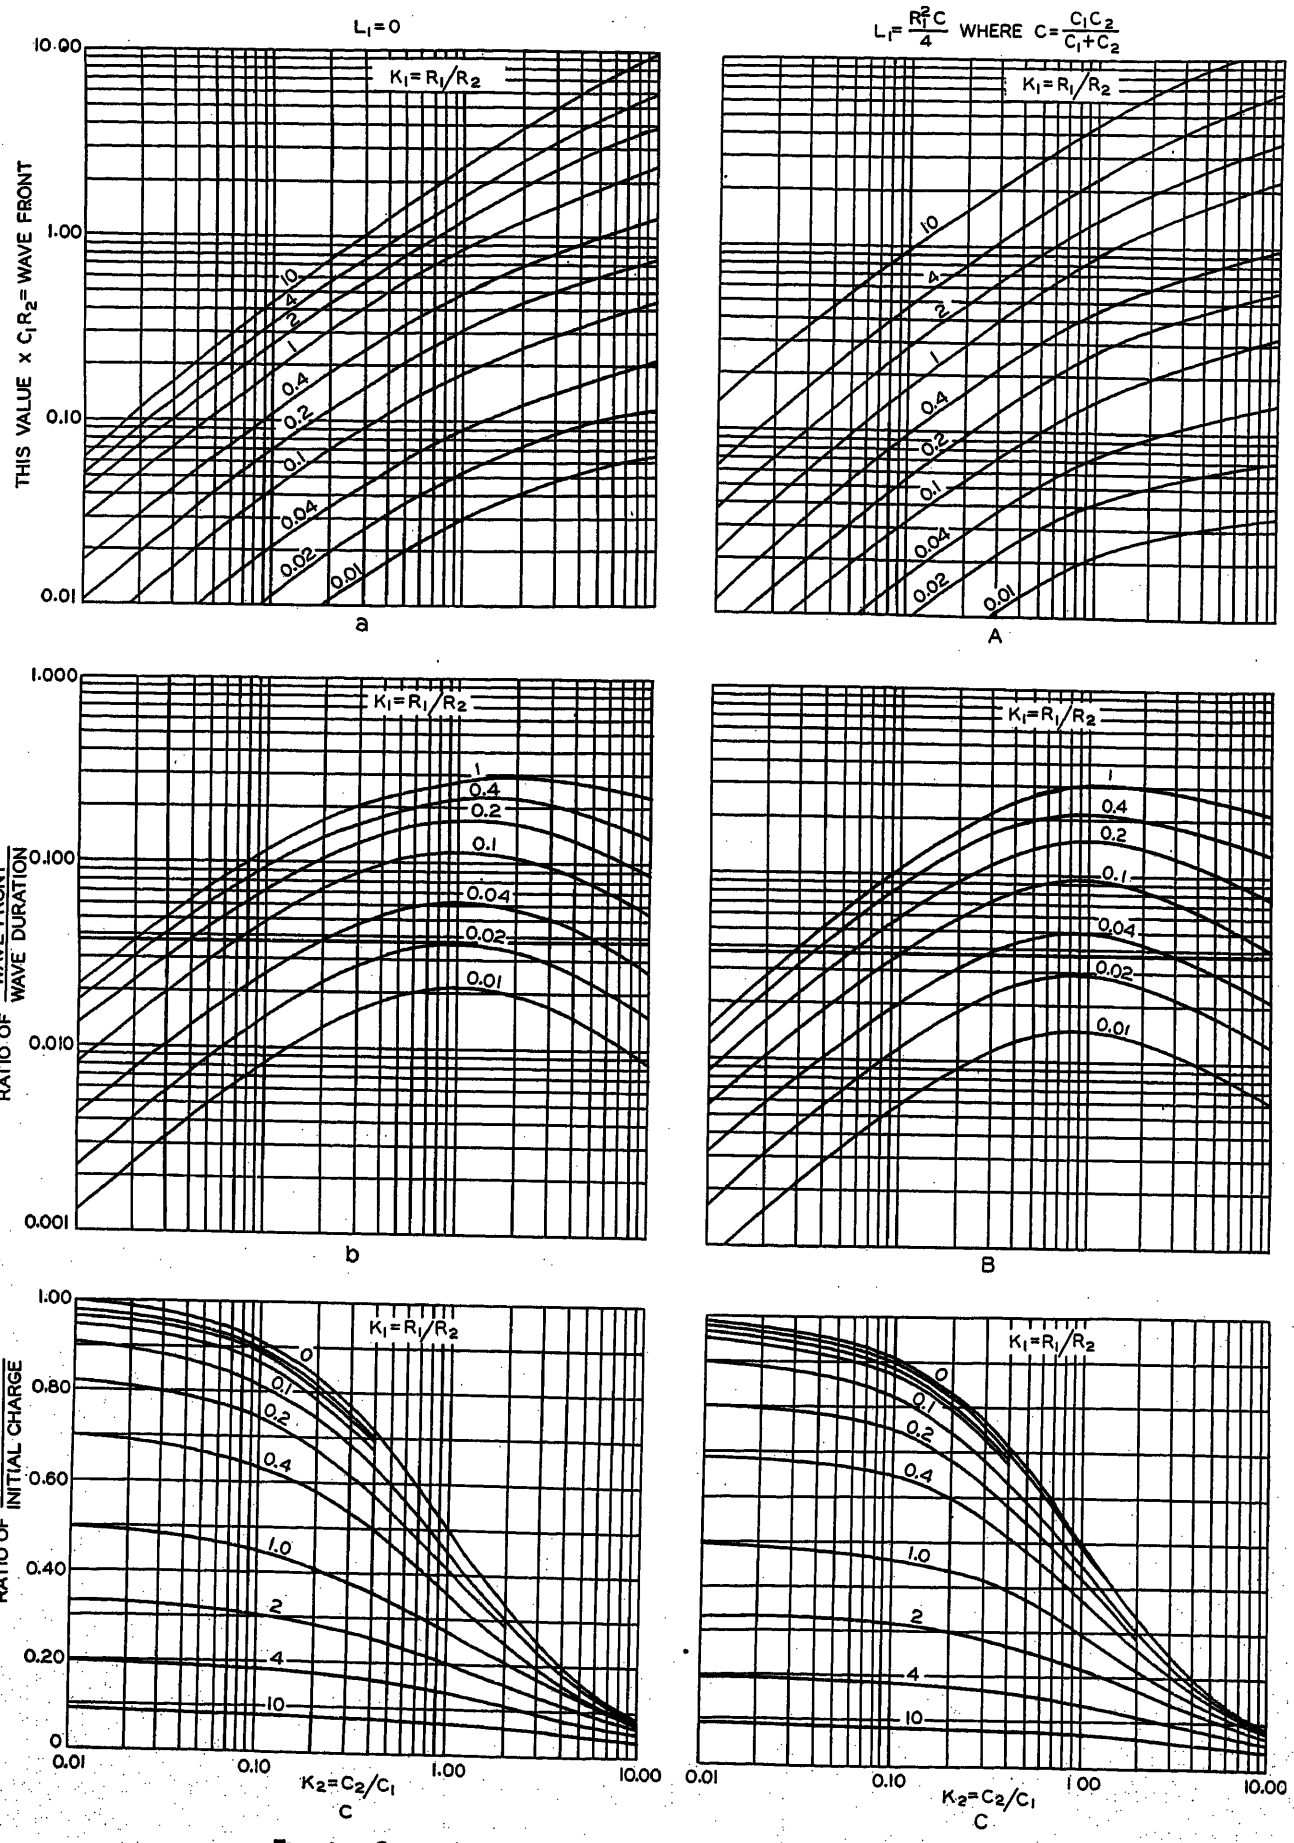

**Fig. 4. Curves for wave shape as related to circuit constants**

front could be calculated between points other than the zero and the crest points of the wave. Some laboratories may wish to use the slope equal to the tangent at the mid-point (50 per cent crest) of the front, others may wish to use the slope determined by 2 points on the front such as the points at 10 and at 90 per cent of crest, and so on. After the method of determining the slope had been agreed upon, the slopes could be determined from a set of calculated fronts, then tabulated similarly to charts I and II and plotted similarly to figure 4 so that any desired time rate of voltage rise could be easily applied to a test piece.

## Accuracy of Charts and Curves

The charts were calculated on the calculating machine and on the slide rule with the intent that the third significant figure of the $F$, $D$, and $C$ values would be approximately correct. On the curves of figure 4 the second significant figure should be approximately correct.

## Oscillograms Verifying Tables and Curves

Up to this point the paper has been devoted to presenting the desirability of comparing and securing impulse voltage test waves on the basis of ratios between circuit constants. In practice, isolated, lumped circuit constants cannot be dealt with and the distribution of the generator capacitors, the effect of stray capacitance, and the idiosyncrasies of the divider and oscillograph must be considered. In general most of these factors are pretty well under control as proved by the fact that cathode-ray oscillograms closely duplicate calculations.

To show this verification, 2 oscillograms are shown in figures 6 and 7 and compared with the calculated charts and curves. In figure 6 a 1.9x40 wave is shown. $C_1$ = 0.00926 microfarad, $C_2$ = 525 micromicrofarads, $L_1$ = 110 microhenrys, $R_1$ = 1,250 ohms, $R_2$ = 4,250 ohms, the charged voltage on the generator = 1,300 kv, and the test-piece voltage = 932 kv. Therefore the similarity between the test results and the charts results can be compared as follows:

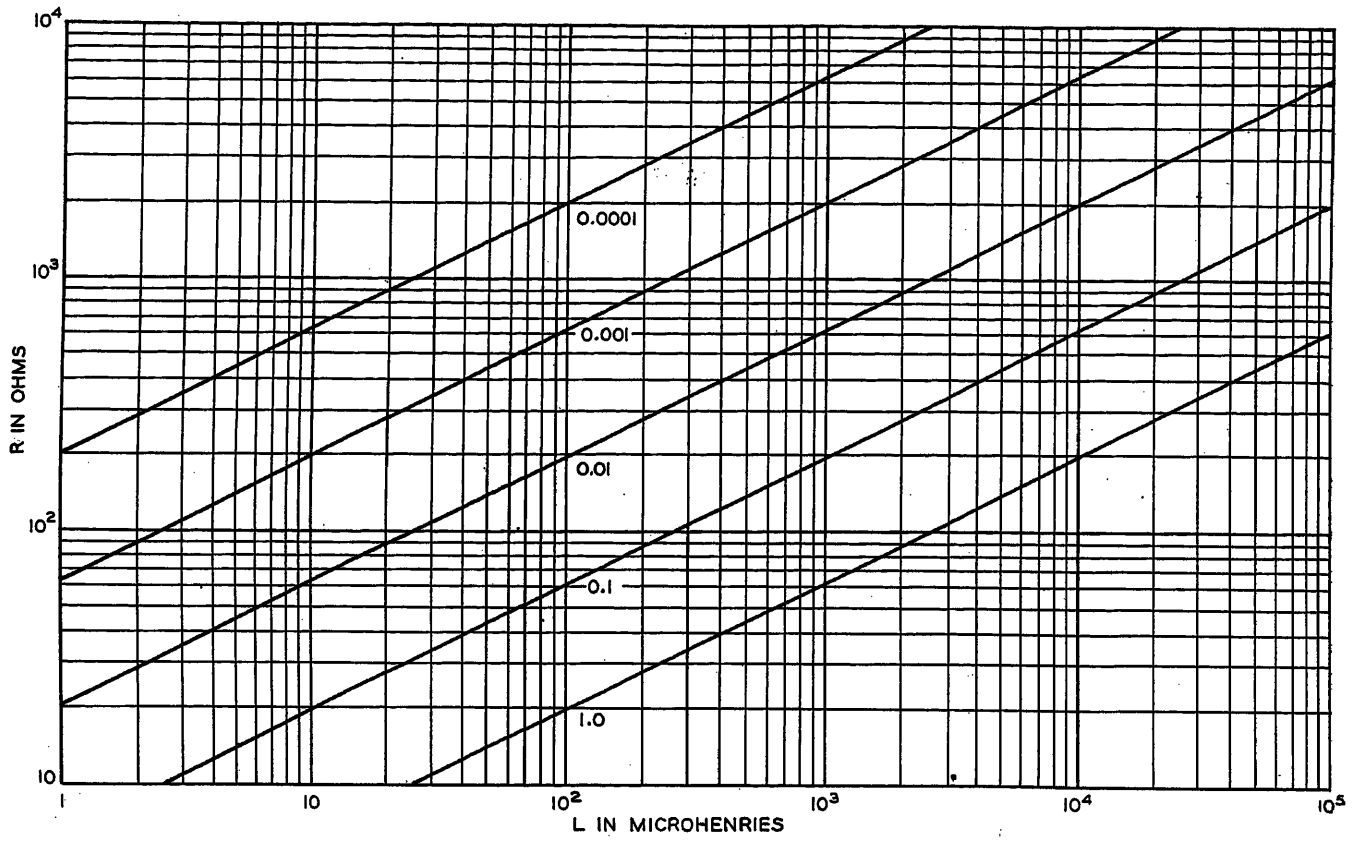

**Fig. 5. Relations between inductance, resistance, and capacitance**

Numbers on curves are capacitances in microfarads $L = R^2C/4$

| Constant | By Test | By Chart |
|---|---|---|
| $K_1$ | 0.30 | 0.30 |
| $K_2$ | 0.057 | 0.057 |
| Front | 1.9 microseconds | 1.9 microseconds |
| Duration | 40 microseconds | 39 microseconds |
| Crest | 72 per cent | 71 per cent |
| $R$ | 0.047 | 0.048 |
| $L$ | 110 microhenrys | 110 microhenrys |

In figure 7 a 1.4x44 wave is shown. $C_1$ = 0.00476 microfarad, $C_2$ = 0.00035 microfarad, $L_1$ = 160 microhenry, $R_1$ = 1,375 ohms, $R_2$ = 10,700 ohms, the charged voltage

on the generator = 550 kv, and the test-piece voltage = 446 kv. Then

| Constant | By Test | By Chart |
|---|---|---|
| $K_1$ | 0.128 | 0.128 |
| $K_2$ | 0.073 | 0.073 |
| Front | 1.4 microseconds | 1.5 microseconds |
| Duration | 44 microseconds | 44 microseconds |
| Crest | 81 per cent | 80 per cent |
| $R$ | 0.032 | 0.034 |
| $L$ | 160 microhenrys | 154 microhenrys |

The values from these 2 oscillograms check closely the values from the charts and curves even though the charts were calculated for wide ranges of values.

Thus these charts can be used with a capacitance meter to determine the constant of the impulse generator circuit for any desired wave shape. These are also conveniently used to supplement the electric transient analyzer[8] in the solution of problems involving impulse generator transients.

## Conclusions

In conclusion the following observations can be pointed out:

1. With widely different values of circuit constants the same wave front, wave shape, and crest can be obtained.

2. Wave shapes depend upon the ratios between circuit constants and may frequently be compared to advantage on this basis.

3. A comparison with oscillograms shows that the charts in this paper are accurate enough for practical work and the examples show how easily the charts can be used for selecting circuit constants.

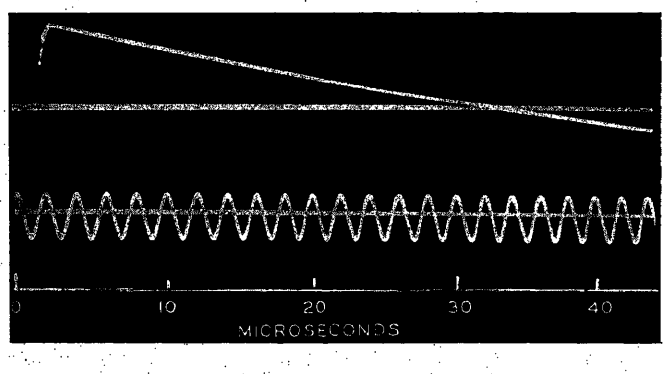

Fig. 6. Oscillogram for 1.9x40 microsecond wave

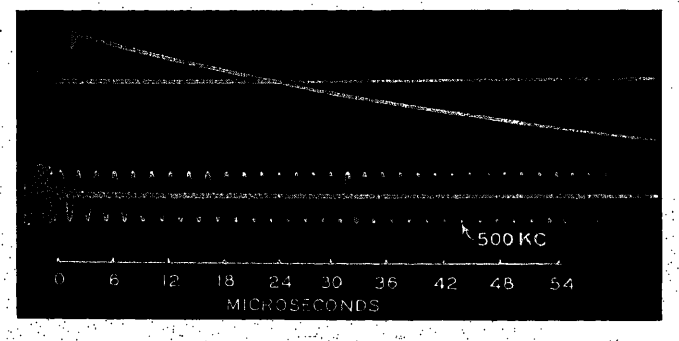

Fig. 7. Oscillogram for 1.4x44 microsecond wave

## Appendix I

Referring to figure 1, the equation[7] for voltage across the capacitance load is

$$\frac{E_{c2}}{E_{c1}} = \frac{1}{n-m}\left[\frac{\epsilon^{-mt} - \epsilon^{-nt}}{C_2R_1}\right]$$

This may be rewritten

$$\frac{E_{c2}}{E_{c1}} = \frac{1}{b-a}\left[\frac{\epsilon^{-T} - \epsilon^{-bT}}{K_1K_2}\right]$$

where

$K_1 = R_1/R_2$
$K_2 = C_2/C_1$
$a = mC_1K_2$
$b = nC_1R_2$
$t = TC_1R_2$

## Appendix II

Referring to figure 2, the equation[7] for voltage across the capacitance load is

$$\frac{E_{c2}}{E_{c1}} = \frac{1}{C_2L_1}\left[\frac{\epsilon^{-\alpha t} - \epsilon^{-\beta t}\left\{\cos \omega t + \frac{\beta - \alpha}{\omega}\sin \omega t\right\}}{(\alpha-\beta)^2 + \omega^2}\right]$$

This may be rewritten

$$\frac{E_{c2}}{E_{c1}} = \frac{4(K_2+1)}{(K_1K_2)^2}\left[\frac{\epsilon^{-aT} - \epsilon^{-bT}\left\{\cos wT + \frac{b-a}{w}\sin wT\right\}}{(a-b)^2 + w^2}\right]$$

where

$L_1 = R_1^2C/4$
$C = (C_1C_2)/(C_1 + C_2)$
$K_1 = R_1/R_2$
$K_2 = C_2/C_1$
$a = \alpha C_1R_2$
$b = \beta C_1R_2$
$w = \omega C_1R_2$
$t = TC_1R_2$

## Inductive Co-ordination

(*Continued from page 26*)

phone pairs, and the importance, therefore, of suitable telephone-circuit transpositions.

Figure 5 shows exposure conditions such as may be encountered in a small community serving a nearby rural area and table IX shows the noise conditions at several locations during heavy power loads.

The extent to which various measures of co-ordination could be applied to reduce the noise induction or to restrict the extent of special arrangements is shown in table X.

It is evident from table X that, for the conditions assumed, the use of reasonably co-ordinated telephone-circuit transpositions will be necessary to care for the stations served by open wire. Ordinarily the use of such transpositions in combination with such other measures as are reasonably effective would serve to take care of the stations served by telephone cable and would limit the extent to which special telephone-station apparatus might be needed for the stations served by the longer open-wire extensions.

## Lightning Investigation on Transmission Lines

(*Continued from page 106*)

in the tower legs and counterpoise wires on the Glenlyn-Roanoke line for 11 cases in which a comparison could be obtained. It was assumed that the total counterpoise current was twice the current measured in one long and one short wire. This comparison shows the summation of the tower currents to be 0.95 of the summation of the counterpoise currents.

It is quite important in considering the comparison between leg currents and counterpoise currents to bear in mind that some leg current may pass directly to earth through the tower footings without passing through the counterpoise wires. Also the counterpoise wires may occasionally carry some current which passes through cross members of the tower structure and is not included in the leg measurements. In all cases polarity indicated the current to be traveling from the free end of the counterpoise to the tower and from the bottom of the tower to the top.

## A Review of Overhead Secondary Distribution

(*Continued from page 122*)

panies *A* and *C*. Replacements are favored by companies *B*, *D*, and *E* but frequently involve re-using transformers in new locations. Only one of the companies anticipates a general replacement of secondary conductors. This company has assumed a 15-year life for triple-braided weatherproof conductors, which apparently has influenced their choice of the replacement method.

Experience records indicate that conductors remaining in service in the same location have been used to a large extent for more than 15 years. While it is true that in case of replacement, it would generally become necessary to scrap such conductors, this should be avoided, if possible, as wires would continue to be serviceable for a good many more years if left in place in the same location. Some real savings are possible therefore by selecting the most economical wire size for the first installation and adding or respacing transformers.

Replacement costs of transformers should also be studied carefully whenever additional capacity is required. Since overloaded operation is considered permissible this should be given first consideration where voltage regulation permits. Additional transformers and subdividing secondaries with possibly some relocations should come next, and finally replacements. A table of annual costs for various per cent loadings of transformers and the net cost of replacements will prove very helpful in selecting the most economical method. Table III contains such typical information. While this information will vary somewhat for various companies, due possibly to a difference in operating or accounting practices, the table is shown here as a typical means of finding the best solutions.

Table IV shows a comparison of accumulated annual costs and indicates the economy of using transformers as long as possible in the same location. In order to benefit fully through long use of transformers, it is necessary to provide new poles, or poles in good condition, for new transformer installations.

# AIEE Winter Convention Program Provides Attractive Features

TECHNICAL developments in many specialties and attractive social functions comprise the program for the Institute's 1937 winter convention, which will be held in New York, N. Y., January 25–29. Headquarters will be in the Engineering Societies Building, 33 West 39th Street, and registration will begin at 10:00 a.m. on Monday. Thereafter technical sessions, conferences, and committee meetings, together with the social functions, the smoker, Edison medal presentation, dinner-dance, and inspection trips in the city and vicinity provide ample opportunity for a busy and profitable week. In addition, for those who would enjoy a few days vacation in a mild climate during midwinter a Bermuda cruise has been arranged as a post-convention trip. The women's entertainment committee, under the chairmanship of Mrs. George Sutherland, also is arranging a most attractive program for the visiting women. A summarized schedule of events is given in an accompanying tabulation.

### Edison Medal Presentation

The AIEE 1936 Edison Medal will be presented to Doctor Alex Dow at a special session of the convention to be held in the engineering auditorium Wednesday evening, January 27, at 8:15 p.m. Doctor Dow was awarded the medal "for outstanding leadership in the development of the central station industry and its service to the public." A biographical sketch of Doctor Dow is given on page 197 of this issue.

### Technical Program

The technical program is comprised of 13 technical sessions at which a wide variety of timely technical papers will be presented and discussed. The tentative technical program announced in ELECTRICAL ENGINEERING for December 1936, pages 1388–9, is complete with the changes which have been made in the following sessions. These sessions, as revised, are repeated for convenience.

### Selected Subjects

ELECTRONIC TRANSIENT VISUALIZERS, H. J. Reich, University of Illinois.
December issue, pages 1314–18

STUDIES OF STABILITY OF CABLE INSULATION, Herman Halperin and C. E. Betzer, Commonwealth Edison Company. October issue, pages 1074–82

PROPOSED TRANSFORMER STANDARDS, J. E. Clem, General Electric Company.
January issue, pages 32–6

A NEW ELECTROSTATIC PRECIPITATOR, G. W. Penney, Westinghouse Electric & Manufacturing Company. January issue, pages 159–63

### Induction Machinery

INDUCTION MOTOR RESISTANCE RING WIDTH, P. H. Trickey, Diehl Manufacturing Company.
February 1936 issue, pages 144–50

INDUCTION MOTORS UNDER UNBALANCED CONDITIONS, E. O. Lunn, Peterson and Cowan Elevator Company, Ltd. April 1936 issue, pages 387–93

INDUCTION MOTORS ON UNBALANCED VOLTAGES, H. R. Reed and R. J. W. Koopman, Michigan College of Mining and Technology.
November issue, pages 1206–13

CAPACITOR MOTORS WITH WINDINGS NOT IN QUADRATURE, A. F. Puchstein and T. C. Lloyd, Robbins & Myers, Inc.
November issue, pages 1235–9

AN ANALYSIS OF THE SHADED POLE MOTOR, P. H. Trickey, Diehl Manufacturing Company.
September issue, pages 1007–14

### Synchronous Machinery

NEGATIVE-SEQUENCE REACTANCE OF SYNCHRONOUS MACHINES, W. A. Thomas, Antioch College.
December issue, pages 1378–84

CONTRIBUTIONS TO SYNCHRONOUS-MACHINE THEORY, A. S. Langsdorf, Washington University.
January issue, pages 41–8

OPERATIONAL SOLUTION OF A-C MACHINES, A. R. Miller and W. S. Weil, Lehigh University.
November issue, pages 1191–1200

TWO-REACTION THEORY OF SYNCHRONOUS MACHINES, S. B. Crary, General Electric Company.
January issue, pages 27–31

SYNCHRONOUS MACHINE WITH SOLID CYLINDRICAL ROTOR, C. Concordia and H. Poritsky, General Electric Company. January issue, pages 49–58

### Electrical Machinery

SELF-REGULATED COMPOUND RECTIFIERS, W. M. Goodhue and R. B. Power, Harvard University.
November issue, pages 1200–06

ABRASION—A FACTOR IN ELECTRICAL BRUSH WEAR, V. P. Hessler, Iowa State College.
January issue, pages 8–12

ARC CHARACTERISTICS APPLYING TO FLASHING ON COMMUTATORS, R. E. Hellmund, Westinghouse Electric & Manufacturing Company.
January issue, pages 107–13

**Table I—Issues of "Electrical Engineering" Containing 1937 Winter Convention Papers**

| | | |
|---|---|---|
| February | 1936 | 1 paper |
| April | 1936 | 1 paper |
| August | 1936 | 4 papers |
| September | 1936 | 5 papers |
| October | 1936 | 3 papers |
| November | 1936 | 6 papers |
| December | 1936 | 10 papers |
| January | 1937 | 25 papers |
| February | 1837 | 1 paper |

CONTACT DROP AND WEAR OF SLIDING CONTACTS, R. M. Baker and G. W. Hewitt, Westinghouse Electric & Manufacturing Company.
January issue, pages 123–8

In addition to the technical conferences which were announced, an informal technical conference on the subject of noise will be held on Wednesday afternoon.

### Smoker

Winter convention smokers for the last few years have been increasing so in popularity that it has become a difficult problem for the committee to meet satisfactorily the ticket demand. This year they believe

### Summarized Schedule of Principal Events

**Monday, January 25**

10:00 a.m. Registration
2:00 p.m. Opening of convention
2:30 p.m. Parallel technical sessions:
—Communication
—Selected subjects

**Tuesday, January 26**

10:00 a.m. Parallel technical sessions:
—Power transmission
—Tensor analysis
2:00 p.m. Address
2:45 p.m. Parallel technical sessions:
—Power distribution
—Tensor analysis (continued)
6:30 p.m. Smoker at the Commodore Hotel

**Wednesday, January 27**

10:00 a.m. Parallel technical sessions:
—Induction machinery
—Protective devices
2:00 p.m. Parallel technical sessions:
—Synchronous machinery
—Electronics
8:15 p.m. Edison Medal presentation

**Thursday, January 28**

10:00 a.m. Parallel technical sessions:
—Electrical machinery
—Electrophysics
2:00 p.m. Parallel technical sessions:
—Instruments and measurements
—Electric welding demonstrations
7:00 p.m. Annual dinner-dance

**Friday, January 29**

All day Inspection trips

**Saturday, January 30**

3:00 p.m. "Monarch of Bermuda" sails on post-convention cruise to Bermuda

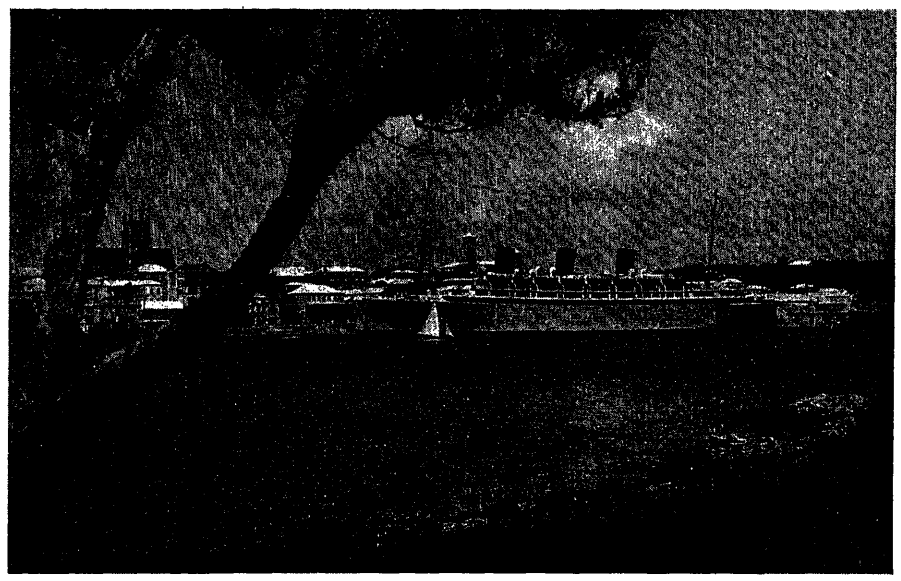
that problem is solved, as the Grand Ballroom and West Ballroom at the Hotel Commodore have been engaged. The seating will be at tables of 10 with ample space to move around; an excellent supper served by the experienced Commodore staff and a satisfactory view for all of a full-sized stage will insure everyone's having a pleasant evening. The entire West Ballroom will be available as a lounge with service bar. Those planning to attend are urged to send in their reservations to the AIEE Smoker Committee, 33 West 39th Street, New York, N. Y., at an early date. All tables will be reserved. Tickets will be $3.50 per person.

### Dinner-Dance

Continuing a social activity that has proved very popular in the past, a dinner-dance has been scheduled for Thursday evening, January 28, at the Hotel Astor, Broadway between 44th and 45th Streets. A combination dinner, dance, and buffet supper again will be featured. The flexibility of this arrangement will provide a very pleasant evening, which may be enjoyed by all according to their tastes, in one of New York's most popular hotels.

The Astor has been entirely redecorated and refurnished, making the surroundings more luxurious than ever. The Grand Ballroom and adjacent facilities will be reserved for the Institute's members and guests. Music will be furnished by George Ellner's Orchestra.

The program of the evening will be:



7:00 p.m. ..... Dinner
9:00 p.m. to 2:00 a.m. ..... Dancing
Midnight to 2:00 a.m. ..... Buffet supper

The rates for tickets will be the same as last year:

Dinner and dance ..... $5.00 per person
Dance and buffet supper ..... 3.00 per person
Dinner, dance, and buffet supper .. 6.50 per person

The dinner-dance committee requests early purchase of tickets. Dinner reservation requests should indicate names of guests and the desired seating arrangement. Tables will be set up for 8 or 10 places, and every effort will be made to comply with the requests of members. Reservation requests should be sent to the AIEE Dinner-Dance Committee, 33 West 39th Street, New York City, N. Y., and checks should be made payable to H. H. Henline, national secretary.

# Post-Convention Cruise to Bermuda Offered

A post-convention cruise to Bermuda will be offered to Institute members and their friends attending the AIEE 1937 winter convention. The party will sail on the "Monarch of Bermuda," which is shown above in the Hamilton Harbor, Bermuda, a thoroughly modern vessel in every respect. Those taking this cruise will have an opportunity to visit the engine room and the bridge of this quadruple-electric-turbine vessel, and to see the electrical equipment in action at sea.

### Inspection Trips

A variety of interesting places has been included in the inspection trips arranged for the convention this year. An attempt has been made to arrange some trips during the week as complementary to the technical sessions. As in previous years, Friday has been set aside exclusively for inspection trips. The tentative schedule of inspection trips, which is subject to change, follows:

**Monday, January 25**

Sponsored broadcast, RCA Studios
Edison Wonder House

**Tuesday, January 26**

Public Service Electric and Gas Company—mercury turbine
S. H. Kress and Company—lighting and air conditioning
RCA Radiotron Company
The M. W. Kellogg Company—welding

**Wednesday, January 27**

Weston Electrical Instrument Corporation—cable testing equipment
Columbia Presbyterian Medical Center—Sloan X-ray generator

**Thursday, January 28**

Associated Press
Third Avenue Railway Company—grid-controlled rectifier
Board of Transportation, New York City—power-control board

**Friday, January 29**

Brooklyn Navy Yard
New York Stock Exchange
"Monarch of Bermuda"
Hastings-on-Hudson Mill, Anaconda Wire and Cable Company
Warner Brothers moving picture studio
National Broadcasting Company studios

Arrangements have been made to secure a very limited number of tickets to the General Electric Company "Hour of Charm" radio broadcast featuring Phil Spitalny and his all-girl orchestra. This program is given in the National Broadcasting Company studios on Monday afternoon. It is hoped that interested out-of-town members will indicate their desire for tickets when they register.

The Columbia Presbyterian Medical Center will exhibit the 1,000,000 volt high-frequency X-ray generator placed in operation this year. This generator was seen under construction by many members during the convention last year.

Interesting trips to plants of manufacturers of thermionic tubes, electrical instruments, welding equipment, and wire and cable have been arranged. A sightseeing tour of New York will be arranged for interested members if weather conditions are favorable.

**Table II—A Few of the Hotels Available**

| Hotel | Location | Rooms With Private Bath | |
|---|---|---|---|
| | | Single | Double |
| Astor | Broadway and 44th St | $3.00– 6.00 | $4.50– 7.50 |
| Biltmore* | Madison Ave. and 43d St | 5.00–10.00 | 7.00–12.00 |
| Bristol* | 129 W. 48th St | 2.50– 4.00 | 3.00– 6.00 |
| Commodore | Lexington Ave. and 42d St | 3.00– 5.00 | 4.50– 8.00 |
| Edison | 228–248 W. 47th St | 2.50– 5.00 | 4.00– 8.00 |
| Governor Clinton | 31st St. and 7th Ave | 3.00– 5.00 | 4.00– 7.00 |
| McAlpin | Broadway and 34th St | 2.50– 7.00 | 4.00– 9.00 |
| Montclair* | Lexington Ave. and 49th St | 3.00 | 4.00– 4.50 |
| Murray Hill | Park Ave. and 40th St | 2.50– 5.00 | 3.50– 6.00 |
| New Yorker | 8th Ave. and 34th St | 3.50– 8.00 | 5.00–10.00 |
| Pennsylvania | 7th Ave. and 32d St | 3.50– 6.00 | 5.00– 9.00 |
| Plaza | Fifth Ave. and 59th St | 6.00 | 8.00 |
| Roosevelt | Madison Ave. and 45th St | 4.00– 8.00 | 6.00–12.00 |
| Vanderbilt | Park Ave. and 34th St | 3.50– 5.00 | 6.00– 8.00 |
| Waldorf-Astoria | Park Ave. and 50th St | 6.00– 8.00 | 9.00–11.00 |

* See advertising section for further details.

In addition to scheduled inspection trips, the committee will be pleased to arrange special trips for individuals and small groups. A list of possible items of interest will be available at the committee desk during the convention.

### Bermuda Cruise Offered

For the first time, a post-convention cruise, to Bermuda, will be offered to Institute members and their friends. The party will leave New York on January 30, by the "Monarch of Bermuda"—a magnificent hotel on water with the appointments of an exclusive club. The cruise will include 3 days at the Hotel Bermudiana, Hamilton, which will give an opportunity to visit the near-by caves and submarine coral gardens, and to drive, rest, or golf on some of Bermuda's fine courses. Returning, the party will reach New York on the morning of February 5. The inclusive prices for the entire trip begin at $86.25. This includes all necessary expenses of the trip except the Bermuda tax of 12 shillings, 6 pence (about $3.25) which is payable in Bermuda. Reduced rates for rooms on shipboard are offered, as well as special rates at the Hotel Bermudiana, and stopover privileges for as long as desired. Members wishing to take this cruise are urged to make their reservations at once to avoid possible disappointment. Reservations may be cancelled later, if necessary. Detailed information may be obtained from Leon V. Arnold, 36 Washington Square, West, New York, N. Y.

### Women's Entertainment

The women attending the convention this year are assured of plenty to occupy their time. The women's entertainment committee, under the chairmanship of Mrs. George Sutherland, is rapidly completing the details of a most attractive program. Monday, January 25, 1937, the first day of the Convention, will be devoted to registration at the women's headquarters on the 10th floor. On Tuesday several novel and interesting tours are scheduled with attendance at a radiobroadcast for the evening. On Wednesday there will be luncheon and bridge at the Engineering Woman's Club, and the Edison Medal presentation and lecture in the evening. Thursday will be devoted to a visit to the Edison Wonder House with the Dinner-Dance at the Hotel Astor for the evening. On Friday a visit is arranged to the Morgan Library. This necessarily will be for a limited group. If demand warrants, a visit to the Hayden Planetarium also will be provided.

### Hotel Rates

Reservations for hotel accommodations should be made by writing directly to the hotel of your preference. In table II is included a brief list of some of the leading hotels in the vicinity.

### Register in Advance

Members in near-by Districts should fill in and post promptly the mail registration card which was included with the mailed announcement of the winter convention sent them. This will permit the committee to have badges ready and prevent congestion at the registration desk upon arrival. There will be a registration fee of $2 for non-members with the exception of Enrolled Students of the Institute, and the immediate families of members.

The personnel of the 1937 winter convention committee is as follows: C. R. Beardsley, *chairman;* H. E. Farrer, *secretary;* T. F. Barton, O. B. Blackwell, E. E. Dorting, A. G. Oehler, C. S. Purnell, S. A. Smith, Jr., George Sutherland, and F. P. West. The chairmen of the subcommittees completing the arrangements are: C. M. Gilt, *dinner-dance;* E. S. Banghart, *smoker;* E. R. Thomas, *inspection trips;* and Mrs. George Sutherland, *women's entertainment.*

## Student Conference Held by Middle Eastern District

The annual conference of Branch counselors and chairmen of the Institute's Middle Eastern District (2) was held at Ohio State University, Columbus, Friday and Saturday, November 13–14, 1936. The official attendance at the conference consisted of the 34 delegates listed in table I. The meeting was attended also by National Secretary H. H. Henline and W. H. Harrison, vice-president of the Institute representing the Middle Eastern District. The student attendance at the evening meeting Friday night was 75, and at the final joint meeting on Saturday, 64.

Following registration, which was held from 5 to 7 p.m. Friday, the evening meeting opened with a dinner. After dinner, Professor F. C. Caldwell gave the address of welcome, following which there were several talks. Professors H. W. Bibber and W. L. Everett, of Ohio State, outlined in detail the course in electrical engineering as it is taught at that institution. Professor E. O. Lange spoke on Branch activities, and recommended that all Branches consider seriously the installation of new officers at a much earlier date in the spring. National Secretary Henline presented a historical outline of student Branches and the national AIEE organization. Vice-President Harrison, who spoke on District activities, convinced all present that engineering societies offer some exceptional opportunities to engineers at the present time and that all student engineers should associate themselves actively with the engineering society of their choice. Professor E. E. Kimberly, chairman of the Institute's Columbus Section, and V. Frederiksen, secretary of that Section, outlined the constructive work being done between the Section and the Ohio State University Branch.

On Saturday morning, November 14, the group was taken on an inspection trip of the laboratories at Ohio State. This was followed by separate meetings of the Branch chairmen and counselors. The student group with R. P. Stokely, chairman of the Ohio State Branch presiding, carried out informal discussion of: (1) participation by students in meetings; (2) credit for attendance; (3) competition for prizes; (4) encouragement of attendance of upperclassmen, sophomores, and freshmen; (5) inspection trips; and (6) social activities.

At the counselors session, there was some discussion concerning the student convention of the Branches in the east section of the District to be held at Johns Hopkins University, Baltimore, Md., next spring. It was decided that the Branches at George Washington University, the University of Maryland, and the Catholic University of America be invited to participate in this convention, since they are situated near Baltimore. It was the consensus of opinion that Branches situated in a central area should work as a unit in holding student Branch conventions.

It was decided that the next District

## Membership—

Mr. Institute Member:

Your response to our request for names of prospective members has been very helpful so far this year. We need your continued aid to reach the goal of 2,000 applications by May. Whether you have already suggested some one or not, send in the name of a good prospect now.

The busy season of the Institute year is now well under way. Take your fellow engineer who is not a member to your Section meetings, to the convention technical sessions, to the dinner-dance and the smoker, and show him what we do. When he is interested, send his name to your Section membership committee chairman. If you start the job he will finish it.

Vice-Chairman, District No. 3
National Membership Committee

**Table I**

| Branch | Counselor | Delegate |
|---|---|---|
| Univ. of Akron | J. T. Walther | |
| Bucknell Univ | | Ripple Schumaker |
| Carnegie Inst. of Tech | M. S. Schonvizner | J. C. Lynch |
| Case School of Applied Science | A. C. Seletzky | J. A. Harshaw |
| Catholic Univ. of America | | |
| Univ. of Cincinnati | L. R. Culver | B. Baumzweiger |
| Drexell Inst. of Tech | E. O. Lange | H. W. Graybill |

| Johns Hopkins Univ | J. H. Lampe | H. B. Peck |
| Lafayette College | F. W. Smith | R. S. Baum |
| Lehigh Univ | J. L. Beaver | T. R. Brown |
| Univ. of Maryland | L. J. Hodgins | W. G. Calder |
| Ohio Northern Univ | B. F. Wyandt | Glen Griffith |
| Ohio State Univ | F. C. Caldwell | R. P. Stokely |
| Ohio Univ | A. A. Atkinson | G. M. Kanable |
| Pennsylvania State College | L. A. Doggett | H. B. Stockham |
| Univ. of Pennsylvania | | R. S. Graham |
| Univ. of Pittsburgh | H. E. Dyche | E. B. McKinney |
| Princeton Univ | | |
| Swarthmore College | | |
| Villanova College | H. S. Bueche | |
| West Virginia Univ | A. H. Forman | M. W. Henderson |

conference of Branch counselors and chairmen should be held at Akron in October 1937, in conjunction with the District meeting to be held there at that time. Professor A. G. Ennis of George Washington University, was elected chairman of the conference for the year beginning August 1, 1937. Professor E. O. Lange was elected as a delegate to the Institute's 1937 summer convention to be held June 21–25, 1937, at Milwaukee, Wis.

At the conclusion of these sessions, the counselors and students reconvened for a final joint session during which the proceedings at the separate sessions were summarized.

## Eta Kappa Nu Announces Awards

Frank M. Starr (A'30), central station engineering staff, General Electric Company Schenectady, N. Y., has been named by Eta Kappa Nu, honorary electrical engineering society, as America's outstanding young electrical engineer for 1936. Mr. Starr was selected from 47 nominees, and he becomes the first to be so recognized by this society in its plan to recognize outstanding young electrical engineers. (See announcement in March 1936 issue of ELECTRICAL ENGINEERING, pages 306–07.) Four other candidates were selected as recipients of honorable mention certificates; these men are: P. L. Bellaschi (A'28, M'34) development and research engineer, Westinghouse Electric & Manufacturing Company, Sharon, Pa.; E. W. Boehne (A'29) engineer, large oil circuit breaker engineering department, General Electric Company, Philadelphia, Pa.; A. C. Seletzky (A'29, M'35) assistant professor of electrical engineering, Case School of Applied Science, Cleveland, Ohio; and C. G. Veinott (A'28, M'34) electrical engineer, Westinghouse Electric & Manufacturing Company, Springfield, Mass. Biographical sketches of the recipients may be found in the "personal" columns of this issue.

The awards were made by a committee composed of: E. B. Meyer (A'05, F'27, past-president) chief engineer, electric engineering department, Public Service Electric and Gas Company, Newark, N. J.; L. W. Morrow (A'13, F'25) general manager, fiber products division, Corning Glass Works, Corning, N. Y.; the late General R. I. Rees; C. A. Butcher (M'22) eastern engineering manager, Westinghouse Electric & Manufacturing Company, New York, N. Y.; Everett S. Lee (A'20, F'30) engineer, general engineering laboratory, General Electric Company, Schenectady, N. Y.; and R. I. Wilkinson (A'35) engineer, Bell Telephone Laboratories, New York, N. Y.; the last 2 men are past-presidents of Eta Kappa Nu.

The recognition plan sponsored by Eta Kappa Nu is designed: (1) to assure due and appropriate honors to young electrical engineers for "meritorious service in the interest of their fellowmen"; (2) to give the engineering profession concrete examples of what young men under 35 years of age and not more than 10 years out of college can be expected to achieve; and (3) to inspire by these young men's careers, and furnish guides for, undergraduates and new engineering graduates to take up their own professional development as soon as possible. A very broad range of accomplishments from scientific research to civic and political activity and artistic creation is recognized, the aim being to encourage engineers to obtain a truly liberal and humanistic perspective at an early point in their careers.

Nominations of candidates for the 1936 recognition were received from heads of electrical engineering departments of colleges and universities throughout the country, from Sections of the AIEE, and from individual members of the Eta Kappa Nu Association. Mr. Starr will have the honor of being the first to have his name placed on a large bronze bowl created by Eta Kappa Nu, which will be kept on display at the headquarters of the AIEE in the Engineering Societies Building in New York. Mr. Starr will also be presented with a smaller reproduction of the bowl, engraved with a brief résumé of his accomplishments, at the citation ceremonies to be held in New York on the evening of January 25, 1937, during the AIEE winter convention.

## Future AIEE Meetings

**Winter Convention**
New York, N. Y., Jan. 25–29, 1937

**North Eastern District Meeting**
Buffalo, N. Y., May 5–7, 1937

**Summer Convention**
Milwaukee, Wis., June 21–25, 1937

**Pacific Coast Convention**
Spokane, Wash., Date to be determined

**Middle Eastern District Meeting**
Akron, Ohio, Fall 1937

## District and National Prizes for 1936 Technical Papers

All who have presented technical papers before the Institute during the calendar year 1936 are eligible under the AIEE paper prize regulations for competitive consideration for one or more of the established prizes. Papers are eligible for submission to the prize committees regardless of whether presented before a Branch meeting, a Section meeting, a District meeting, or a national convention, the several classes providing for equitable competition. Both District and national prizes are awarded each spring for papers presented during the preceding calendar year. Rules governing the awards were outlined in the December 1935 issue of ELECTRICAL ENGINEERING, pages 1414–15.

Although all 1936 papers are *eligible* for consideration, every paper for which prize consideration is desired must be *submitted* specifically for that purpose (except as noted below) not later than February 15, 1937, through the District secretary for consideration for the District prizes, or through the national secretary's office for consideration for the national prizes. There is no provision for automatic consideration of papers, with the exception that those approved by the technical program committee and presented at national conventions or District meetings, will be considered by the national prize committee for the national "best paper" and "initial paper" prizes without being formally offered for competition.

## Executive Committee Meets at Institute Headquarters

A meeting of the executive committee of the American Institute of Electrical Engineers was held at Institute headquarters, New York, N. Y., December 10, 1936, in place of the regular meeting of the board of directors.

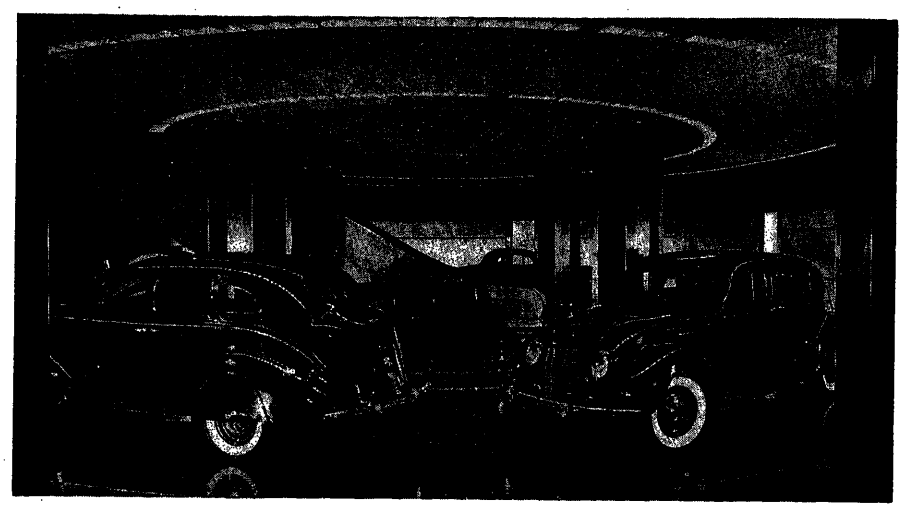
Present: A. M. MacCutcheon (chairman), O. B. Blackwell, Everett S. Lee, E. B. Meyer, L. W. W. Morrow, W. I. Slichter; National Secretary H. H. Henline.

Reports were presented and approved of meetings of the board of examiners held October 28 and December 2, 1936. Upon

the recommendation of the board of examiners, the following actions were taken: 3 applicants were transferred to the grade of Fellow; 17 applicants were transferred and 14 were elected to the grade of Member; 76 applicants were elected to the grade of Associate; 560 Students were enrolled.

Disbursements in November amounting to $20,511.61 were reported by the finance committee and approved.

Report was made and approved of the appointment, upon the nomination of the standards committee, of H. W. Samson as AIEE representative on the sectional committee on standardization of graphical symbols and abbreviations (Z32) of the American Standards Association.



Further consideration was given to the subject of broadening Institute activities to cover discussions of social and economic subjects. At its October 1936 meeting, the board of directors passed a motion concurring in the suggestion that such topics are of general interest to electrical engineers, calling attention to the fact that the Institute offers opportunity for discussion of such questions, and suggesting that papers on these subjects be submitted to the proper committees of the Institute for consideration for national presentation and publication. After a discussion of the procedure to be followed in this matter, it was voted that a special committee on broadening of Institute activities be appointed, consisting of the chairman of the technical program committee as chairman, and the chairmen of the committees on code of principles of professional conduct, co-ordination of Institute activities, economic status of the engineer, Institute policy, legislation affecting the engineering profession, publication, and Sections.

Other matters were discussed, reference to which may be found in this or future issues of ELECTRICAL ENGINEERING.

## Weston Library Willed to Newark Engineering College

By the terms of the will of the late Doctor Edward Weston (A'84, M'84, HM'33, past-president) the Newark (N. J.) College of Engineering is to receive his general and technical library with a sum sufficient to provide for housing and maintaining it. The library is reported to contain complete sets of the proceedings of scientific societies not only in America, but from many foreign countries. In addition to his library, Doctor Weston willed the college the drawings and designs for his many patents and discoveries and much data accompanying them of great general interest and historical value. The college is planning to gather together this material and arrange it in such manner as to form a proper record of Doctor Weston's contribution to science and technology.

Doctor Weston was a member of the original board of trustees of the Newark Technical School, predecessor of the Newark College of Engineering, in which capacity he served for many years. Although forced to retire from the board because of increasing business obligations, he maintained an active interest in the college until his death, which occurred on August 20, 1936. A biographical sketch of his career appeared in the September 1936 issue of ELECTRICAL ENGINEERING, page 1049.

New automobile showroom in Chrysler Building, New York, N. Y., has distinctive lighting

## AIEE Officers to Be Nominated Soon

In accordance with the Institute's by-laws, the national nominating committee of the AIEE will meet during the winter convention, New York, N. Y., January 25–29, 1937, for the purpose of nominating national officers to be voted upon by the membership in the spring of 1937. Members of the national nominating committee, named in accordance with the Institute's by-laws, are as follows:

*Representing the Board of Directors*

O. B. Blackwell — A. C. Stevens
N. E. Funk — J. B. Whitehead

(One additional member to be appointed)

*Representing the 10 Geographical Districts*

1—T. H. Morgan, Worcester Polytechnic Institute, Mass.
2—W. E. Wickenden, Case School of Applied Science, Cleveland, Ohio.
3—E. B. Meyer, Public Service Electric and Gas Company, Newark, N. J.
4—E. E. George, Tennessee Electric Power Co., Chattanooga, Tenn.
5—K. L. Hansen, Harnischfeger Sales Corporation, Milwaukee, Wis.
6—A. L. Turner, Northwestern Bell Telephone Company, Omaha, Neb.
7—J. W. Ramsay, University of Texas, Austin.
8—H. S. Lane, Pacific Gas and Electric Company, San Francisco, Calif.
9—R. E. Kistler, Pacific Telephone and Telegraph Company, Seattle, Wash.
10—C. V. Christie, McGill University, Montreal, Quebec, Can.

The provisions of the AIEE constitution and by-laws relating to nomination of officers were given in ELECTRICAL ENGINEERING for November 1936, page 1278, wherein members were invited to submit suggestions for nominations not later than December 15, 1936. The methods whereby nominations also may be made independent of the nominating committee were given in that item. Briefly, independent nominations may be made by a petition of 25 or more members sent to the national secretary at Institute headquarters, not later than March 25, to be placed before the nominating committee for inclusion in the ballot of such candidates as are eligible. Petitions for the nomination of vice-president may be signed only by members within the District concerned.

## New York Gathering Honors Memory of Rudolph Diesel

In commemoration of the 40th anniversary of the introduction of Diesel power into the United States, some 250 or more leaders in American business, industry, engineering, research, and education gathered at the Waldorf-Astoria Hotel in New York City, December 2, for a special luncheon which coincided with "Diesel Day" at the then current annual power show in New York.

Diesel, Paris-born Bavarian refrigerating engineer, had specialized in the study of thermodynamics and was much impressed with the Carnot theory of a perfect engine, the continued study of which subject led him toward his ultimate development. In 1892 he obtained his first German patent covering claims for both simple and compound Diesel engines, the suggested fuel being coal dust. Later patents included the use of petroleum oils and the employment of high-pressure air to inject the oil charge into the cylinder. Early development, however, was slow, and it was Fate's decree that never during the inventor's lifetime did his engine become generally recognized as an important source of power. Doctor Diesel disappeared from a ship while en route from Germany to England, during September 1913, on the eve of his engine's career.

In 1896, Adolphus Busch of Anheuser-Busch fame acquired the American Diesel license, and built in St. Louis, Mo., a 60-horsepower 2-cylinder unit, which, placed in service in 1898, is said to be the first Diesel engine in the world to be put actually into industrial service. In the interim, re-

search and industrial progress, with their by-products of improved knowledge of thermodynamics and vastly improved materials of construction have permitted the development and improvement of the Diesel engine to a point where the new horsepower placed in service during 1936 is estimated at 2,100,000.

Chairman of the committee of arrangements was Gordon Rentschler, president of The National City Bank of New York; master of ceremonies was Radio-Commentator John B. Kennedy. Feature speakers, each of whom spoke briefly from the point of view of his own business activities, included: Edward B. Pollister, president, Busch-Sulzer Brothers Diesel Engine Company; Capt. Edward V. Rickenbacker, vice-president, Eastern Air Lines; Col. Robert H. Morse, president, Fairbanks-Morse & Company; Thomas H. Beck, president, Crowell Publishing Company; C. L. Cummins, president, Cummins Engine Company; Edward G. Budd, Edward G. Budd Manufacturing Company (streamlined trains); R. U. Blasingame, president, American Society of Agricultural Engineers; David S. Sarnoff (via radio from Chicago) president, Radio Corporation of America; B. C. Heacock, president, Caterpillar Tractor Company; and Charles F. Kettering (via radio from Detroit) vice-president in charge of research, General Motors Corporation, who emphasized the extent of the internal combustion engine market in America, by pointing out that during 1936 some 200,000,000 horsepower in new motors cars had been manufactured.

## Insulation Stability Research to Be Extended

Engineering Foundation, with the sponsorship of the AIEE, has appropriated $5,000 for an experimental research on the stability of impregnated paper insulation. The work is to be done in the school of engineering of The Johns Hopkins University, Baltimore, Md., under the direction of Doctor J. B. Whitehead (A'00, F'12, past-president) professor of electrical engineering.

This work will be an extension of that completed several years ago by Doctor Whitehead and associates on the stability of impregnated paper as related to the physical properties of the impregnating oil. The new work will include a similar series of accelerated life tests as related to variations in the physical and chemical properties of the paper.

The present appropriation and plans are for a period of a year, but it is expected that both will be continued a second year.

## Noble Prize Awarded to Institute Member

The Alfred Noble Prize for 1936 has been awarded to Abe Tilles (A'30, M'36) instructor in electrical engineering at the University of California, Berkeley, for his paper "Spark Lag of the Sphere Gap." This paper, which received the Institute's 1935 Pacific District prize for best paper, was published in ELECTRICAL ENGINEERING for August 1935, pages 868–76, and was presented at the AIEE Pacific Coast convention, Seattle, Wash., August 27–30, 1935. An item regarding Doctor Tilles is given in the personal columns of this issue. Presentation of the award will be made at the AIEE 1937 winter convention.

The Alfred Noble Prize was instituted in 1929 in honor of Alfred Noble, past-president of the American Society of Civil Engineers and the Western Society of Engineers, and consists of a $500 cash award and an engraved certificate. The award is made to a member of any grade of either the American Society of Civil Engineers, the American Institute of Mining and Metallurgical En-

## Ambrose Swasey Receives Hoover and VDI Medals

Ambrose Swasey (center), "Knight of the Kindly Heart," Honorary Member of the Institute, founder and patron of The Engineering Foundation, as he appeared at the Astor Hotel in New York City, December 2, 1936, celebrating his ninetieth birthday by receiving simultaneously the Hoover Gold Medal, highest American engineering award, and the Gold Medal of the Verein Deutscher Ingenieure, outstanding German award. At Mr. Swasey's right is Herbert Hoover (HM'29), for whom the medal was named and to whom in 1930 its first award was made "for distinguished public service." Mr. Swasey is the second to receive the award. At Mr. Swasey's left is Dr. Gano Dunn, past-president of the Institute, and chairman of the Hoover Medal board of award. Other details pertaining to the award and its recipient were given in the November 1936 issue of ELECTRICAL ENGINEERING, pages 1278–9 and 1288.

In connection with the presentation ceremonies, Doctor Dunn outlined medallist Swasey's long and colorful career. Mr. Hoover amplified this in his "tribute to Mr. Swasey as an engineer for his 70 years of active service to engineers and to humanity," stating that the "sum of Mr. Swasey's contributions has brought more comfort and more security to more human beings than have come from any one other individual." Incidentally, Mr. Hoover flung an engineer's challenge to engineers by stating emphatically that "the engineer no longer can hold himself to design and administration, but must range out into broader fields if humanity's problems of today are to be solved satisfactorily."

gineers, The American Society of Mechanical Engineers, the American Institute of Electrical Engineers, or the Western Society of Engineers, for a technical paper of particular merit accepted by the publication committee of any of the foregoing societies for publication, in whole or in abstract in any of their respective technical publications, provided the author, at the time the paper is accepted in practically its final form, is not over 30 years of age. The recipient of the prize is selected by a committee of 5 members, consisting of one representative of each society, the award being based upon papers published by the societies within the 12 months preceding July 15 of each year.

The first award of the Alfred Noble Prize was made in 1931, and the second award, in 1932, was made to F. M. Starr (A'30).

# Letters to the Editor

**CONTRIBUTIONS to these columns are invited from Institute members and subscribers. They should be concise and may deal with technical papers, articles published in previous issues, or other subjects of some general interest and professional importance. ELECTRICAL ENGINEERING will endeavor to publish as many letters as possible, but of necessity reserves the right to publish them in whole or in part, or reject them entirely.**

**ALL letters submitted for consideration should be the original typewritten copy, double spaced. Any illustrations submitted should be in duplicate, one copy to be an inked drawing but without lettering, and other to be lettered. Captions should be furnished for all illustrations.**

**STATEMENTS in these letters are expressly understood to be made by the writers; publication here in no wise constitutes endorsement or recognition by the American Institute of Electrical Engineers.**

## Engineering Education—Opinions and Influencing Factors

*To the Editor:*

In their closing discussion on their paper "Engineering Education—Opinions and Influencing Factors" (see ELECTRICAL ENGINEERING, October 1936, page 1147), Professors King and Eshbach raise certain questions that should be answered. One of these points was discussed in my paper "A New General Engineering Curriculum" as presented before the electrical engineering conference of the Society for the Promotion of Engineering Education in Madison, Wis., in June 1936 (see *Journal of Engineering Education*, volume 26, number 10, June 1936, page 826).

The members of the committee that worked out the details of this new general engineering curriculum, debated at length concerning the choice of a proper descriptive name for this new curriculum. They felt that "basic" engineering most nearly described the content, but recognized the fact that this term had no generally accepted meaning in either the engineering world or in industry. At the same time, the committee realized that "general" engineering, in its ordinary usage, connoted considerable emphasis upon managerial studies, and usually a wide range of electives in liberal amounts. Finally, it was decided that perhaps it was best at first to label it, in the college catalog, as "general engineering" with the subtitle description of "composite course including the basic essentials of civil, electrical, industrial, and mechanical engineering."

It was recognized immediately that professional society activities would be a necessary concomitant of the academic program of study. A local General Engineering Society was formed and started functioning immediately after the curriculum was opened. Meetings are held just as frequently as those of the student branches of the various national engineering societies. Also, the General Engineering Society participates jointly with the other student engineering societies in the activities of the local engineering society, which includes in its membership students from all engineering departments. Senior students in general engineering are encouraged to attend in rotation the meetings of the student branches of the 4 national societies sponsored by the 4 co-operating departments, in addition to the meetings of their own General Engineering Society. In this way they get well acquainted with national professional engineering societies and should have every incentive for associating with one of the national engineering societies as soon as they become placed in industry.

Respectfully yours,

ALBRECHT NABTER (A'23, M'30)
Professor and Head of Electrical Engineering Department, Oklahoma Agricultural and Mechanical College, Stillwater

## The Measure of an Engineer

*To the Editor:*

In his response, in receipt of the Lamme medal, Doctor Vannevar Bush stated that engineers were responsible and honest people, but too often inclined to mind their own business. ("The Measure of an Engineer," ELECTRICAL ENGINEERING, August 1936, page 854.)

Such modesty and a minding of his own business are very practical guides to the engineer's conduct in his social community. Viewing socio-economic matters of the past and present he is not so much inarticulate as incoherent, as would be a medical person should he presume to speak on such matters. Let the engineer stick out his neck too far, he will receive, as descriptive of society's understanding of his stimuli, such trivia as:

**". . . but think of his power. Think of the temptation of playing with his switchboard just for the fun of it. In his place and at his age I do not think I could have resisted it."**

This appeared in an article "Notes on the Conventions," by R. deR. deSales, published in *Atlantic Monthly*, September 1936 issue.

There is a wide gulf between the ideas of Doctor Bush and those of M. deSales. Remember, however, the latter is a journalist. He writes for the general public. He thus reflects their viewpoint. What he asks us to "think" the public in general thinks. Note that there is no reference to responsibilities on the part of the technician he refers to, but merely to the hilarious effect that might capriciously be brought about by a wholesale confusion.

To get some further notion of the public mind and its relation to any sort of science, let us assume M. deSale's attitude and apply the words to one or 2 other classes of persons. First, let us think of medical doctors: ". . . but think of his power. Think of the temptation of playing with his patient just for the fun of it. In his place . . . etc." "An unthinkable and monstrous idea!"—thus we could expect to hear from common men filled with a thumping indignation.

But let us continue with possible other changes in the original quotation. Though the thought intrigues, we pass charitably over the substitution of "plaintiff," or "defendant" or "witness" for "switchboard." Rather put "printing-press" in its place, meantime thinking "journalist" instead of "engineer." M. deSales himself would doubtless be among the most notable in rightly professing that inherent responsibility which the true journalist feels.

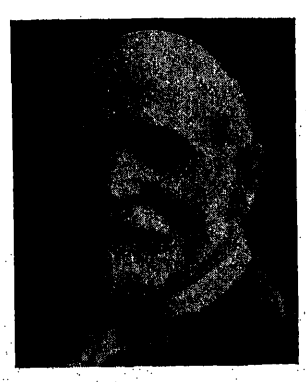
Yet it cannot be too clearly stated that his original words represent a popular conception of the mischievous possibilities inherent in a position of control and assigned as admissible to engineers' mentalities. It represents the popular mind's notion of the mental set of scientists. These are the persons whom the public suspects of being that vast impersonal THEY in vexatious control of present-day developments and operations.

So, in all sincerity, I beg those who are capable to give us further encouragement along the line of Dr. Bush's "central function" thesis. The engineer needs encouragement to apply the principles of scientific action to human affairs rather than feeling pressure to rush himself uncritically at the "success" demands of a business-based social order. He needs his backbone stiffened so that he may courageously focus back the ills of society on itself by applications of science, not to try to use it to produce any sort of palliatives. In war, physicians attend the wounded, even though in their hate of war they know that larger mass death would sooner terminate hostilities. Such behavior is an aspect of scientific method applied to human behaviors. The public considers such action worthy.

The proper rôle of an engineer at a political convention is likewise a scientific one. If the proceedings are consequential, well and good. Should they be so much twaddle, it is his true office to let that fact appear. But in the cheerful disorder of his mind Johnny Q. Public is a long way from any such realization.

Yours very truly,

J. ANDREW DOUGLAS (A'18, M'29)
Physics and General Science Teacher, Murphy High School, Mobile, Alabama

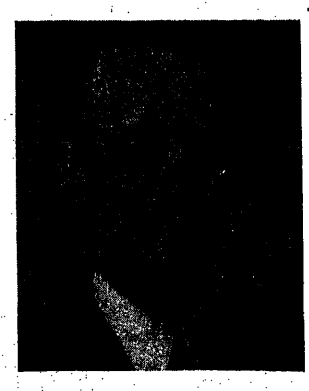


# Personal Items

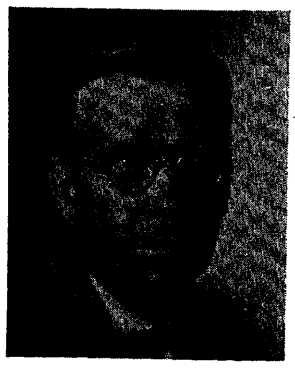
ALEX DOW (A'93, F'13, member for life) president, Detroit (Mich.) Edison Company, has been awarded the AIEE Edison Medal for 1936 "for outstanding leadership in the development of the central station industry and its service to the public." The medal, which was founded by friends and associates of the late Thomas A. Edison (A'84, M'84, HM'28), and is awarded annually for "meritorious achievement in electrical science, electrical engineering, or the electrical arts," will be presented to Doctor Dow during the Institute's winter convention at New York, N. Y., January 25–29, 1937. Doctor Dow was born in Glasgow, Scotland, in 1862, and although he is not a graduate of a technical school, he has received the honorary degrees of master of engineering (1911) and doctor of engineering (1924) from the University of Michigan and doctor of science (1935) from the University of Detroit. During the period 1874–82, he was employed as junior clerk and stenographer in a railroad office and in the offices of a steamship company in Liverpool, England. In 1882 he came to the United States, and was employed in various departments of the Baltimore and Ohio Railroad Company. Later he was transferred to the Baltimore and Ohio Telegraph Company to take charge of local line and instrument maintenance, with some construction and experimental work on telephones. In 1888 he was employed by the Brush Electric Company, Cleveland, Ohio, as installation electrician in the Chicago (Ill.) office, becoming district engineer in that office in 1889. In 1893, he accepted the opportunity to design and supervise the construction of the original public lighting plant of the city of Detroit, and in 1896 he became vice-president and general manager of the Edison Illuminating Company of Detroit. This company was succeeded by the Detroit Edison Company in 1903, and Doctor Dow was retained as vice-president until 1913, when he was made president. He became a naturalized citizen in 1895. Doctor Dow has been a leading pioneer in the United States in the engineering, rate making, and general operation of the electric light and power utility, and is given credit for both the engineering and financial success of his enterprises. He has supervised the design and construction of several generating stations of the Detroit Edison system, and he is called the father of the so-called "big" steam boiler in the United States, having installed 2,350-horsepower boilers at a time when 600- to 750-horsepower units were commonly considered large. He was the first to adopt the underfeed stoker for large installations, and much of the earlier development of this type of equipment was made in his power plants. In addition to his electric utility activities, Doctor Dow served the city of Detroit as the engineer member of the Board of Water Commissioners from 1916 to 1921, and again from 1925 to 1927. He is a member of The American Society of Mechanical Engineers (president 1928), American Society of Civil Engineers, the Institution of Electrical Engineers (Great Britain), and the Detroit Engineering Society (charter member and past-president). He has recently been elected an honorary member of both the ASME and the ASCE. For his paper "On the Schooling of Engineers" (published in the December 1934 issue of ELECTRICAL ENGINEERING, pages 1589–91), he was awarded the AIEE 1935 national prize for best paper in public relations.

O. E. BUCKLEY (M'19, F'29) director of research for the Bell Telephone Laboratories, Inc., New York, N. Y., has been elected executive vice-president. Doctor Buckley was born at Sloan, Iowa, August 8, 1887, and received the degrees of bachelor of science from Grinnell College (1909) and doctor of philosophy from Cornell University (1914). In 1936 the honorary degree of doctor of science was conferred upon him by Grinnell College. Doctor Buckley was an instructor in physics at Grinnell College during 1909–10, an assistant in physics at Cornell University 1910–12, and instructor 1912–14. He was then employed in the engineering department of the Western Electric Company until he was given charge of the signal corps laboratory of the U. S. Army in Paris, France, during 1917–18. After he returned to the company (from which Bell Telephone Laboratories, Inc., later was derived) he engaged in work on continuously loaded cables. In 1927 Doctor Buckley was made assistant director of research, and 6 years later became director of research, a position in which he had charge of fundamental studies in a great variety of fields. Since 1926 Doctor Buckley has been a member of the Institute's committee on electrophysics, and from 1929–31 he was its chairman. During the period 1929–31 he was a member of the meetings and papers committee (now technical program) and since 1934 he has been a member of the committee on research. He is a member of the Franklin Institute, American Physical Society, and American Association for the Advancement of Science.

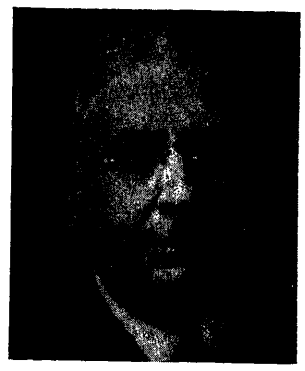
O. B. BLACKWELL (A'08, F'17, vice-president) formerly manager of staff departments, Bell Telephone Laboratories, Inc., New York, N. Y., has been elected vice-president of the laboratories with responsibility for the development of communication apparatus and telephone systems. Mr. Blackwell was born at Bourne, Mass., August 21, 1884. Receiving the degree of bachelor of science from Massachusetts Institute of Technology in 1906, he immediately entered the engineering department of the American Telephone and Telegraph Company. In 1914 he became transmission and protection engineer, and with the formation of the department of development and research in 1919 he became transmission development engineer. When that department was consolidated with Bell Telephone Laboratories in 1934, Mr. Blackwell was appointed director of transmission development. In 1935 he was made manager of staff departments. In his new position as vice-president he will have charge of the apparatus development, systems development, and protection development departments. His individual contributions to the communication art have been to the practical theory of transmission and crosstalk and to many problems which have arisen in transmission development. Mr. Blackwell has served on the Institute's committee on communication 1918–26 (chairman 1922–25) and from 1935 to the present time; in 1936 he was elected a vice-president representing the New York City District and was appointed a member of the standards committee. He is a member of the plant co-ordination committee and the joint sub-committee on development and research of the Edison Electric Institute and Bell System, and a member of the standards council of the American Standards Association.



E. W. BOEHNE (A'29) engineer in the large oil circuit breaker engineering department of the General Electric Company, Philadelphia, Pa., has received honorable mention in connection with the selection by Eta Kappa Nu, honorary electrical engineering society, of America's outstanding young electrical engineer for 1936 (see page 193). Mr Boehne was born at Laramie, Wyo., June 2, 1905. Following graduation in 1926 from the Agricultural and Mechanical College of Texas, Mr. Boehne entered the General Electric Company at Lynn, Mass., for a year and then undertook graduate work at Massachusetts Institute of Technology, receiving the degree of master of science in 1928. He was one of 2 men from that institution selected to take the advanced course

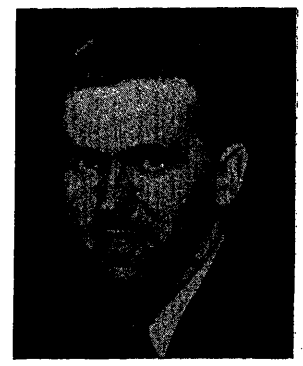


ALEX DOW



O. E. BUCKLEY

O. B. BLACKWELL



M. J. KELLY

J. H. HERRON

F. M. STARR

ABE TILLES

in engineering of the General Electric Company at Schenectady, N. Y. Since 1933 he has been in the switchgear plant of that company at Philadelphia. He has specialized in the protection of electrical equipment from surges due to lightning and switching, his early work on the calculation of arrester performance in connection with choke coils being notable. He was closely associated with the design of 287-kv circuit breakers for the Boulder Dam-Los Angeles transmission line, and is the author of several Institute papers. Mr. Boehne is a member of the Franklin Institute, and is interested in the activities of the Roerich Society, whose aim is "world peace through the arts."

M. J. KELLY (M'26, F'31) vacuum tubes and transmission instruments director, Bell Telephone Laboratories, Inc., New York, N. Y., has been appointed director of research. He was born at Princeton, Mo., February 14, 1894, and received the degrees of bachelor of science (1914) and master of science (1915) from the University of Missouri. In 1919 he received the degree of doctor of philosophy from the University of Chicago and in May 1936 he received an honorary degree of doctor of engineering from the University of Missouri in recognition of his contributions to communication engineering. Doctor Kelly joined the engineering department of the Western Electric Company, now Bell Telephone Laboratories, in 1919 and since then has been continuously engaged in researches in electronics and in the development of thermionic devices of all types. In 1922 he was placed in charge of the vacuum-tube development of the laboratories. In 1935 in addition to that work he was placed in charge of the development of transmitters and receivers for telephone instruments. Now, as director of research, he is in charge of all of the research activities of the laboratories. Doctor Kelly has served on the Institute's committees on communication and standards since 1934.

J. H. HERRON (M'35) president, The James H. Herron Company, Cleveland, Ohio, has been elected president of The American Society of Mechanical Engineers for the year 1936–37. Mr. Herron was born at Girard, Pa., January 4, 1875, and received the degree of bachelor of science in electrical engineering at the University of Michigan in 1909. From 1889 to 1897 he was employed in Erie, Pa., and subsequently was assistant engineer in charge of power for the Cambria Steel Company, Johnstown, Pa.; vice-president and chief engineer of the Bury Compressor Company, Erie; manager of the Motch & Merryweather Machinery Company, Detroit, Mich.; and chief engineer and works manager of the Detroit Steel Products Company. Since 1909 he has been president of The James H. Herron Company, engineers and chemists. He is also president of the Paragon Laboratories, director of the Baldwin Farms Land Company, and secretary of the National Engineering Inspection Association. He is the author of articles on metallurgical subjects published in technical periodicals, and is the inventor of the air-compressor inlet-valve unloader and of numerous devices for use with air compressors and metallurgical furnaces. Mr. Herron has served The American Society of Mechanical Engineers as manager (1922–25) and as vice-president (1934–36), and was president of the Cleveland Engineering Society during the year 1917–18. His other society affiliations include the American Society of Civil Engineers, American Institute of Mining and Metallurgical Engineers, American Chemical Society, American Society for Testing Materials, British Iron and Steel Institute, Society of Automotive Engineers, American Concrete Institute, and American Association for the Advancement of Science.

F. M. STARR (A'30) central station engineer, General Electric Company, Schenectady, N. Y., has been named by Eta Kappa Nu, honorary electrical engineering society, as America's outstanding young electrical engineer for 1936. Details of the award are given elsewhere in this issue. Mr Starr was born at Fowler, Colo., February 26, 1905, and was graduated with special honors from the University of Colorado in 1928 with the degree of bachelor of science in electrical engineering. He then joined the General Electric Company, entering on the test course at Schenectady, N. Y. The following year he entered the engineering general department and for the past 5 years has been a member of the central station engineering department. Mr. Starr's contributions to the electrical art have been chiefly in the field of central station design and power distribution. His researches and inventions in the devising of equivalent circuits for simulating complex networks resulted in the widespread adoption of new and more exact methods for calculating system performance under both normal and emergency conditions. His later work in establishing methods for detecting faults on ungrounded lines, and his study on the design, operation, and economics of various types of distribution systems, particularly networks, have also attracted wide attention. Mr. Starr has presented several papers before the Institute and received the Alfred Noble prize for his paper on equivalent circuits presented in 1932. The degree of electrical engineer was conferred upon him in 1933 by the University of Colorado in recognition of his work.

L. H. HILL (A'22, M'29) who has been assistant engineer in charge of transformer design for the Allis-Chalmers Manufacturing Company at Milwaukee, Wis., has been appointed engineer-in-charge of the transformer division. Mr. Hill was born at Toms River, N. J., March 8, 1899, and received the degree of electrical engineer from Cornell University in 1922. During the period 1920–22 he served as an instructor at the university, and following graduation accepted the position of design engineer in the transformer engineering department of the Westinghouse Electric & Manufacturing Company. In 1928 he became manager of the transformer division of the American Brown Boveri Electric Corporation at Camden, N. J., having charge of engineering and sales for the division. This company was absorbed by Allis-Chalmers Manufacturing Company in 1931, at which time Mr. Hill was made assistant engineer in charge of transformer design. Recently Mr. Hill was appointed vice-chairman of the national convention committee preparing for the 1937 summer convention of the Institute at Milwaukee.

ABE TILLES (A'30, M'36) instructor in electrical engineering at the University of California, Berkeley, has been awarded the Alfred Noble Prize for 1936, as reported elsewhere in this issue. The award was made for his paper "Spark Lag of the Sphere Gap," which was presented at the AIEE Pacific Coast convention, August 27–30, 1935. Doctor Tilles was born at New York, N. Y., March 10, 1907. In 1928 he received the degree of bachelor of science in mechanical engineering and electrical engineering with highest honors

from the University of California. In 1932 he received the degree of master of science in electrical engineering, and in 1934 that of doctor of philosophy in electrical engineering. During the period 1928–30 he was employed in the testing laboratories of the Bureau of Power and Light, Los Angeles, Calif., and in 1930 was for a time engaged in work for the testing and research laboratories of the California State Division of Highways at Sacramento before joining the faculty of the University of California as an associate. He was appointed instructor in 1933, specializing in electric power transmission and telephone transmission lines and transmission networks. Doctor Tilles received the annual best paper prize of the Pacific District at the 1936 AIEE summer convention for the same paper for which he now receives the Noble prize. He is counselor of the University of California Branch, and a member of Eta Kappa Nu and Sigma Xi.

ROSCOE SCHAEFFER (A'32, M'36) formerly resident electrical engineer for the Byllesby Engineering and Management Corporation, Oklahoma City, Okla., has been transferred to the Oklahoma Gas and Electric Company, Oklahoma City, as superintendent of engineering of that company. Mr. Schaeffer was born at Ludlow, Ill., in 1892, and was graduated from Iowa State College in 1915, with the degree of bachelor of science in electrical engineering. Upon graduation he served briefly as assistant superintendent of a small municipal power plant before entering the employ of the General Electric Company, Schenectady, N. Y., in 1916, serving first as a test engineer and subsequently as an assistant foreman and an assistant to the electrical superintendent of the Schenectady works of that company. In 1919 Mr. Schaeffer accepted a position as assistant engineer on standards with the Remy Electric Company, Anderson, Ind., where he remained for one year before affiliating himself with the William A. Baehr Company, Chicago, Ill., as resident engineer in charge of transmission-line construction at Ada, Okla. In 1923 he became assistant to the construction superintendent of the Oklahoma Gas and Electric Company, and later was made assistant to the general superintendent of operation of that company before being transferred to the Byllesby Engineering and Management Corporation in 1926.

C. G. VEINOTT (A'28, M'34) electrical engineer, Westinghouse Electric & Manufacturing Company, Springfield, Mass., has received honorable mention in connection with the selection by Eta Kappa Nu, honorary electrical engineering society, of America's outstanding young electrical engineer for 1936 (see page 193). Mr. Veinott was born at Somerville, Mass., February 15, 1905, and received the degree of bachelor of science in electrical engineering from the University of Vermont in 1926. He then entered the student course of the Westinghouse company at East Pittsburgh, Pa., and since then has been engaged chiefly with the problems of rotating machinery, making notable contributions. He was transferred to the small-motor engineering department at Springfield in 1929, and has been associated with the development of new methods of analysis of losses in single-phase motors, noise prevention studies, and new means of calculating single phase and polyphase induction motors. Mr. Veinott holds patents for disk-type thermostatic protection of motors, and has actively participated in the design and development of fractional-horsepower motors. Recently he was appointed to have charge of sales and engineering on all fractional-horsepower motors for fans and blowers. Mr. Veinott is the author of a number of papers, some of which have been presented to the Institute. He has been a member of the Institute's electrical machinery committee since 1934, and has been active in the work of the Springfield Section, of which he is now chairman.

J. M. TODD (M'32) consulting electrical engineer, New Orleans, La., has been elected a vice-president of The American Society of Mechanical Engineers for the year 1936–37. He was born at Franklin, La., May 25, 1896, and received the degrees of bachelor of engineering (1918) and mechanical engineer (1930) from Tulane University. He served (1918–19) as a lieutenant in the U.S. Army, seeing service in England and France, and in 1919 became chief engineer of the Marrero, La., plant of Penick and Ford, Inc. From 1921 to 1928 he was associated as assistant engineer with A. M. Lockert & Company, mechanical engineering contractors in New Orleans. He has since been retained as consultant in mechanical and electrical problems by the Orleans Parish School Board, the Board of State Engineers, the city of New Orleans, and Tulane University. Mr. Todd has been a member of the Institute's membership committee since 1935, and is a past-president of the Louisiana Engineering Society.

A. C. SELETZKY (A'29, M'35) assistant professor of electrical engineering, Case School of Applied Science, Cleveland, Ohio, has received honorable mention in connection with the selection by Eta Kappa Nu, honorary electrical engineering society, of America's outstanding young electrical engineer for 1936 (see page 193). Doctor Seletzky was born at Novostavtzy, Volynia, Russia, May 29, 1905. In 1927 he received the degree of bachelor of engineering and in 1930 that of doctor of engineering from The Johns Hopkins University, and in the latter year became an instructor in electrical engineering at Case School of Applied Science. He was made assistant professor in 1933. Doctor Seletzky is noted for his research work, which ranges from new analyses of various types of electric circuits and bridges to methods of magnetic analysis, thermionics, power transmission circuits, and a-c circuit theory. Doctor Seletzky is a second lieutenant in the Ordnance Reserve of the U.S. Army and has worked at Watertown Arsenal. He is the author of a number of AIEE papers and of papers published by the Franklin Institute. Since 1933 he has been a member of the AIEE committee on instruments and measurements, and is now serving as counselor of the Branch at Case School of Applied Science and as chairman of the membership committee of the Cleveland Section.

E. W. BURBANK (A'25, M'30) district manager, Allis-Chalmers Manufacturing Company, Dallas, Texas, has been elected a manager of The American Society of Mechanical Engineers for the year 1936–37. He was born at Sunbury, Ohio, February 15, 1889, and received the degree of bachelor of engineering from Tulane University in 1911. He then entered the employ of the Allis-Chalmers company as a student apprentice. Between 1913 and 1916 he was engaged in the experimental design and development of hydraulic machinery and in conducting extensive tests on this type of equipment. In 1916 he was transferred to the sales department and was sent to New Orleans, La., as sales engineer becoming district manager at Dallas 5 years later. He is a member of the American Petroleum Institute and the Dallas Technical Club.

P. L. BELLASCHI (A'29, M'34) section engineer in charge of transformer engineering, Westinghouse Electric & Manufacturing Company, Sharon, Pa., has received honorable mention in connection with the selection by Eta Kappa Nu, honorary electrical engineering society, of America's outstanding young electrical engineer for 1936 (see page 193). Mr. Bellaschi was born at Piedmont, Italy, February, 13, 1903, and came to the United States with his parents in 1913. In 1926 he received the degree of bachelor of science in electrical engineering from Massachusetts Institute of Technology and, following a year in the Westinghouse student course, received the degree of master of science in electrical engineering in 1928. Since that time he has been with the Westinghouse company in various capacities. Mr. Bellaschi is well known for his work in the field of lightning investigation, and has made many important contributions and discoveries. Many papers based on his researches have been published, both in the United States and in Europe. In 1936 he received a Westinghouse award of merit in recognition of his work in high-voltage research. Mr. Bellaschi has been active on the committees of the Sharon Section of the Institute. He is a member of the Associazione Elettrotecnica Italiana.

G. H. DUNSTAN (A'28) formerly assistant professor of general engineering at the University of Southern California, Los Angeles, now is enrolled as a graduate student at the University of Iowa, Iowa City. Mr. Dunstan is specializing in hydraulic engineering.

VINCENT HACKETT (A'36) student engineer, General Electric Company, Schenectady, N. Y., has been transferred to the Philadelphia, Pa., works of that company.

H. J. MASSHARD (A'24) formerly with the International Paper Company, New York, N. Y., now is employed by the Scott Paper Company, Chester, Pa.

# Obituary

CHARLES LEGEYT FORTESCUE (A'03 F'21) consulting transmission engineer, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., died December 4, 1936. Doctor Fortescue was born at York Factory, Manitoba, Canada, November 7, 1876, and received his earlier education at a private school in England. In 1898 he received the degree of bachelor of science from Queen's University, Kingston, Ont., and in that year joined the Westinghouse Electric & Manufacturing Company as an apprentice. The university conferred upon him a doctor's degree in 1931. From 1901 to 1918 he was in the transformer engineering department, and from 1918 to 1926 he was manager of the porcelain, insulator, and transmission engineering department. Since 1926 Doctor Fortescue had been consulting transmission engineer. Perhaps the best known of the many contributions to the engineering art that are credited to Doctor Fortescue is the development of the mathematical system known as "symmetrical coordinates" or "symmetrical components" and application of it to the solution of problems involving polyphase systems. For this work he was awarded the gold medal of the Franklin Institute in 1931. Other fields of his work were studies of stability and lightning protection. Doctor Fortescue also is credited with many improvements in transformer design, advancement of the art of measurement of high voltage by the sphere spark gap, development of basic principles for the form and proportions of insulating surfaces, and contributions to the design of transmission systems, receiving nearly 200 patents. He is said to have developed the first commercial 100,000-volt transformer, and advanced the theory that direct strokes were the cause of trouble on transmission lines. Many papers on various subjects were presented by him before the Institute, and others were published elsewhere. Doctor Fortescue had been a member of the Institute's committee on power transmission and distribution since 1932, serving previously from 1925 to 1929. He also had been a member of the committees on telegraphy and telephony (now communication) 1914–17, and electrophysics 1916–17 and 1920–31.

CLINTON JESSE AXTELL (A'09, M'30) assistant engineer of the control division, transportation engineering department of the General Electric Company, Erie, Pa., died October 16, 1936. He was born at Axtell, Kans., April 4, 1883, and was graduated from Kansas State College in 1904. For a short time he was employed by the Jackson (Mich.) Light and Power Company, then entered the testing department of the General Electric Company at Lynn, Mass. In 1907 he was transferred to Schenectady, N. Y., remaining until 1910. Between 1910 and 1913 he was employed by the Commonwealth Power Company of Michigan, the International Railway Company, Buffalo, N. Y., and the Cleveland (Ohio) Railway Company. He then returned to the General Electric Company in the railway department division, becoming assistant engineer of the division in 1930. He made many important contributions to the development of railway equipment and was an authority on electric control for all types of transportation vehicles including ships and naval equipment.

A. W. RUSSELL (A'31) chief engineer of the Hollywood mill, Buckeye Cotton Oil Company, Memphis, Tenn., died recently according to word just received at Institute headquarters. Mr. Russell was born December 22, 1876, at Little Rock, Ark. During the period 1910–19 he was chief engineer of the Little Rock (Ark.) Railway and Electric Company. In 1923 he was appointed chief engineer of the National Cotton Seed Products Corporation, where he remained until he entered the employ of the Buckeye Cotton Oil Company in 1929, as supervisor of power in the Memphis mills of that company. He was appointed chief engineer of the Hollywood mill in 1933.

# Membership

## Recommended for Transfer

The board of examiners, at its meeting on December 2, 1936, recommended the following members for transfer to the grade of membership indicated. Any objection to these transfers should be filed at once with the national secretary.

**To Grade of Fellow**

Bennett, C. E., electrical engineer, Federal Power Commission, Washington, D. C.
Bossard, G. L., president and director of engineering research, General Kontrolar Company Inc., Dayton, Ohio.
Lane, F. H., manager, engineering and construction, Byllesby Engineering and Management Corporation, Chicago, Ill.
MacNaughton, A. K., supervising engineer, The Commonwealth and Southern Corporation of New York, Birmingham, Ala.
Watson, A. E., associate professor of electrical engineering emeritus, Brown University, Providence, R. I.
5 to Grade of Fellow

**To Grade of Member**

Beck, Lester E., assistant professor of electrical engineering, Purdue University, West Lafayette, Ind.
Bodicky, A., underground engineer, Union Electric Light and Power Company, St. Louis, Mo.
Brady, G. B., assistant division superintendent, Oklahoma Gas and Electric Company, Enid, Okla.
Dueland, R., electrical engineer, Parsons, Klapp, Brinckerhoff and Douglas, New York, N. Y.
Dutton, T. D., district plant engineer, American Telephone and Telegraph Company, Washington, D. C.
Gerell, G. W., relay engineer, Union Electric Light and Power Company, St. Louis, Mo.
Hoyle, E. R., electrical engineer, Sinclair Oil and Refining Company, Houston, Texas.
Musgrove, A. M., Jr., assistant engineer, Public Service Electric and Gas Company, Englewood, N. J.
Nuttall, A., electrical engineer, Trinidad Leaseholds Ltd., Pointe-a-Pierre, B. W. I.
Stone, E. W., assistant superintendent, electric testing department, Central Illinois Light Company, Peoria, Ill.
Talley, T. J., 3rd, technical employee, American Telephone and Telegraph Company, Philadelphia, Pa.
Watts, F. W., vice-president, United Electric Controls Corporation, Hoboken, N. J.
Weiser, R. G., assistant engineer, Brooklyn Edison Company, Brooklyn, N. Y.
13 to Grade of Member

## Applications for Election

Applications have been received at headquarters from the following candidates for election to membership in the Institute. If the applicant has applied for direct admission to a grade higher than Associate, the grade follows immediately after the name. Any member objecting to the election of any of these candidates should so inform the national secretary before Jan. 31, 1937, or March 31, 1937, if the applicant resides outside of the United States or Canada.

Allen, R. T., Jr., Consumers Power Company, Jackson, Mich.
Andrews, N. R. (Member), National Sugar Refining Company of New Jersey, Long Island City, N.Y.
Armstrong, D. K., Union Oil Company, Oleum, Calif.
Armstrong, H. R., Detroit (Mich.) Edison Company.
Barrow, L. G. (Member), Brooklyn (N. Y.) Edison Company, Inc.
Behar, M. F. deM., (Member), Instruments Publishing Co. Pittsburg, Pa.
Bose, C. C. (Member), Indiana Bell Telephone Company, Indianapolis.
Bowen, R. E., Jr., City Light & Water Division, Memphis, Tenn.
Brandt, T. F., (Member), Ohio Brass Co. Barberton
Campbell, S. M., Cleveland Electric Illuminating Company, Ohio.
Capel, C. C., Indiana Bell Telephone Company, Indianapolis.
Dausman, O. D., Indiana Bell Telephone Company, Indianapolis.
Denison, H. C., Oklahoma Gas and Electric Company, Oklahoma City.
Dixon, A. R. American Tel. & Tel. Co., New York, N. Y.
Dotterweich, W. A. (Member), Consumers Power Company, Jackson, Mich.
Dunnewold, L. J., Indiana Bell Telephone Company, Indianapolis.
Dublin, M., Department of Docks, North River, New York, N. Y.
Falk, K. K. (Member), Bendix Products Corporation, South Bend, Ind.
Ferguson, B. (Member) 319 Homebuilders Bldg. Phoenix, Ariz.
Foster, C. D., Portland (Ore.) General Electric Company.
Green, I. V., Indiana Bell Telephone Company, Indianapolis.
Griffith, H. D., Westinghouse Electric & Manufacturing Company, Springfield, Mass.
Gruenberg, A. T., Gruenberg Elec. Co. Inc., New York, N. Y.
Heathman, E. J., Southwestern Bell Telephone Company, Bristow, Okla.
Henson, C. A., Pacific Gas and Electric Company, Sacramento, Calif.
Hyland, G. A., Westinghouse Electric and Manufacturing Company, Wilkes Barre, Pa.
Jack, C. R., 715 S. W. King Ave., Portland, Ore.
Johnson, J. E., Philadelphia (Pa.) Electric Company.
Johnson, W. C., Allis Chalmers Manufacturing Company, Chattanooga, Tenn.
Jones, D. J. (Member), Vapor Car Heating Company, Chicago, Ill.
Kanouse, E. L., Los Angeles (Calif.) Bureau of Power & Light.
Killoran, J. M., The Cleveland (Ohio) Electric Illuminating Company.
Langhauser, G. E. (Member), New York and Queens Electric Light and Power Company, Flushing, N. Y.
Larlee, D. H., Brooklyn (N. Y.) Union Gas Company.
Langhus, L., Cenral Electric and Telephone Company, Sioux City, Ia.
Lehman, A. J., Freeport Sulphur Company, Freeport, Texas.
Lincks, G. F., General Electric Company, Pittsfield, Mass.
Linders, J. R., Cleveland Electric Illuminating Company, Ohio.
Linke, H. M., Spruce Falls Power and Paper Company Ltd., Kapuskasing, Can.
Low, A. A. (Member), Brooklyn (N. Y.) Edison Co. Inc.
Mancib, A. S. (Member), Weston Electric Institute Corporation, West Somerville, Mass.
Markus, H. F., Arsenal Technical Schools, Indianapolis, Ind.
Mascaro, W. O., Atlantic Refining Company, Philadelphia, Pa.

McDowell, J. A., Sherwin Williams Company, Dallas, Tex.
Meyer, J. E., General Laminated Products Inc., New York, N. Y.
Meyer, J. M., Meyer Instrument Company, San Francisco, Calif.
Moody, W. S., General Electric Company, Schenectady, N. Y.
Muehlig, R. E., Westinghouse Electric & Manufacturing Company, Boston, Mass.
O'Brien, E. W. (Member), Southern Power Journal, Atlanta, Ga.
Packer, W., 1826 E. 82nd St., Cleveland, Ohio.
Pefferly, W. J., Phelps Dodge Copper Products Corporation, Detroit, Mich.
Personeus, L. H., Puget Sound Power and Light Company, Seattle, Wash.
Pierson, W. H., Croft Place, R. F. D. 3, Huntington, L. I., N. Y.
Powers, C. F., C. F. Powers Company, Cleveland, Ohio.
Risseeuw, E. J., Allis-Chalmers Manufacturing Company, Milwaukee, Wis.
Rivero, A. (Member), New York (N. Y.) Edison Company.
Robinson, W. F., Pacific Telephone and Telegraph Company, Portland, Ore.
Rockwell, F. H., United Light and Power Engineering and Construction Company, Kansas City, Mo.
Royal, A. B., Louis-Allis Company, Milwaukee, Wis.
Schoenfeld, S. S., Department of Parks, Bronx, N. Y.
Sessions, A. P. (Member), Southern California Edison Company, Ltd., Los Angeles, Calif.
Shepherd, R. H., R. H. Shepherd Company, Vancouver, Can.
Snowden, W. H., *Electrical West*, San Francisco, Calif.
Stahl, C. D., Oklahoma Gas and Electric Company, Ardmore.
Stanley, L. L., Klein & Saks, New York, N. Y.
Steinback, E. T., Homestake Mining Company, Lead, S. D.
Stinchcomb, L. M. (Member), H. B. Sherman Manufacturing Company, Battle Creek, Mich.
Stokien, A., Brooklyn (N. Y.) Edison Company, Inc.
Swenson, C. R., Indiana Bell Telephone Company, Indianapolis.
Taylor, A. Y., Rural Electrification Administration, Washington, D. C.
Thompson, J. K., France Manufacturing Company, Cleveland, Ohio.
Uphouse, W. F. (Member), Southwestern Bell Telephone Co. St. Louis, Mo.
Waag, H. B., North Eastern Coustruction Co. New York, N. Y.
Wald, S., 2715 Webb Avenue, New York, N. Y.
Williams, H. F., Bussmann Manufacturing Company, St. Louis, Mo.
Williams, N. W., CCC-SCS Iowa No. 18, Clariton, Iowa.
Wood, A. H., Virginia Electric and Power Company, Richmond, Va.
77 Domestic

Foreign

Lucas, F. N., Bardez Elec. Supply Co. Ltd., Mapuca, Bardez Goa, Portuguese India.
Robinson, J. E. L. (Member), Ferranti Ltd., Hollinwood, Lancashire, England.
Simmonds, J. C., University College, Nottingham, Eng.
Sreenivasaiengar, M., International General Electric Company (India) Ltd., Bombay, India.

# Engineering Literature

## New Books in the Societies Library

Among the new books received at the Engineering Societies Library, New York, recently, are the following which have been selected because of their possible interest to the electrical engineer. Unless otherwise specified, books listed have been presented gratis by the publishers. The Institute assumes no responsibility for statements made in the following outlines, information for which is taken from the preface of the book in question.

SCIENTIFIC BASIS OF ILLUMINATING ENGINEERING. (Electrical Engineering Texts). By P. Moon. N. Y. and Lond., McGraw-Hill Book Company, 1936. 608 p., illustrated 10x6 in., cloth, $5.00. A textbook on the engineering of lighting. Presents the details of current practice and a thorough treatment of the scientific fundamentals. The text is based on courses at the Massachusetts Institute of Technology.

Die SCHLAUCHELEKTRODE zur LICHTBOGENSCHWEISSUNG von KUPFER. By W. Lessel. Berlin, VDI-Verlag, 1936. 57 p., illustrated, 8x6 in., paper, 3.80 cm. Describes a new process for arc welding copper for which several important advantages are claimed.

RADIO AMATEUR'S HANDBOOK. 14th ed. American Radio Relay League, West Hartford, Conn., 1936. 536 p., illustrated, 10x7 in., paper, $1.00 in U.S.A.; cloth, $2.50 in all countries. A reference book for amateurs, intended to provide accurate information on the practical design and construction of sending and receiving apparatus and the operation of amateur radio stations.

PRINCIPLES of ELECTRICAL ENGINEERING, Theory and Practice. By G. C. Bialock. 2 ed. N. Y. and Lond., McGraw-Hill Book Company, 1936. 584 p., illustrated, 9x6 in., cloth, $4.00. Provides a course in electrical theory and practice adapted to the needs of students who are preparing for work as civil, mechanical, or chemical engineers, but it may also be used by students of electrical engineering as an introduction.

Great Britain. Mines Dept. REPORT OF H. M. ELECTRICAL INSPECTOR of MINES for the Year 1935. London, His Majesty's Stationery Office, 1936. 78 p., illustrated, 10x6 in., paper (obtainable in British Library of Information, New York, $0.45). Presents statistics upon the use of electrical mining machinery and upon the accidents resulting from the use of electricity in mines.

ELEMENTS of PROBABILITY. By H. Levy and L. Roth. Oxford, England, Clarendon Press; N. Y., Oxford University Press, 1936. 200 p., illustrated, 9x6 in., cloth, $5.00. Presents an elementary treatment of the subject and provides a detailed criticism of the various self-contained theories of probability.

Das ELEKTRISCHE EISENBAHNWESEN der GEGENWART. (Elektrische Bahnen Ergänzungsheft, Jahrgang 1936.) Ed. by W. Wechmann. Berlin, Verlag für Sozialpolitik, Wirtschaft and Statistik, 1936. 212 p., illustrated, 12x8 in., paper, 6 rm. Contains 9 lectures by various authorities on the electrical railway.

EINFÜHRUNG in die KLASSISCHE ELEKTRODYNAMIK. By J. Fischer. Berlin, Julius Springer, 1936. 199 p., illustrated, 10x7 in., cloth, 13.80 rm. Presents the classic theory of electrodynamics, intended for advanced students.

BEITRAG zur BERECHNUNG von MASTFUNDAMENTEN. By H. Fröhlich. 3 ed. Berlin, Wilhelm Ernst and Sohn, 1936. 81 p., illustrated, 10x7 in., paper, 7.50 rm. (5.65 rm. in U.S.A.). Provides a study of the design of foundations for the masts and towers of transmission lines.

INDUSTRIAL DUST. By P. Drinker and T. Hatch. N. Y. and Lond., McGraw-Hill Book Co., 1936. 316 p., illus., 9x6 in., cloth, $4.00. Discusses the problem of dust control in its relation to the health of workmen, and presents methods for designing and operating dust-control equipment.

ENGINEERING ALLOYS, Names, Properties, Uses. By N. E. Woldman and A. J. Dornblatt. Cleveland, Ohio, American Society for Metals, 1936. 622 p., tables, 10x6 in., lea., $10.00. Contains the trade names, manufacturers, composition, properties, and uses of 8,200 engineering alloys.

ELEMENTS of MECHANICS. By H. A. Erikson. 3 ed. N. Y. and Lond., McGraw-Hill Book Co., 1936. 269 p., illus., 8x6 in., cloth, $2.25. A text based on a course at the University of Minnesota.

DESCRIPTIVE GEOMETRY PROBLEM BOOK. By F. W. Bubb. N. Y., Macmillan Co., 1936. Diagrs., 8x11 in., paper, $1.75. Contains 300 problems on detachable sheets of white paper.

PUBLIC UTILITY INDUSTRIES. By G. L. Wilson, J. M. Herring, and R. B. Eutsler. N. Y. and Lond, McGraw-Hill Book Co., 1936. 412 p., illus., 9x6 in., cloth, $3.50. Affords a survey of the economic, legal, and social characteristics of public utility enterprises.

TEXTBOOK of ILLUMINATION. By W. Kunerth. 2 ed. N. Y., J. Wiley and Sons, 1936. 276 p., illus., 10x6 in., lea., $3.00. A short course in illumination, intended for undergraduates.

TELEVISION with CATHODE RAYS. By A. H. Halloran. San Francisco, Pacific Radio Publishing Co., 1936. Illus., 7x5 in., lea., $2.75. The operating principles of the cathode-ray tube and its application to television are explained in terms that can be understood by the amateur radio operator and radio service man.

PHYSIK und TECHNIK der ULTRAKURZEN WELLEN, v. 2. By H. E. Hollmann. Berlin, Julius Springer, 1936. 306 p., illus., 9x6 in., cloth, 33 rm. Describes the practical applications of ultra-short waves, and discusses reception, detection, and transmission.

INDUCTIVE CO-ORDINATION of ELECTRIC POWER and COMMUNICATION CIRCUITS. By L. J. Corbett. San Francisco, J. H. Neblett Pressroom Ltd., 500 Sansome St., 1936. 161 p., illus., 9x6 in., cloth, $3.00. Discusses the factors involved and suggests methods by which detrimental effects can be remedied. Written from the point of view of the power engineer, but considers the problems of the communication engineer also.

HEAVISIDE'S OPERATIONAL CALCULUS, as applied to Engineering and Physics. (Electrical Engineering Texts.) By E. J. Berg. 2 ed. N. Y. and Lond., McGraw-Hill Book Co., 1936. 258 p., illus., 8x6 in., cloth, $3.00. Contains appendices in which various numerical problems are solved. Additional information on the theory of the use of the "unit function" is given.

Der ERDSCHLUSS in HOCHSPANNUNGSNETZEN. By H. Weber. Munich and Berlin, R. Oldenbourg, 1936. 107 p., illus., 10x7 in., paper, 5.80 rm. Discusses the phenomena accompanying grounds in 3-phase distribution systems and the methods of preventing them. Intended for operating engineers and students.

ELEKTROTECHNIK und WITTERUNG. By U. Retzow. Berlin, Julius Springer, 1936. 121 p., 9x6 in., paper, 6.60 rm. Discusses the effects of weather in electrical engineering, including the influence of meteorological elements on overhead lines, the use of wind for generating electricity, influence of altitude on power stations, and disturbances of radio transmission.

Die ELEKTRISCHE KRAFTÜBERTRAGUNG, v. 3, pt. 1. Bau und Betrieb des Kraftwerkes. By H. Kyser. 3 ed. Berlin, Julius Springer, 1936. 573 p., illus., 10x6 in., cloth, 45 rm. Devoted to the mechanical equipment of electric power plants from a practical point of view for the designer and operator.

ELECTRONICS and ELECTRON TUBES. By E. D. McArthur. N. Y., John Wiley and Sons, 1936. 173 p., illus., 9x6 in., $2.50. Describes the fundamental principles governing the action of all electron tubes; mathematics is used sparingly. A chapter is devoted to electron tube construction. Much of the book has appeared serially in the *General Electric Review*.

ELECTRICAL LABORATORY EXPERIMENTS, Theory and Practice. By V. Karapetoff and B. C. Dennison. N. Y., John Wiley and Sons, 1936. 487 p., illus., 9x6 in., lea., $4.00. An abridgment of Karapetoff's "Experimental Electrical Engineering," prepared to meet the demand for a less comprehensive book with the same general method of treatment but better adapted to the average undergraduate course.

**Engineering Societies Library**
29 West 39th Street, New York, N. Y.

MAINTAINED as a public reference library of engineering and the allied sciences, this library is a cooperative activity of the national societies of civil, electrical, mechanical, and mining engineers.

Resources of the library are available also to those unable to visit it in person. Lists of references, copies or translation of articles, and similar assistance may be obtained upon written application, subject only to charges sufficient to cover the cost of the work required.

A collection of modern technical books is available to any member residing in North America at a rental rate of five cents per day per volume, plus transportation charges.

Many other services are obtainable and an inquiry to the director of the library will bring information concerning them.

# Industrial Notes

**Corning Glass Expands.**—To meet the increased production demands, plant facilities of the fibre products division of the Corning Glass Works are being enlarged, and work is well under way in the erection of 3 new buildings having a total area of 46,000 sq. ft. L. W. W. Morrow, formerly editor of the "Electrical World," was recently appointed general manager of this division. Principal applications of the new glass fibre include building insulation, refrigerator linings and air conditioning filters. Potential markets include wire and cable covering and innumerable textile applications to which an inorganic thread or cloth made of glass can be applied. The new glass cloth is heat resistant, waterproof, and non-corroding.

**Copperweld Appointment.**—Roy C. Raasch has recently been appointed field representative for the Copperweld Steel Co., with headquarters at Chicago, Ill. For the past few years he has been in the engineering department of a large utility company.

**Tower Order to Blaw-Knox.**—According to a recent announcement, the Blaw-Knox Co., Pittsburgh, Pa., has received an order for approximately 2000 tons of transmission towers (which will number about 250) for a 220,000 volt line of the Pennsylvania Water & Power Co. of Baltimore.

**New Connector.**—Burndy Engineering Co., Inc., New York City, has announced an addition to their line of grounding connectors "Groundem," type GH. This low-cost connector is for use in joining a ground lead to a driven rod or pipe. Its construction permits it to be slipped over the top of the rod as a one-piece assembly, or, in the event that the rod or pipe has been splayed from driving, it may be readily disassembled and slipped around the conductors. The Groundem is constructed entirely of noncorrosive copper alloys, making it resistant to underground conditions. It is installed with an ordinary wrench and is made in three sizes, each of which will take a range of rod and wire diameters.

**Pacific Electric Now Home Owned.**—According to a recent announcement, the interest of the General Electric Co. in the Pacific Electric Manufacturing Corp., has been purchased by Joseph S. Thompson, president of the latter company. Some eight years ago General Electric secured a virtual half interest in the west coast company, but with the sale of the stock the latter is now an entirely independent organization. It operates a factory occupying two city blocks in San Francisco and a small branch maintenance and storage plant at Gary, Ind. Incorporated in 1906, it is engaged in the manufacture of high voltage air break switches, oil circuit breakers, high voltage fuses and kindred apparatus.

**Calculating Board Kept Busy.**—With increasing loads racing toward the capacity of equipment, many power companies find it necessary to solve quickly new generation and distribution problems. Five companies wishing to determine accurately the added power needed and the load limits and stability of their systems have recently engaged the Westinghouse a-c calculating board to analyze their problems. During the past year eighteen major system studies, involving plants up to 500,000 kva capacity, have been completed on this uniquely efficient board. These systems included eight utilities, six government projects, two industrial plants and two foreign power systems. This is the largest a-c calculating board built to date, and with its 300 circuits it can readily duplicate, by miniature replica, any power system in this country. With its aid, system stability, power factor correction, load-voltage regulation studies and the best location for new generating, transformer and line equipment are readily determined.

# Trade Literature

**Distribution Capacitors.**—Bulletin 3381, 16 pp. Describes the use of "Permittors" (capacitors) for power factor correction in distribution circuits. Products Protection Corp., New Haven, Conn.

**Meters.**—Catalog Sec. 42–210, 16 pp. Describes various types of polyphase detachable meters, applications, construction, operation, adjustment, outline dimensions and wiring diagrams. Westinghouse Electric & Mfg. Co., E. Pittsburgh, Pa.

**Stopwatches.**—Folder. Describes and illustrates 40 different types of stopwatches for industrial and laboratory use. Circular describes stopwatch repair service. A. R. & J. E. Meylan, 268 W. 40th St., New York.

**Motor Repair Supplies.**—Catalog 49, 48 pp. Describes insulation, wire, tools and supplies for the motor repair shop. Prices are included. Reading Electric Co., 227 W. Van Buren St., Chicago, Ill.

**Circuit Breakers.**—Bulletin GEA-2450, 4 pp. Describes type AE-1 air circuit breakers for industrial and central station auxiliary service; 250 volts d-c; 600 volts a-c; 15–600 amperes, 20,000 amperes interrupting rating. General Electric Co., Schenectady, N. Y.

**Measuring Instruments.**—Catalog-type broadside "Power Plant Measuring Instruments, Telemeters, and Automatic Controls." Specific applications are illustrated in electrical generation and transmission, steam generation and distribution, hydro- and diesel power generation, in which the equipment is used. Leeds & Northrup Co., 4962 Stenton Ave., Philadelphia, Pa.

**Oilostatic Transmission System.**—Bulletin, 16 pp. Describes the Bennett Oilostatic transmission system, in which the insulated power cables are installed in buried metal pipe filled with oil maintained under a constant high pressure. Includes details of construction, cable design, cable splices, terminals, pressure maintaining equipment, etc., as well as a detailed outline of all information required to make a study of an Oilostatic application. The Okonite-Callender Cable Co., Paterson, N. J.

**Monel Metal.**—Bulletin, 48 pp. The publication has been prepared primarily as a guide book to Monel and other non-ferrous nickel alloys in the fields of engineering applications. It also covers the corrosion resistance and other properties of these metals. Twenty sub-divisions are included, each devoted to specific problems in fields from hydroelectric and steam power plants to highway maintenance, refrigeration and automobiles. The booklet also describes some of the newer forms of the alloy, including "K" and "S" Monel, etc. International Nickel Co., 67 Wall St., New York City.

**Synchronous Motors.**—Bulletin 1154A, 28 pp. Describes the construction and applications of modern, coupled and engine-type synchronous motors that may now be obtained with torque characteristics suitable for practically any drive, fifty horse power or over, where the squirrel cage induction motor could be used. It deals with the increasing usage of this type of motor due to its uniform high efficiency, at fractional as well as at full loads, and at all speeds, together with its all important function of power factor correction. Allis-Chalmers Mfg. Co., Milwaukee, Wis.

**Industrial Wiring Survey.**—Bulletin, 40 pp. This publication has been designed to facilitate investigation of the condition of the electrical equipment and wiring in industrial plants from the standpoint of ability to carry load, surplus or spare capacity, system defects, safety, deterioration and obsolescence. It gives the logical procedure for making such a survey, provides convenient space for recording findings, and includes recommendations for plans or plot sketches of the existing layout. It is stated that such a study will disclose the weaknesses, if any, in the electrical system, and become a permanent record for determining what parts of the system may be extended under pressing conditions. Anaconda Wire & Cable Co., 25 Broadway, New York City.

**New Clip-On Ammeters.**—Bulletin, 4 pp. Describes a complete new line of dual range clip-on ammeters now available. Originally introduced some 6 years ago, this instrument was at first available only in the standard 0–100/500 ampere combination. Recently additional low and high range combinations have been added to the line so that it is now stocked in 4 standard low range combinations and 3 high range combinations. With these instruments it is possible to measure currents from 1/5 ampere up to 1,000 amperes without opening the circuit or shutting down the equipment under test, or removing insulation from the conductors. The instruments are supplied with fully insulated clips as well as Bakelite handles and may be used with equal safety on insulated or bare conductors. Many minor improvements have been incorporated in the new line. Ferranti Electric, Inc., 30 Rockefeller Plaza, New York City.

# High Lights

**Water-Level Control.** Control of the water level in a model of the Cape Cod (Mass.) Canal and the automatic recording of water level at several points during studies of flow were accomplished electrically by utilizing the capacitance between the water itself and a plate suspended above it, together with suitable vacuum-tube amplifiers, grid-controlled arc-discharge tubes, and Selsyn motors (*pages 237–44*).

**Engineers and Economics.** Successful economic planning is most hopefully to be looked for if the planners are guided by the approach and method characteristic of an engineer. However, individuals combining this with other essential traits are regarded as rare (*pages 206–07*).

**Japanese Progress.** The characteristics of the Japanese people, their educational system, and cultural and industrial development are reported by a visitor to Japan who finds that country well-equipped to compete with the western world (*pages 208–15*).

**Electrical Machinery.** Reactance of end connections and eddy currents in rotor bars are the subjects of 2 papers in this issue. In one the use of image conductors in iron, of Rayleigh insulating partitions, and of images of conductors in these partitions are shown to afford an attack on the problem of end-connection reactance (*pages 257–60*). The other paper shows that from oscillograms of eddy currents in the rotor bars of a squirrel-cage induction motor, the magnitude of the power loss caused by eddy currents, and its variation with load, may be determined (*pages 253–6*).

**Switchboards.** The power plant at Boulder Dam has been equipped with switchboards notable for their size and for the combination of designs and methods that heretofore have been used individually but seldom together (*pages 224–36*).

**Lightning Investigation.** Data obtained from the measurement of lightning currents in tower structures, counterpoises, and ground wires on a 132-kv line indicate that stroke currents rarely exceed 150,000 amperes and that adequate shielding of lines at station entrances is necessary (*pages 245–52*).

**Stability.** A comprehensive review of the subject of stability of large power systems is presented in a report of an AIEE subcommittee. A summary of the recent practices regarding stability features of many power systems throughout the United States is included (*pages 261–82*).

**Tube Nomenclature.** A committee of the American Standards Association is attempting to simplify the nomenclature of electronic tubes, and toward that end has obtained an agreement by 2 large manufacturers to abandon trademark rights to several names. A tabulation indicating the initial step is given in this issue (*page 284*).

**Unemployment Among Engineers.** Unemployment data from 52,589 engineers throughout the United States, obtained in the 1935 survey of the engineering profession conducted by the United States Bureau of Labor Statistics shows that more than 1/3 of all engineers reporting were unemployed at some time during the years 1929–34; half of these were unemployed for more than a year. The largest proportion unemployed at any one time was about 11 per cent (*pages 216–23*).

**Correction.** An error in photoengraving shifted from its correct position the center vertical scale of figure 11 of the paper "Pole Flexibility as a Factor in Line Design" by Howard P. Seelye and Myron Zucker, as reproduced on page 97 of the January 1937 issue. The corrected figure is shown here.

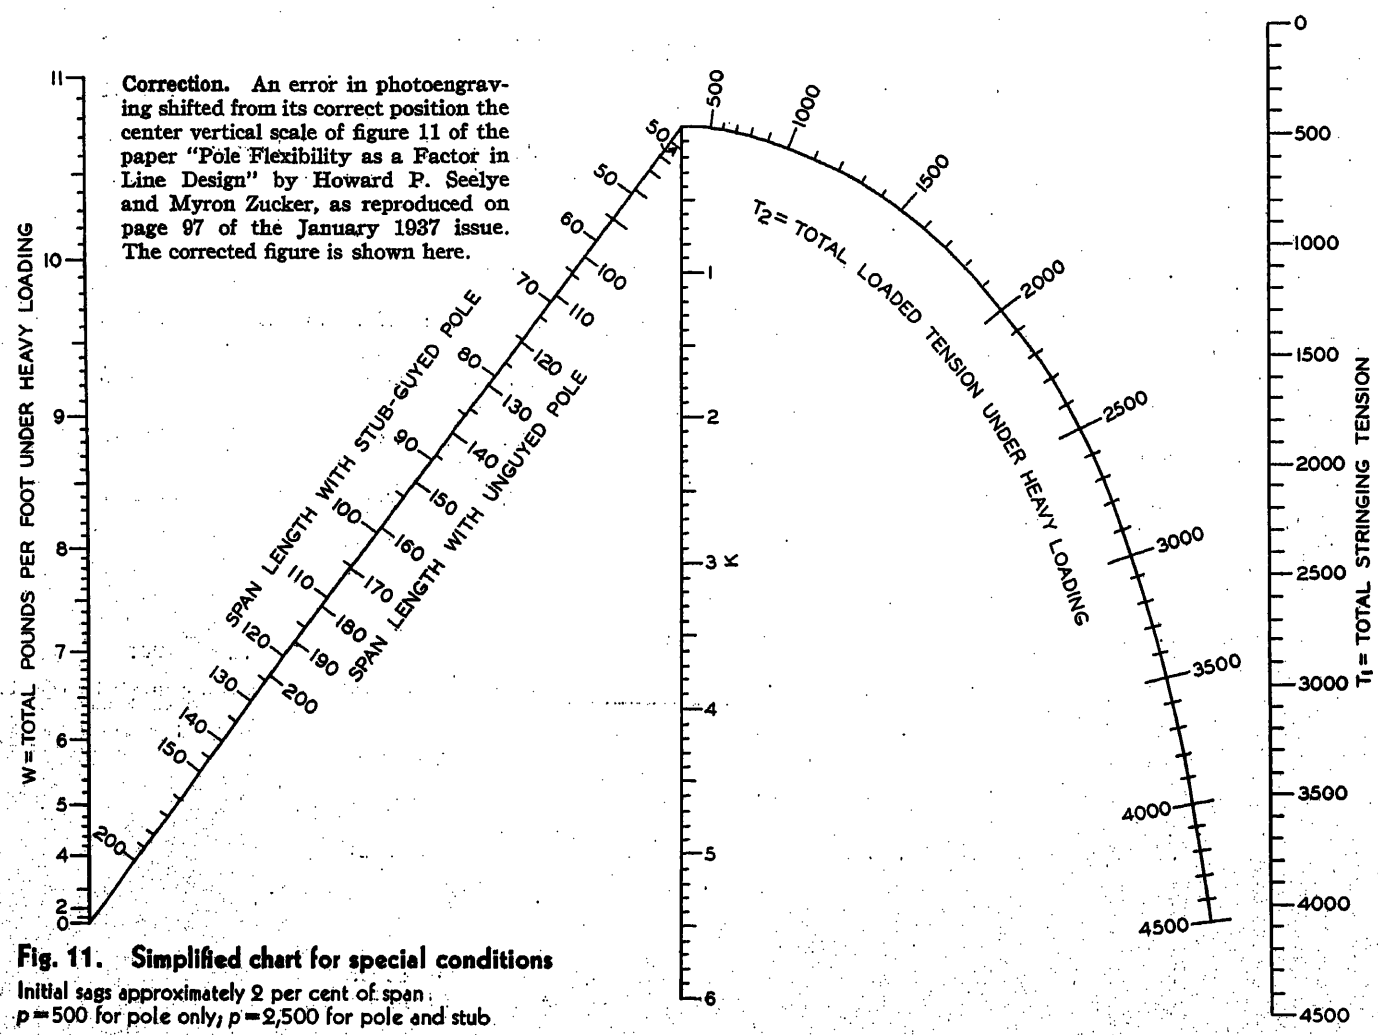

**Fig. 11. Simplified chart for special conditions**

Initial sags approximately 2 per cent of span.
$p = 500$ for pole only; $p = 2{,}500$ for pole and stub.

# The Challenge of 1937

1936 is now history. Whatever we have accomplished, or failed to accomplish, is written into the records and we cannot change it. The engineer is interested in history as a guide to the future, but what most intensely interests him is that which he may accomplish in the future. Every keen-minded member of the American Institute of Electrical Engineers is greatly interested in the future accomplishments of the organization.

We are not satisfied with the performance of our organization, and I hope that we never will be. The greatest stimulus to future accomplishment is a sane and healthy dissatisfaction with the past.

Although not satisfied, we can secure a certain degree of comfort through comparison. I think that we will not suffer in comparison with other technical societies. They too wish to accomplish more than they have in the past. In a broader sense, are we entirely satisfied with affairs throughout the world? Are we entirely satisfied with affairs in our own country? Yet is it not the best country in which we can live? Likewise is not our organization the best one available to us for our professional advancement? Our problem is to make it the best organization possible.

With privilege comes responsibility. It is the privilege of the Institute to represent professionally the electrical engineers of America, and this high privilege implies a deep responsibility of which we should ever be conscious.

During the last year, have we adequately represented the electrical engineering profession in our technical activities? I think we have, but I know that we can do better in 1937. A greater participation of the Sections in the national technical activity is desirable. This does not mean that each Section must set up a technical committee corresponding to each of the national technical committees, but rather that each Section has the privilege of selecting 1, 2, or more technical committees in the work of which that Section is particularly interested. This opportunity is a real challenge to each Section for 1937. I would suggest that the Sections start by selecting the one technical committee in the work of which they are most interested, and organize within the Section a corresponding technical committee. In this way it is possible for every Section to contribute to the national technical activity. The chairman of such a Section technical committee would be a very logical nominee by the Section for membership on the corresponding national technical committee the following year.

Has the Institute in 1936 effectively embraced its opportunity in advancing the professional standing of its members? Here lies another challenge for 1937.

Should there be a gradual and intelligent broadening of the sphere of Institute activities? This deserves very earnest consideration. As one example of what can be accomplished, I was very favorably impressed by a paper "The Engineer's Responsibility to Society" which was presented by a student member at a recent Branch conference held in Pittsburgh, Pa.

Are we satisfied with the 1936 record of members added to our rolls? Before answering, let us consider why a professional engineering society desires addition to its membership. If there be electrical engineers who are qualified for membership but who are not members, the society will be more truly representative of the electrical engineering profession if they were offered the opportunity of joining. If they would then participate in the activities of the organization, it is obvious that the organization would more nearly measure up to its opportunities. The increased financial support from such new members would enable the organization more successfully to carry on all its work. The challenge of 1937 will not be successfully met unless every qualified electrical engineer is offered the opportunity of enrolling in our ranks.

I firmly resolve to do all in my power to meet the inspiring challenge of 1937, and I ask every one of our more than 15,000 members to make the same resolution.

PRESIDENT AIEE

# Engineers and Economics

By MORRIS E. LEEDS
FELLOW AIEE

**The characteristics of engineering that should give the engineer a stronger sense of economic and social responsibility than is sometimes felt by those in other professions are discussed in this article, which suggests that an engineering approach should be made to economic problems.**

MANY individual engineers undoubtedly feel a peculiar sense of obligation to make some contribution to the solution of our economic difficulties, and I think we may safely say that engineers collectively in their organizations share that feeling. The individual sense of responsibility is manifested by numerous writings and statements of men in the profession. As a result of collective efforts we have had the reports of the committee of the American Engineering Council on the relation of production, distribution and consumption, out of which grew a real, though unsuccessful, effort on the part of the Engineering Foundation and the American Engineering Council to plan for such work under engineering auspices with an even broader committee, including representatives of labor and the public.

Of course, engineers are not the only groups that have made such efforts. Many reports addressed to aspects of economics have been issued, representing trade organizations, chambers of commerce, etc., but these have generally concerned themselves quite narrowly with the needs of those for whom they spoke and have assumed, if they considered it at all, that the general welfare would coincide with their own. They do not show the disinterested breadth of view which led the engineers' committee to state as its objective:

"The selection and recommendation of such governmental, financial, and business policies as will maintain in the United States a standard of living that is high, broadly distributed, and free from severe fluctuations."

I wish to discuss particularly those characteristics of engineering which in my judgment should give the engineer a stronger sense of economic and social responsibility than is felt by his brethren of industry and the other professions.

There are those who say that his responsibility is a natural consequence of his conspicuous success. Pursuing his work along the lines of the definition now more than a century old—"the art of directing the great sources of power in nature for the use and convenience of man"—the engineer has done his full part in providing us very rapidly with such a wealth of machinery for producing goods and services and providing transportation and communication, that this good fortune has come on us more quickly than we have learned to manage it, and, lacking that management skill, has become temporarily and in part a misfortune. It is argued that the engineer having contributed so largely to this condition now has the obligation to extend his art to the field of social and political economy so as to make his other contributions an unmixed blessing. There is something in this viewpoint, but responsibility in that sense belongs also to scientists, inventors, perfecters of management, and other innovators. To my thinking, the chief reason for the engineer's responsibility lies in his possession of an approach and method which have been so perfected that they are uniquely valuable for producing practical results under imperfectly understood and complicated circumstances, where, as in the economic realm, traditional methods fail and it is not obvious how to proceed.

The essentials of the engineering approach and method, I take it, are these:

A clear conception and precise statement of the objective to be achieved.

A consideration, as thorough as practicable, of all the factors—be they physical, social or psychological—which will influence or may be employed in getting the desired results; and on the basis of this knowledge—

The formulation of the most effective plans for achieving results that can be developed in the allowable time.

This may seem to many of you to be little more than elementary common sense. Good sense I believe it to be, but common I think it is not.

I have just now referred to this approach and method as uniquely characteristic of the engineer, and taking these steps all together I believe they are. Others may clearly conceive and precisely define their objectives, but in practical affairs that is rare.

Business men for the most part work in fields where experience, tradition, and the pressure of circumstances serve to guide their plans and policies.

Scientists weigh the facts pertinent to their subject perhaps more thoroughly than do engineers, but they seek perfection of classification and description, extension of knowledge and theory, rather than the development of workable plans—and that is a highly significant distinction. Moreover, they are not hampered by a date on which the report is due, while the engineer is almost always limited in that respect. I have heard it said recently that a recognized authority, who has published extensively on the business cycle, has said that he needs 5 years more before he will be in a position to

Written especially for ELECTRICAL ENGINEERING, based on a paper presented at the corporation dinner of the Brooklyn Polytechnic Institute on June 16, 1936. Manuscript submitted January 7, 1937; released for publication January 7, 1937.

MORRIS E. LEEDS is president of the Leeds and Northrup Company, Philadelphia, Pa.

talk definitely about controls. Contrast that viewpoint with, let us say, a bridge engineer. His plans must be ready in a certain time; and if a new material which promises lighter and better structure cannot be sufficiently time-tested to be used safely, he must plan a heavier one known to be safe.

I know of no science, trade, or profession other than engineering that has perfected an approach and method that are so clearly right for dealing with our muddled economics.

Let me explain at this point that when I speak of economic plans I am not talking of something new and strange. Any measure for getting an economic result, such as a tax bill or a tariff act, is an economic plan; and any discussion by which such bills are formulated is economic planning of a sort.

We do not want planning of the Russian type, or except for emergencies, even that of our own War Industries Board. With us economic plans will become effective only as they commend themselves to our people and their legislative representatives. Planning for democratic acceptance *is* going on continuously in an unorganized way through public discussion, in magazines, pamphlets, and books, and a great amount of useful educational work is being done which ranges in value from the ephemeral and trivial to the publications of such men as Maynard Keynes and those of such bodies as the Brookings Institution and the National Bureau of Economic Research. But in spite of this extensive discussion, we still seem far from agreement as to the best means of dealing with our very serious unemployment situation, for instance, and this is only one of a number of important subjects on which we do not have a united or settled opinion. Let me illustrate by reminding you of a few of them.

**How can taxes be levied so as to bring in the desired revenue and distribute the burden equitably?**

**How shall they be apportioned between the states and the nation?**

**Should taxes be used for other purposes than to raise revenue, as the import taxes are used to encourage domestic production?**

**Can they be planned to moderate instead of intensify the business cycle?**

**Will prosperity be enhanced by a policy which excludes practically everything that we can produce in our own country, or by one that encourages a large exchange with other countries; or if by some intermediate position, how shall that position be determined?**

**How are we to maintain balance between production and consumption; between agriculture and industry, etc.?**

**At various stages of national wealth, what proportion of the total should be expended publicly by government?**

**What about foreign debts, credit and finance?**

It is in connection with this complex situation that economic plans are to be developed, and in order to be effective they must have popular democratic acceptance. I repeat that success is most hopefully to be looked for if the planners are guided by the engineer's approach and method. Thus guided:

**1. They would clearly envisage their objective and would probably state it in some such language as the engineers did, that is, a level of national prosperity that is high, widely and fairly distributed, and free from serious interruptions.**

**2. They would take into consideration all the factors, be they physical, social, or psychological, which will influence or may be employed in getting the desired results. This will include an understanding of the conditions necessary for getting popular acceptance.**

**3. On the basis of the available knowledge they would present the best practical plan for achieving the results that the time available permitted. The time factor is important. The plan must be one that can be put through at some specific time, and one that will work after it is enacted, with conditions as they are.**

It may be questioned whether those who have attained proficiency in some branch of their profession will thereby be best fitted to translate this fundamental engineering attitude to such an alien field as economics. An essential condition is that all the pertinent factors, including the social and the psychological, be taken into consideration. Perhaps the engineer, who has become accustomed to and has chiefly dealt with the dependable phenomena of the physical world, would thereby be unfitted for dealing with economic phenomena in which human will and emotion and mass psychology play so large a part. The practice of engineering will not in itself familiarize one with the vast body of economic fact and theory.

This is my conception of the kind of men who would best qualify for economic planning. They will be men who understand the engineering approach and method, whether trained in the profession or out of it. They will be men who have so risen above any particular industry or profession, through which they have achieved eminence, that they will be able to see society and its needs as a whole. They should have the steadiness and dependability which come from successful adjustment of their own affairs to practical conditions, and, along with those qualities, should be marked by a high degree of social idealism. A rare type! There are many men who have the first of these qualifications; many who have the second; few who combine them. Of the few men whom I know or know about who seem to have these qualifications, one is an engineer, another was a lawyer and is now a judge, and a third is a business man.

So I conclude, you see, that it is not the vast knowledge of the engineer nor the skills and techniques of the profession, useful as these may be, that put him in position to make a uniquely valuable contribution to the art of dealing with complex economic situations, but I believe he can make such a contribution by passing over into the field of economic practice his habitual way of looking at and dealing with problems, which leads him to see clearly what he wants to accomplish, to take into account systematically all the factors and circumstances which will influence results, and then plan so that the objective may be achieved as nearly as possible by the time wanted and under existing conditions.

It is interesting to consider how the engineering profession might make this contribution. Individual engineers can emphasize the engineering method in their own discussion of economic subjects and urge it in connection

(*Concluded on page 215*)

# Industrial and Cultural Japan

By DUGALD C. JACKSON
PAST-PRESIDENT, AIEE

**Education and industrial development in the Japanese Empire are here described as seen by the author during his visits to that country, in which he recently delivered a series of lectures under the Iwadare Foundation.**

JAPAN and its industries present a picture of interest and significance from many angles. The facts and opinions outlined in this paper were secured in 2 visits to Japan 6 years apart and each of some weeks' duration, a considerable part of the time of each visit having been spent in observing as a matter of personal interest the education and the industry in that engaging country.

## Characteristics of the Japanese People

The population of the Japanese empire is now counted as about 95,000,000 people. These are included in the islands of Japan proper and in Chosen (Korea), which is a peninsula of the Asiatic mainland, the island of Taiwan (Formosa), and a few small islands. It is a notably literate population, vying with the United States in the percentage of literacy. The Japanese people are full of sentiment for their ideals in art and literature, for their interpretation of heroes and heroism, and for the beauties of nature as exhibited in Japan; but they also are realists—shrewd and practical.

Americans generally have heard much of the sentimentalism of the Japanese people and have heard little of the other side of their nature and habits. The exaggerated sentimentality of Pierre Loti's writings and the sympathetic interpretation of Lafcadio Hearn have influenced American thought on one side only, and we have not secured a balanced view of this people. There is a degree of reason in this. Even the British poet laureate, Masefield, mystically traces in glamorous words the lure of the broad Orient in his poem describing the stores of the Eastern Merchants:

"We have been told that in the East are things
Flame-guarded by the Phoenix' burning wings,
The Sunstones of the Everlasting Kings;

"The Moonstones from the Woman of the Sea,
The Changestones that compel Eternity
To that which *is*, but yet can never be.

* * * * *

"And silks, that the worm spins and man refines,
Silk of the East with sunlight in its lines
That, at each turn, with other color shines."

* * * * *

In the light of such delightful legends it was easy for Americans to fall under the spell proclaimed by the sentimentalists. It was also easy for a pragmatic people to miss the truth on the other side. We did so in distress over an embarrassing influx into California of low-class coolies, a third of a century ago, and we assumed a patronizing attitude toward the Japanese because some of our citizens (in contact with an inferior class) confused that class with the entire race and dubbed the race inferior.

The recent strong place in the world of affairs that has been assumed by the Japanese nation emphasizes the importance of a fuller examination of the facts and a better understanding by Americans of the Japanese people, their ambitions and their ideals.

In their original feudal stage the Japanese authorities seem to have had neither desire for, nor strong antipathy toward, contact with foreigners. However, clashes with western traders and western proselytizers, who refused to yield to feudal regulations, led to exclusion of foreigners from Japanese soil and the prohibition of almost all trading contacts or privileges. Lasting several hundred years (during which the expostulations of western nations were rebuffed), this state of affairs was disturbed by Commodore Perry of the United States Navy who, in 1853, on behalf of our Government, made approaches to the Japanese authorities for the purpose of establishing mutual relations of friendly nature between the 2 nations and their citizens. Contact having been made, he then temporarily withdrew.

Commodore Perry returned to Japan in 1854, and this time succeeded in opening restricted diplomatic and commercial relations for the United States. European nations joined with America in this opening of Japan anew to foreign intercourse. Our earliest official commercial agent, Townsend Harris, was fortunate in his qualities of forbearance in a somewhat hostile setting, tolerance toward (to him) strange religious beliefs, and competence of imagination for picturing the points of view of alien peoples. The European nations were not so free from the arrogance that arose from an assumed superiority of intellectual level. Neither have we Americans been at all times free from arrogance since the days of Commodore Perry and Townsend Harris, but Harris has stood (in the imagination of the Japanese people) as a representative of the friendly qualities of the American people. We likewise have touched the hearts of the Japanese at other times and by other means, of which a notable example arose through the noble manner, as well as the magnitude,

Written especially for ELECTRICAL ENGINEERING. Manuscript submitted December 21, 1936; released for publication January 6, 1937.
DUGALD C. JACKSON is professor emeritus and honorary lecturer at Massachusetts Institute of Technology, Cambridge. He was president of the Institute 1910–11. In 1929 he visited Japan as a delegate to the World Engineering Conference in Tokyo; in the latter part of 1935 he served as lecturer at the invitation of the Institute of Electrical Engineers of Japan under the Iwadare Foundation.

of our aid to Japan on the occasion of that cataclysmic Yokohama-Tokyo earthquake and conflagration of 1923, which destroyed over 100,000 lives and rendered 1¾ millions of people homeless. The cost to Japan of reconstruction which followed that disaster is estimated at more than 5 billion yen.

Through such relations the informed Japanese feel a deep sense of gratitude toward the United States and its people. But this is offset by the sense of resentment which rests on the whole Japanese population, for what they consider our not infrequently patronizing attitude toward them due to racial differences.

Now the Japanese nation has come to vie with the western nations in diplomacy, industry, education, and international commerce. They started on their career in these fields short of 70 years ago. Their progress in industrial affairs during the 70 years, while in competition with the most active industrial developments of the western world, proves them to be a people of intellectual power rivaling the intellectual powers of their western competitors, as was foreseen by Theodore Roosevelt in 1906. We of the United States are their most important customers in international trade. They are high in order of importance among our customers. Our greatest commercial importation from them is raw silk. Their purchases from us include much cotton, but (although they have become great industrialists themselves) also include considerable machinery and other products of manufacture.

## Japanese Education

It is time for the American people to awaken to the fact that the Japanese are a highly educated people possessing intellectual powers rivaling our own and inventive genius in government and industry which has become matured and capable by experience. Japan is a nation with which (as in the case of other strong nations) we are having and will continue to have commercial rivalries and causes of friction demanding tactful adjustment; but it is a nation which cannot afford serious differences with us, nor can such differences become acute without loss to ourselves.

For satisfactory acquaintance between the peoples of 2 nations it is desirable that each of the peoples shall know something of the educational processes carried on in the other nation. Only through such knowledge can truly friendly relationships grow up and be maintained; and only through such knowledge can misconceptions arising from false diplomacy or errors of commercial processes be avoided, or (if occurring) can be prevented from becoming causes of friction. If one knows the processes of education of a people, one may, in a sense, claim to know the characteristics of that people. The writer's observations in his 2 visits to Japan, 6 years apart, each of some weeks' duration, as already said, added to a long life spent in American industry and engineering education, indicate a definite lack of understanding among the Americans and the Japanese people regarding the processes of education in the other nation. In each nation there are but few individual exceptions to this lack. It is also notably true that the Americans lack understanding of the Japanese civilization and that the Japanese (except for a relatively few individuals among the whole) equally lack a conception of the American land or the lives of its people. Space available gives but little opportunity to deal with these features, but the importance of the matter justifies as full an outline as practicable.

In 1868 the Japanese Emperor Meiji shook off the control of the Shogun and took full administrative control in the nation. Feudalism was overthrown. The Meiji Emperor was a man of force and character with a will for the betterment of his people. With the advice and aid of commissions of able Japanese statesmen sent to Europe and America to gather data and formulate recommendations, a parliamentary government was formed, financial and commercial processes were outlined, and education for the masses was established.

By 1872 a unified plan for elementary, intermediate, and higher education was outlined for Japan, following rather clearly the French standards in the elementary and intermediate processes. By 1880, attendance at school by children up to certain ages was made compulsory. These educational processes established under the Meiji Emperor have reasonably well fulfilled the expectation for old Japan which is set forth in the Imperial Proclamation, which reads: "Henceforward education shall be so devised that there shall be no ignorant family in the land and no family with an ignorant member."

The elementary educational processes have been modified from time to time since the early establishment of general education, and various later doctrines which have served well in Europe and America have been introduced, besides modifications which seem best suited to the national requirements of the Japanese people. In no land is the welfare of the school children more cherished than in Japan, and solicitous attention is given to their physical welfare as well as their intellectual welfare. As an evidence of the results of care for the physical welfare, statistics are given which

**Edison memorial at Yawata, site of original source of bamboo for incandescent-lamp filaments; Professor Jackson is in the center of the group**

show that the stature of the children is increasing in height compared with earlier groups. The children also are taken on visits to beauty centers (which are so numerous in Japan), to notable temples and shrines, to museums of art, and to centers of creative thought.

It is now characteristic of the schools that the children work at desks, sitting on benches, instead of following the old Japanese custom of sitting on the floor with little tables before them. The children are usually in uniform dress, which is determined by government, those for the boys corresponding to trousers and jacket suits such as we often see in the west, and for the girls, to skirt and blouse suits, such as we also see in the west. These garments are much more convenient for wear during active exercise or when sitting at the desks than the old-time kimono garments, although the latter are commonly worn at home on account of their relative comfort.

**Ancient flowering cherry tree in Kyoto, said to be 400 years old**

The elementary education covers a period of a half-dozen years or more. The instruction is done in the Japanese language and no foreign language is taught in most of the elementary schools. The children follow educational processes that are not particularly different from those of the western world but much more attention is given to bringing the pupils in contact with the national ideals than we usually find in the western schools. Indeed, the attention which is given to the health of the children and the supervision of their athletic exercises match our best efforts; and the children's organized visits to seats of great national reputation and natural beauty, and to important shrines and temples, excel the corresponding procedures which we find in the west.

Through these processes, the children grow up in Japan with a wonderful appreciation of the beauties and the symmetries of nature and art in their country, besides being educated in the usual fashion that we associate with literacy. The selection of school teachers is made under rigorous requirements relating to preparation for the teaching work.

Secondary education is carried on equally scrupulously in Japan, although a much smaller percentage of the children transfer from the elementary education into the secondary education than we now find in America. That is, the compulsory education in Japan only applies (for most part) to the elementary portion and the age at which children are released from the compulsion is several years younger than it is in certain of our states. In thinking of these things, however, we must remember that the statutes of Japan apply to the whole nation, with the exception of special provisions made for Chosen and Taiwan, while in the United States we have requirements of different scope in the different states.

For the secondary education, one finds schools of general education (usually referred to as middle schools) and also vocational schools, all of excellent grade. In these schools a foreign language is included, which is usually English, French, or German. Since the emphasis is on English, it is possible for an English-speaking visitor to Japan to find a considerable competency in English among the Japanese, and it is almost always easy to find an interpreter. The structure of the Japanese language is so markedly different from English or any other of the western languages that the usual visitor from the west is not quickly tempted to try to learn something of the native language, as he is when visiting in western countries which are neighboring on his own.

Among the vocational schools there are very adequate groups which deal with the particular problems of agriculture, industry, and commerce.

The university program of Japan now is quite extensive. There are in old Japan 6 Imperial universities, and one each in Chosen and Taiwan. These universities, supported by the government, are all of fine order. They are reinforced by many other universities, higher scientific schools, higher commercial schools, research institutes, and other higher institutions which have not yet reached (or are not intended for) the scope required for designation as Imperial universities, which designation is conferred under statute by the Ministry of Education. Some of the institutions other than Imperial universities are the result of private endowments, but many are sup-

ported by government funds in a manner similar to the support of Imperial universities. Some are sustained for limited purposes, such as education and research in the fields of medicine, engineering, agriculture, or other fields of special import, or as institutes of research in particular branches of science. Important research in fields of science, with emphasis on applied science, is also fruitfully supported by government ministries and by private industrial organizations. An official organization, which is somewhat analogous to our National Research Council, is supported by the government.

While schooling is compulsory through adolescence, the admissions to Imperial universities and other government-supported institutions of higher education and research are usually by competitive examination accompanied by rigorous limitation in the numbers of students accepted. Consequently the numbers of students in the universities and higher professional schools are apparently less, proportionally, than we have in America. This seems notably true of the engineering classes, medical classes, and classes of students in other professional branches; but the standards of work in these branches are established on an admirably high level. For intermediate work in these branches there are available a certain proportion of polytechnic schools, commercial schools, schools of practical agriculture, and such like.

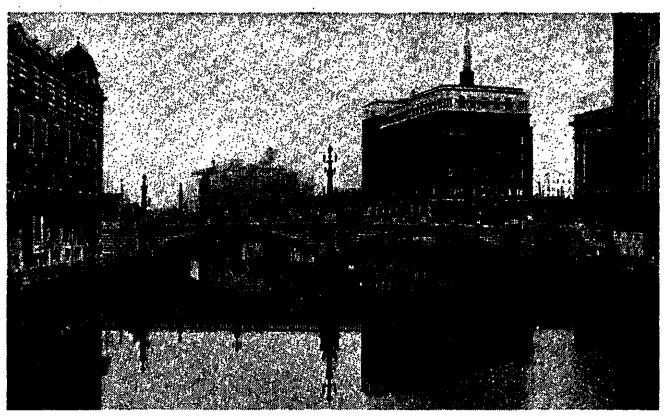
Education in science is recognized by the Japanese government and people to be a feature of great importance during the expansion of the Japanese industries which now is going on. A country coming in the last part of the nineteenth century, as a novice, to develop a western type of education in science and an active participation in industrial production, appropriately may give first encouragement to rigorous education and research in improved applications of science, and rely at first on the already established nations for the production of fundamental, new, discoveries on which to build further. This is especially true where ready money is not easily forthcoming for budgets. The wisdom of the Japanese led them originally to that practice, but they are now established in full appreciation of the advantages to themselves of supporting a suitable part of the world's work of research in the fundamental aspects of science. They do the latter without lessening their attention to further creative work in the useful applications of science or lessening their enthusiasm for art and literature.

## Japanese Industrial Development

Japan is deeply affected by the electric forces set up by industrialization, which draw people into increasingly populous urban areas. Tokyo, the national capital, is associated with Yokohama and 2 intervening smaller industrial municipalities to make an industrial area of continuous urban population, which is the third largest continuous urban population in the world, being exceeded only by New York and London. This is Japan's greatest center of commerce, finance, industry, and dipolmacy. The seat of the Imperial government (with its imperial residence, its ministries, and parliament house) is located in Tokyo. The area is one of great intellectual and commercial activity.

Osaka is another center of great industrial and business activity, like Chicago, with several million inhabitants. Nagoya is still another large and important industrial municipality. In addition, industrial activity is widely spread over the home islands of Japan. The continuing repute that the Japanese are solely copyists and cannot become creative industrialists is belied by the factories scattered through a wide area in which are manufactured a variety of originally designed products, often made on Japanese machine tools, Japanese looms, and other Japanese machinery.

**A very old Japanese bridge of wood, bronze, and iron, reputed to have been built in 1673**



The Japanese build their own ships and now bid for ship construction for other nations. They build their own railroad motive-power and rolling stock. They design and manufacture their own electrical machinery. They are beginning the manufacture of automobiles. They manufacture their own steel, although most of the

A panoramic view of the Inawashira power development, one of those which provide hydroelectric power to the Tokyo Electric Company

iron ore and much coal must be imported. They are rapidly developing in the field of chemical manufacture. They are notable in the manufacture of textile goods and ceramic goods. And so on it runs through a wide range of manufactured commodities and specialties. The Japanese are pressing for an increased export trade. They are keen competitors, and we must be sagacious as well as alert in protecting our trade situation, even in our home markets, if we are to succeed in doing so without serious friction.

The Japanese were copyists (indeed, they were assiduous copyists) in the early days of their era of industrialization, as we also were copyists when we were young in industrialization, and the Germans were copyists (often to the distress of American makers of machine tools and other machines) in the early days of their industrialization. Like these other nations, the Japanese have become competent to stand, industrially, on their own feet although the nation woefully lacks possession of sources of many needed raw materials.

A view in reconstructed Tokyo, showing the Sumida River

It is difficult for Americans, living in a continental country possessing sources of raw materials for almost the gamut of our needs, to appreciate the gravity of the situation for an insular nation which lacks in essential supplies, and to further appreciate the pressure for expansion which that situation imposes. In fact, it is even difficult for citizens of Great Britain, a nation that has met such a situation by the development of a surpassingly great sea-borne commerce, to view sympathetically the efforts of a growing industrial nation in seeking to assure its position by gaining a like status.

The Japanese have demonstrated their ambition and their ability, and we must face the fact that they are competent, and also insistent, as competitors for world trade in manufactured products. They came late into this trade as competitors, but they entered it seriously and with the intent to stay. For illustration, with one exception of a wooden ship, no ship of more than 1,000 tons had ever been built in Japan before 1895. Now at least 4 of their competent group of shipyards and navy yards have built ships up to 30,000 tons.

The Japanese are industrious workers and very thrifty. In the agricultural areas, the farm families live from the produce of tiny (in our ideas) farms of from 1 to 3 acres, which they intensively cultivate in every available square foot. Earnings of daughters and sons who have gone into industrial employment bring some ready money to the pockets of farmers, and (to the farmers) the profitable export of manufactured products seems a life line. In their opinion, this life line must be maintained and the nation must be strong in military power and in shipping in order that the life line shall be maintained. The farmers' families work long hours over their crops, but the hours of industrial workers are limited by law to weekly hours that compare on all-fours with those in American factories.

Japan is not a nation of great *per capita* wealth. It is difficult to secure reliable estimates of such wealth, but the Japanese government has published certain estimates which, converted into dollars on the present basis of exchange, make a sorry comparison with our estimated *per capita* wealth. However, such a comparison is superficial and inconclusive. A yen (Japan's principal money unit) buys in Japan about as much food, shelter, and clothing of the character demanded by Japanese as a dollar buys in this country to meet our needs, and on this basis of comparison for the yen Japan possesses *per capita* wealth which is in keeping with that available in several of the important European countries. Although the ratio with our status, even on this basis, may still be low, the Japanese possess a fair amount of working capital, and the development of further capital is progressing with considerable speed.

The exigencies of military expansion are absorbing a great deal of money for nonproductive uses, and the public debt is expanding. When doubt is expressed of the wisdom of this policy, attention is politely directed to the extraordinary magnitude of our "New Deal" expenditures. Pertinent as is this retort, there nevertheless is a difference which weakens the analogy. Of the total present Japanese funded debt, public and private, perhaps one-quarter as much has been borrowed abroad as at home and the debt service siphons a good deal of wealth away from the country. Establishing textile mills and other industrial establishments abroad, as the Japanese have done in China, also draws wealth from its native land, and diverts wages from homeland wage earners. Increased profits accruing to the homeland may not offset these disadvantages in the case of a country which is without excess of wealth, but the Japanese have proved to be astute in commerce and finance and their wisdom may enable them to avoid undue difficulty from the situation.

## Present Status of Japanese Industry

The World War had a great influence on Japanese industry, and nations meeting Japan in lively competition

A scene in Tokyo illustrating the charm of Japanese architecture

for world's trade in manufactured products can lay much of Japan's present industrial stature to the impulse arising out of the demands of that war. Up to 1914 the industrial situation in Japan had been for a decade or more in a state of expansion at a moderate rate, but during the World War, Japanese industries embraced the opportunity for very rapidly expanding their world trade, and industrial production bounded upward accompanied by rapid expansion of plant and enlargement of the number of industrial employees. The principles of mass production, guided by scientific management, were adopted in many localities. Manufacture of iron and steel, electrical machinery, machine tools, textile goods, ceramic goods, chemical goods, matches, portland cement, paper, and other commodities were all pressed forward, as also was the preparation of foodstuffs.

The homeland (that is old Japan, which consists of the islands of Honshū, Kyushū, Shikoku, Hokkaidō, and accessory islands), possesses some 48,000 kilometers of coast line, indented with some 1,900 harbors, of which 153 are important. The great industrial cities are located on these harbors, and deep water is directly alongside many factories. A great deal of local transportation of goods is therefore by water, and shipping is of large importance. Bounties for ship building and subsidies for ship operation have been part of government policy.

Electric power, generated both by fuel and water, has been largely developed, and power transmitted at 154 kv serves the larger centers. It is estimated that $6^{3}/_{4}$ million horsepower in firm power and $13^{1}/_{2}$ million horsepower in 6-months' power may be secured from water power when the potential hydroelectric plants are all developed. As coal is of reasonable price, much fuel-generated power is associated with the water power. If any reader desires more specific information regarding the Japanese electrical industries, he may refer to my very brief article relating to them which was published in *Electrical World*, July 18, 1936. It is said that seven-eighths of the houses of the homeland use electricity, but the domestic use of kilowatt-hours is actually small because of the few lamps installed in most houses and the low wattage of those installed, and modest incomes preclude the general purchase of electric household appliances.

Mining is a very old art in Japan, and a long list of minerals are mined; but, of the more important mineral ores and commodities, the supply from Japanese soil is insufficient for present industrial demands and importation has to be resorted to. Nevertheless, Japan now is producing most of its own requirements in iron and steel, using mostly imported iron ore and some imported coal.

Industrial wages of Japan are small (when converted to American money at the rates of international exchange) compared with wages in this country, but (as previously pointed out) this makes an inconclusive comparison. In comparison with cost of food, clothing, and shelter in the 2 countries, the Japanese working people are as well paid as our working people were some decades ago, and in the many plants, of many varieties of production, which I have visited, the working people look healthy, well fed, contented, and interested in their work. Our manufacturers who feel the pinch of Japanese competition must come to understand that the Japanese accomplishments are not secured by oppression or exploitation of the working people. Acumen and good management, associated with an as yet relatively very low cost of living, make the combination that has brought the Japanese competition to success. Aid to export business given by the government has also contributed its advantages to the Japanese exporters.

As to the manufacturing processes of the Japanese, they are good. They have been greatly improved during the past half-dozen years. Accuracy in mass production is secured in the factories. Committees participate in

A Japanese private garden at Kyoto

international standards conferences and set standards of construction and manufacture for Japan. Refined testing machines, measuring instruments, and other instruments of precision of Japanese manufacture are now generally available. Research laboratories, working devotedly on the problems within their respective fields, are a general feature of the industries, the government ministries, and departments of universities.

As household industries were developed in feudal times and have continued to the present time, many items of industry are still produced in this informal manner. Such products are likely to be of variable quality, or of low grade, and the government is reported to have plans for putting all such products through tests and inspection in case the products are intended for exportation. This has already been done, for perhaps a dozen years, for raw silk, and may now be in practice for other commodities.

## Ethics and Religion of the Japanese

Shintoism and Buddhism are the religions most influential in Japan, but Shintoism is easily the first in influence, being bound up with the cult of the 3 sacred objects (the sword, the jewel, and the mirror), and the divine paternity of the Emperor. The Japanese are fundamentalists on the divine descent of the Emperor, and their ethics are bound up with that tenet. This gives an aspect to Japanese ethics which is not found in the ethics recognized in western nations, or recognized among the Chinese whose ethics came down through the illuminating interpretation of Confucius.

Perhaps part of the friction between the Americans and the Japanese arises from this component of ethics which lacks mutuality. We compose 2 peoples with present-day cultural ideals somewhat alike, with ethics similar in the main, but with one deeply modifying aspect which pertains to the beliefs of the people of one of the nations. The highest ideal of a Japanese citizen is sincerely bound up in loyalty to the Emperor and the welfare of the nation. The honor of the Japanese individual lies there first. Man-to-man relations and commercial relations trail after, as a matter of fundamental religion.

The western world has been in diplomatic and commercial relations with Japan and the Japanese for only about three-quarters of a century. This is a short time within which to secure mutual understanding between 2 self-reliant and ambitious peoples who live in such diverse situations and are of such diverse antecedents. Suddenly established extreme and continuous intimacy requires time for making adjustments before understanding is established and frictions are overcome. This situation of sudden intimacy has been imposed on the relations of the peoples of the United States and Japan by the intimacies due to steam-power transportation and new modes of quick communication. Sufficient time has not yet elapsed for the roughnesses of contact to be smoothed and softened by experience and adjustment.

Can the causes of friction between our 2 nations be eradicated?

In the realm of science, a theory is a statement which is equivalent to the explanation of any relationships which have been discovered to exist between measured apparent facts. This serves as a guide in seeking out additional relationships. The situation in international affairs, unhappily, is too complex for fitting a theory to guide the adjustment of relationships. In the example of these 2 great nations, our differences can only be adjusted by continued mutual observation, self-restraint, tolerance, and good sense, which lead to mutual respect and appreciation.

---

## Engineers and Economics

(*Continued from page 207*)

with discussion by others. But the situation is so vast and complicated and has so many divisions which interact on each other that it seems to be beyond individual effort and to call for the kind of mass attack which our great industries use in their research and engineering departments for dealing with their physical problems. The telephone industry furnishes outstanding illustration of what I mean. Theodore Vail, and the able men who succeeded him, appear to have set for themselves the ideal goal of producing communication machinery through which anyone anywhere in the world may talk to anyone anywhere else, and they have gone an amazing distance toward the realization of that goal. That has involved dealing with a vast complexity of subjects which range from elementary engineering to advanced and difficult mathematics and physics. How far would the art have progressed by now if the leaders of the industry had contented themselves with development by the tedious and uncertain processes by which we have been satisfied for the most part and until recently, to allow our knowledge of economics to translate itself into working plans? They organized for the attack on their problem great research and engineering establishments, staffed them with the ablest men they could command, and backed them financially on a magnificent scale.

A few similar organizations for mass attack on the economic problem are already in existence. The National Bureau of Economic Research and the Brookings Institution, already referred to, are 2 outstanding illustrations. Others, such as the Falk Foundation, The Twentieth Century Fund, and the National Industrial Conference Board, might be mentioned. In varying degrees numerous other organizations deal with limited areas of applied economics. Graduate schools of business administration, management societies, trade associations, etc., are in this class. It is a common experience of engineers, as they rise in their profession, to find themselves drawn more and more into management and administration, and through these interests into association with organizations of the kinds just mentioned. Here they have an opportunity to carry the engineering approach into a field where it is much needed, and to help build on the basis of economic theory and knowledge a socially useful art of economics.

# Unemployment in the Engineering Profession

**Reporting further upon the results of the 1935 survey of the engineering profession conducted by the United States Bureau of Labor Statistics, at the request and with the co-operation of American Engineering Council, this article* presents the Bureau's analysis of the unemployment data obtained.**

AS FAR as is known, the recent depression was unique in its disastrous repercussions upon professional groups. Unemployment has for decades been recognized as a major form of insecurity affecting wage earners, and fairly reliable data concerning this have been made available from time to time. Precise knowledge as to the extent of the depression's impact upon professional workers, however, has been lacking.

As a result of a survey of the engineering profession undertaken in May 1935 by the United States Bureau of Labor Statistics, at the request of American Engineering Council, it may now be said that at the end of 1932 more than $^1/_{10}$ of the engineers were simultaneously unemployed, that at one time or another between the beginning of 1930 and the end of 1934 more than $^1/_3$ of the engineers had some period of unemployment, and that half of those who became unemployed were out of work for more than a year. Unfortunately, there are no comparable data for the other professions.

From the 52,589 reports from professional engineers throughout the country, the following summary analysis of unemployment, including work relief and direct relief, may be presented:

1. Between the end of 1929 and 1932, the percentage of engineers who were unemployed increased from 0.7 to 10.9. At the end of 1934 the percentage was 8.9.

2. At no time was direct relief extensive among engineers, but the development of work-relief programs after 1932 became an important factor. Although 10.9 per cent of all engineers reporting were unemployed on December 31, 1932, less than $^1/_{15}$ of those unemployed were on work relief. On December 31, 1934, 4.0 per cent of all engineers reporting had work relief, that is, almost half the total number of engineers unemployed at that time.

3. The largest number unemployed at any one time was about 11 per cent of the total, but more than a third of the engineers had some period of unemployment within the 5 years, 1930–34.

4. Among those who became unemployed at some time during these 5 years, half were out of employment (except as they found work relief) for more than a year.

5. This experience with unemployment was common to all professional classes of engineers. In 1932 unemployment ranged from 10.1 per cent among chemical and ceramic engineers to 11.6 per cent among electrical engineers. In 1934 approximately 8 per cent of the electrical, mechanical, and industrial and of the mining and metallurgical engineers were unemployed. The percentage of unemployment dropped most among chemical engineers, of whom 6.8 per cent were unemployed in December 1934. There was a slight increase in unemployment among civil engineers from 1932 to 1934.

6. The most marked differences as regards unemployment are those found among the various age groups. The greatest frequency of unemployment was among those who attempted to enter the profession after 1929. Approximately half of them were unemployed at one time or another from 1930 to 1934. Older engineers, who were already professionally established prior to 1929, were less frequently unemployed, though even among those with 20 or more years of experience $^1/_4$ had some unemployment.

7. When the older engineers became unemployed, however, unemployment lasted longer than it did with the younger engineers. Thus, the median period of unemployment for engineers graduating in 1925–29 was 12.1 months, whereas the median for those graduating prior to 1905 was 23.1 months.

8. The effect of this longer period of unemployment among older engineers was cumulatively to produce a higher percentage of unemployment among older engineers than among younger engineers. Thus, in December 1934, 11.5 per cent of the engineers 53 years of age or more were unemployed, in contrast to an average of 7.3 per cent of the younger engineers who were exposed for the same period to the risk of possible unemployment.

9. The type of education the professional engineer had received did effect variations on both the incidence and severity of unemployment. These factors were very much less for postgraduates than for engineers with other types of education. But as between engineers with first degrees in engineering and those whose college course was incomplete or who had attended noncollegiate technical schools, the differentials were very slight.

10. The influence of regional location on unemployment was practically negligible, whether considered from the point of view of differentials in incidence or of severity of unemployment.

The sources of these data are the replies received to a questionnaire mailed to 173,151 engineers. One question called for employment status on each of 3 dates, thus giving a cross section as to employment, unemployment, work relief, and direct relief on December 31, 1929, 1932, and 1934. From these reports the general trends of unemployment have been traced. A second question related to the number of months of unemployment over the 60-month period January 1, 1930, to December 31, 1934. Consequently, it is possible to measure the incidence and severity of unemployment, work relief, and direct relief for 5 years of the depression, as well as at other dates.

In keeping with the other analyses of this survey, these subjects, wherever warranted, are so presented as to determine their significance when related to (1) type of education, (2) professional class, (3) age, and (4) regional location.

## Unemployment at End of 1929, 1932, and 1934

The first part of the discussion will be concerned with trends in unemployment. For the country as a whole

* Essential substance of an article prepared by A. F. Hinrichs, chief economist, and Andrew Fraser, Jr., of the Division of Wages, Hours, and Working Conditions, Bureau of Labor Statistics, United States Department of Labor, which article was published in the January issue of the *Monthly Labor Review*. This is the second of a series of summary articles covering the results of this survey. The first article dealt with the educational qualifications of the engineer, and was published in the *Monthly Labor Review* for June 1936 (page 1528); also reprinted as Bureau of Labor Statistics Serial No. R 400. The essential substance of the first article was published in the August 1936 issue of ELECTRICAL ENGINEERING, pages 863–7. A detailed report of the survey will be published later in bulletin form by the Bureau of Labor Statistics.

there was an appreciable decrease in unemployment among professional engineers between December 31, 1932, and December 31, 1934. Thus, while the proportion unemployed on December 31 rose from 0.7 per cent in 1929 to 10.9 per cent in 1932, it had declined to 8.9 per cent by 1934 (table I).

The decreases in unemployment among engineers from 1932 to 1934 must not be thought to imply an increase in the proportion engaged in engineering employments. While a larger proportion[1] of the engineers were employed in 1934 than in 1932, the gain, if all professional classes are considered in combination, occurred in nonengineering work. Increases of nonengineering employment were particularly important to electrical engineers. Only in the case of mining and metallurgical engineers was there a large increase in the percentage reporting engineering employment.

The most striking fact in table I is the narrow range in the proportions of unemployment among the various professional groups for each of the 3 periods. This is especially true for 1932 with a range of from 10.1 per cent for the chemical and ceramic engineers group to 11.6 per cent for the electrical engineers.

ships occurred in 1934, although, for all but civil engineers the decrease in unemployment was marked.

There is no clear evidence in table I of a relationship between the extent of unemployment among those engineers whose college work was incomplete, or who attended noncollegiate technical schools, and those who had first degrees.

### Age

The outstanding feature of table II is that a larger proportion of the older engineers remained unemployed on December 31, 1934, than was true of those graduating from 1905 to 1932. Further inspection of table II shows very clearly that by December 1934 many of the older engineers were still unable to obtain work; and there is a very strong presumption that the preference in new hirings was given to the younger man. This is partly explicable on the grounds that, first, the older engineers probably were in a better position financially to weather the continuing depression, and second, that the available professional employment opportunities were of such a

**Table I—Per Cent of Engineers of Each Professional Class Unemployed* on December 31, 1929, 1932, and 1934, by Type of Education**

* Including those on direct relief and work relief.
† These figures are believed to be without significance.
‡ The total numbers of engineers in the various classes reporting unemployment is not shown in this article, but will become available in a statistical appendix to be included in the complete report to be published by the Bureau of Labor Statistics. While the percentage of unemployment was 1/5 less in 1934 than in 1932, the number of engineers reporting employment in 1934 was 48,124 as against 40,721 in 1932, due to the entrance of new persons into the profession. The number reporting unemployment dropped from 4,448 in 1932 to 4,288 in 1934, a decline of less than 4 per cent. Due to the overrepresentation of recent college graduates in the sample and the high percentage of unemployment among them, the total number reporting unemployment in 1934 should not be compared with the total number reporting unemployment in 1932.

### Education

The type of education the engineer had received affected the extent of unemployment (table I). Thus, in 1932 the proportion of all postgraduates who were unemployed was only 2/3 that of graduates with a first degree in engineering. Among chemical engineers and mechanical engineers, the difference in favor of the postgraduates was greatest. The smallest difference occurred among civil engineers. The same characteristic relationnature as not to be in keeping with their experience or their customary salary status.

In summary, this analysis of trends shows that: (1) there was a distinct improvement in the unemployment status of professional engineers between December 31, 1932, and December 31, 1934; (2) there were but slight differences in the incidence of unemployment among the various professional classes in 1932 and, except for civil engineers in 1934; (3) engineers who had received postgraduate degrees fared better than engineers with other types of training; and (4) as between older and younger engineers, the former not only felt the effect of the drop in business activity earlier than the latter but unquestionably were still lagging, at least until December 31,

1. It should be emphasized that increases and decreases referred to are with reference to a shifting total sample. See footnote to table I.

1934, in the return to professional activity. In general, it may be said that in this period of contraction of business activity, the inexperienced newcomer had greater difficulty in securing a professional status than any other class, that those with 5 to 25 years' experience fared best as regards unemployment, and that there was little difference (except for chemical engineers) in the percentages of unemployment at a given date between those with less than 5 years' experience and those with more than 25 years' experience.

In a period of expansion the younger and the more inexperienced engineers have a definite advantage. The normal method of recruitment at the bottom is followed. It is to be noted from table II that by December 31, 1934, the percentage of unemployment in all professional classes showed little variation between the age groups that entered the profession as late as 1932 and those with an upper limit of 53 years of age. However, there is evidence that in the 4 largest professional classes unemployment continued to be relatively high among the group of engineers who were more than 53 years of age in 1934.

## Incidence and Duration of Unemployment Among Professional Engineers, 1930–34

The preceding discussion presented unemployment data as of given dates, but gave no measure either of the number who were unemployed at other times during the 5-year period or of the length of unemployment. Light is shed on these points by the data obtained as to the period of unemployment, that is, the number of months during which the engineers were on work relief[2] or were without work of any kind. The data in this section therefore afford a measure of the gross or over-all period of displacement from regular employment, without regard to the mitigating effects of various types of relief.

More than 35 per cent of all the engineers reporting were unemployed at one time or another within these 5 years, as against about 11 per cent who were unemployed on December 31, 1932. The percentage who reported unemployment at some time during the 5 years, January 1, 1930, to December 31, 1934, with a classification by age and type of education, is shown in table III. The slightly lower incidence of unemployment for the "other" engineers is explicable on 2 grounds: (1) As a statistical "freak," arising out of slight differences in the age distribution of graduates and "other" engineers; and (2) the longer experience record of "other" engineers, for the graduate sample is especially heavily weighted by newcomers to the profession during the depression period 1930–34. For each particular age group shown in the table there is a slightly higher percentage of unemployment.

It is evident from table III that unemployment was greatest among the newcomers to the profession and decreased with the age of the engineer. In all professional groups there appeared an age beyond which there was apparently a common risk of unemployment. That age varies among the several professional classes. For civil engineers it was 43 years, whereas for electrical, and mechanical and industrial engineers it occurs after 33 years of age.

It may be noted that for the 2 youngest age groups the percentages affected by unemployment are practically the same for all 3 types of education, with roughly half the engineers who entered the profession during the depression period reporting some period of unemployment.

These findings seem definitely to extend the conclusions reached earlier as regards the influence of educational background. Table I showed less unemployment in 1932 and 1934 among those with post-graduate degrees than among those with first degrees, but there were no decisive differences between first-degree graduates and "other" engineers. It may now be stated that this was not due to the age composition of the 2 groups, for when age is considered (table III) the college graduate does appear to have an advantage.

For further consideration of the incidence of unemployment by age, the data in table III are shown for 2 distinct groups of engineers, those entering the profes-

* Including those on direct relief and work relief.

† In order to obtain a datum whereby direct comparisons could be made between engineers with and without degrees, the median age of graduation among the several professional classes was computed. This was found to be 23 years. Consequently, the data were so tabulated to permit of groupings by years of graduation and corresponding year of birth for each of the periods 1929, 1932, and 1934. In this table engineers with college degrees in the years indicated are combined with "other" engineers of the ages given in the table.

‡ The criticism has been made that the percentages of unemployment shown here relate to the indefinite group of those "53 and over." The figures would presumably be smaller if the group were closed at 62 years of age. It is quite certain from the contour of the percentages both in 1932 and 1934 that the percentage continues to rise with age. It is also certain that the high percentages shown are due to the persistence of unemployment when it occurs, rather than to a rising risk of unemployment.

2. Excluding work on P.W.A. projects and in nonrelief administrative positions in the public service.

sion during the depression years 1930–34 and the 4 older groups who had entered the profession prior to 1929. These 4 older groups had a common experience as regards the period during which they were exposed to the risk of unemployment. However, the younger engineers were exposed to a shorter period of risk, a factor of great importance when the length of their employment is considered. They were also subjected to the necessity of making their way into the profession under singularly difficult conditions. Length of exposure appears to have been a factor even as regards the general incidence of unemployment, for a slightly larger proportion of those who graduated in the period 1930–32 were unemployed during this 5-year period than was the case for those graduating in 1933–34.

For the 4 older groups, all entering the profession before 1930, the largest percentage of unemployment occurred among those who entered slightly before the beginning of the depression. There appears to have been no greater incidence of unemployment among engineers 53 years of age and over than there was among those 43 to 52 years of age. Therefore, relating this analysis to the preceding discussion of table II, it can only be concluded that the higher percentage of unemployment for the oldest age groups as of December 31, 1932, and December 31, 1934, is due not to the more frequent occurrence of unemployment but to the greater length of the period of unemployment when loss of position occurred.

These findings as regards the extent of unemployment among engineers in general are confirmed by the analysis of the separate professional classes of engineers shown in table IV.

This table does not show the percentage of unemployment among engineers with only a secondary-school education, for their number was too small to warrant classification by age. The percentage of unemployment among all such engineers was 22.6.

## Periods of Unemployment

"Gross unemployment" is used in this section to cover periods of work relief or periods without work of any kind. The figures show the median periods of unemployment.[3]

Table V shows the median periods of unemployment, by age, education, and professional classes, during the 5-year period. In connection with the age classifications shown it is important to remember the period of exposure to the possibility of unemployment.

There are significant differences in the period of unemployment as between the various age groups of engineers and as between engineers with different types of educational background. There are real differences between the several classes of engineers, but professional class had a less marked influence on the average period of unemployment than either age or educational background.

The influence of educational background appears to be persistent whether the data are classified for each of the professional classes or for all engineers combined. However, the difference of almost 5 months in the median period shown in table V as between all college graduates without regard to age and all those whose college course was incomplete exaggerates the spread. It may be that there was no spread in the case of the older engineers; the impossibility of making identical age groupings prevents any other conclusion than that, in the case of older engineers, educational background is no longer a determining factor. Comparison of the median period of unemployment in similar brackets beginning with the engineers who were approximately 30 years of age in 1934 indicates that unemployment lasted only 1 or 2 months longer in the case of those with an incomplete college record. Although in the case of the 2 youngest groups of engineers the college graduate appears to have had some advantage, there is reason to believe that the difference between an average period of $7\frac{1}{2}$ months for the graduates of the classes 1933–34 and $12\frac{1}{2}$ months for those 20 to 24 years of age with an incomplete college record is due in large part to the fact that the latter group had a longer work history and consequently a longer period of exposure. For civil engineers classified on an age basis there was also a persistently longer period of unemployment for those with an incomplete college record.

As between the 2 types of "other" engineers, the difference of 1 month in the average appears to arise from the experience only of the younger engineers. For those over 35 years of age in 1934, there was no difference. In the younger age groups the differences ranged from 1.3 months to 2.5 months, and in all cases, those with an

3. In other words, the middle point, half the engineers having had a longer period and half a shorter period of unemployment.

* Includes periods both of direct relief and work relief.
† Included with mechanical and industrial.
‡ Includes chemical and ceramic, electrical, and mining and metallurgical.
a. The high general average for electrical engineers shown in the table is due to an especially high rate among the newcomers to the profession.
It should be noted that in the case of all graduate engineers, it was necessary to make certain combinations of professional classes. Thus, a small number of ceramic engineers were combined with chemical engineers. Civil, agricultural and architectural engineers were combined, but the group was dominated by civil engineers. Mechanical and industrial engineers were combined, as were also mining and metallurgical engineers. In the case of the "other" engineers there were too few cases of noncollegiate technical-school graduates to warrant tabulation of the period of unemployment by both age and professional class; hence, only the data for those whose college course was incomplete are tabulated. This group has been divided to distinguish civil, agricultural, and architectural engineers from mechanical and all other types of engineer. Inasmuch as the unemployment experience of civil engineers differed from that of all other classes, this grouping into 2 categories makes possible general comparisons between the unemployment experience of graduate engineers and those with an incomplete college course. The percentages of these various professional classes of engineer who reported unemployment at some time during the 5-year period, 1930–34, are shown here by the age groupings heretofore shown.

incomplete college course had the shorter period of unemployment.

The average length of the period of unemployment increased with age. Whether the differential for noncollegiate technical-school graduates of these ages is real, or is due to certain peculiarities of the sample, cannot be said; but for all professional classes of engineers there was also a slight increase in the average period of unemployment among those who graduated before 1925 as compared with those who graduated later. By and large, however, those engineers who were 30 to 40 years of age and became unemployed were unemployed for 12 to 14 months, but within these limits age was not an important factor.

It is interesting to note that the engineer who entered the profession during the period 1930–32 had an average period of unemployment almost identical with th the engineers who had entered just prior to the depr This was true in spite of the fact that the younger m a shorter period of exposure to unemployment; lack of experience obviously militated against absorption.

In general, it may be said that the average pe unemployment for graduate engineers tended to i from about 1 year for those who graduated b 1925–29 to almost 2 years for those who graduate to 1905. The older engineer suffered from unemplo because of its greater length when it occurred rathe because of its greater frequency. Although the p tion of those who became unemployed over the period was only ⅔ as great for the oldest group as for the youngest group to enter the profession p 1930, when unemployment did occur it tended twice as long in the case of the older engineer.

Comparison of the severity of unemployment the professional classes is confined to those 4 age that had entered the profession prior to 1930, for av could not be shown for all age classes of chemic ceramic engineers, as the number of those over 3 of age was too small to allow of subdivision. It is ent, however, that the average period of unemplo was not more than ⅔ as long for chemical and c engineers as for the various other classes. The of unemployment of mining and metallurgical em was probably somewhat shorter in the various age fications than it was for the 3 larger professional cla

The general averages indicate comparatively difference, as regards the period of unemplo between civil engineers and electrical and mecl and industrial engineers.

Although unemployment occurred more freq among civil engineers than in any other engineering its severity was slightly less than for the other class

The median periods of unemployment cited show enough the differences among the various groups. as these average periods were, they still fall short veying the full picture. This may be gathered table VI, which shows the percentage of enginee reported varying periods of unemployment. It only engineers with college degrees received in 1 earlier years, without regard to professional class.

## Public Relief Among Professional Engineers, 1930–34

In the majority of cases engineers survived w public assistance their periods of unemployment 1930 to 1934. This was especially true of thos entered the profession prior to 1930.

The first data to be considered are with refere direct relief. Fewer than 1 per cent of the en reported themselves to have been unemployed on I ber 31, 1929. At that time there were no wor projects and none of the engineers reported ther as on direct relief.[4] Nearly 11 per cent of all en reported themselves as unemployed on Decemb

1932; 31 engineers reported themselves as on direct relief—less than 1/10 of 1 per cent of all the engineers and 1/2 of 1 per cent of the number reporting unemployment.

For the 5-year period as a whole, receipt of some direct relief was reported by 0.8 per cent of all engineers with college degrees and about 2 per cent of those who attended noncollegiate technical schools or who did not complete their college courses.[5]

Engineer's training was required in the administration of many of the projects designed to benefit other groups in the community. There was also a large increase in nonrelief forms of public employment. This was of particular benefit to civil engineers, of whom 8.5 per cent were employed by the Federal Government on December 31, 1929, and 18.6 per cent were so employed on December 31, 1934. For civil engineers the increase in this form of employment was greater than the increase in work relief.

Despite the increase in public employment, work-relief projects were the main source of assistance to those who were unemployed. On December 31, 1932, when nearly 11 per cent of the engineers were unemployed, only 0.7 per cent were on work relief. Two years later 4.0 per cent of all engineers were on work relief, which was approximately half of the total number of engineers unemployed at that time.

The reports for December 31, 1934, show striking differences in the extent of work relief as between civil engineers and other professional groups. At that time 6.6 per cent of all civil, agricultural, and architectural engineers were on work relief, as compared with only 2.3 per cent of all the other professional classes combined. The difference probably reflects chiefly the development of work programs that called especially for the civil engineer's training; it also reflects the fact that the total amount of unemployment among civil engineers in their normal fields increased from 1932 to 1934, whereas it decreased in the other professional classes. The greater amount of work relief among civil engineers balanced their more widespread unemployment. There was comparatively little difference between civil engineers and the other professional groups as regards the net amount of unemployment on December 31, 1934; those entirely without work (including work relief) formed 4.2 per cent of the civil engineers as compared with 5.3 per cent of the other types combined.

Work relief was slightly more common among engineers without college degrees than among those who were college graduates. The situation with reference to direct relief has already been noted. Among the civil engineers 6.2 per cent of the college graduates, as against 7.9 per cent of the others, were on work relief on December 31, 1934. For the 5 years as a whole, 18.4 per cent of the graduate civil, agricultural, and architectural engineers group reported a work-relief experience, whereas 19.6 per cent of this same group of professional classes with an incomplete college course so reported.

Comparison of the proportions receiving work relief at the close of 1932 and 1934 indicates that the older engineers were favored prior to 1932, while the more recent graduates were being favored in 1934. In 1932 the group graduating in the period 1930–32 had a larger proportion of its membership unemployed than any of the other age classes, but the proportion on work relief (0.6 per cent) was slightly less in December 1932 than the proportion among the older engineers (0.8 per cent of those graduating from 1915–29 and 0.7 per cent of those graduating prior to 1915). Among the civil, agricultural, and architectural engineers the difference in favor of the older groups was marked, work relief being reported for only 0.5 per cent of those graduating from 1930 to 1932 as against 1.0 per cent of those graduating from 1915 to 1929. By

| Prior to 1895 | 40+ | 19.4 | 18.3 | 22.0 | 19.2 |

* Includes periods both of direct relief and work relief.
No figure is shown in the table for engineers with a secondary-school education, for its significance is not certain. The median period for such engineers was 12.4 months.

4. In this survey, work relief is defined as emergency employment, usually made available on the basis of need, by such agencies as C.W.A., F.E.R.A., and W. P. A. It does not include engineering work on P. W. A. projects, which should have been reported either as a form of private employment or as Government employment for those engineers working in the Public Works Administration itself. It also does not include engineers hired for strictly administrative work by the various relief administrations. There was some overreporting of work relief and a corresponding underreporting of public employment. Direct relief refers to direct financial or other assistance from any public authority.

5. In New York City, direct relief appears to have been more extensive through the Professional Engineers Committee on Unemployment than through public agencies.

December 31, 1934, this situation had been reversed and there was a larger proportion on work relief among the recent college graduates than among those who had entered the profession prior to the depression. This was especially true of the civil engineers, for whom work relief on December 31, 1934, was reported for 9.4 per cent of those graduating in 1933–34 and 8.3 per cent of those graduating in 1930–32, in comparison with only 6.5 per cent of those graduating in 1915–29 and 4.9 per cent of those graduating prior to 1915. In the other professional groups no real differences between the early and late graduating classes appears. Of the engineers in professions other than the civil-engineering group, who graduated during the years 1930–32, 2.2 per cent were on work relief, but 3.2 per cent of those graduating in 1933–34 reported work relief. In this connection it must be recalled that in 1934 there was a larger proportion of unemployed among those graduating in 1933–34 than among the other age groups.

Thus far, in this section, the discussion of work relief has been confined to the reports for specific dates. For the 5-year period as a whole, a larger number of engineers had some experience with work relief. For all types of engineer, irrespective of background, about 1/8 reported some period of work relief, but very wide differences were shown in the extent of work relief for civil engineers and for other types of engineers. Thus, among engineers with an incomplete college course, 19.6 per cent of the civil-engineer group reported some work relief, whereas classified by year of graduation in the 3 professional groups of civil, electrical, and mechanical engineering.

The differences in the length of the period between the various professional classes are small and show no particular regularity. Essentially, the periods are the same both for civil engineers and for mechanical engineers, though the average period was perhaps somewhat shorter in the case of electrical engineers. Little difference is shown between those who graduated from 1915–29 and those who graduated prior to 1915, but apparently those who graduated prior to 1930 had a slightly longer period of work relief than those who graduated in 1930–32.[6]

Thus far in this discussion, those reporting work relief have been regarded as unemployed. More than 4/5 of those who reported a period of work relief also reported a period of unemployment. However, among the 5,349 engineers with college degrees who reported a period of work relief, 966 reported a period of work relief but no period of unemployment. This situation calls for some explanation though it does not change the general outline of the conclusions reached. There seems to be a slight overreporting of work relief and, therefore, a slight overestimate of unemployment due to the method of adding together periods of unemployment without work of any kind and periods of work relief to determine the gross frequency and period of unemployment. There is also a corresponding underreporting of nonrelief public employment. In this discussion, it is necessary to distinguish 3 age groups, those graduating in 1929 or earlier,

**Table VI—Percentage Distribution of Engineers Graduating From College Prior to 1930, by Period of Unemployment**

| Year of Graduation | Total Reporting in Survey | Total Reporting Unemployment at Any Time During 1930–34 | | Per Cent Whose Reported Unemployment (in Months) Was— | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Number | Per Cent | Under 6 | 6 and under 12 | 12 and under 18 | 18 and under 24 | 24 and under 30 | 30 and under 36 | 36 and under 42 | 42 and under 48 | 48 and over |
| All years prior to 1930 | 24,853 | 6,965 | 100.0 | 21.0 | 21.6 | 16.5 | 12.8 | 9.5 | 7.1 | 5.1 | 3.2 | 3.2 |
| 1925–29 | 6,499 | 2,340 | 100.0 | 23.9 | 25.7 | 19.4 | 13.4 | 7.9 | 4.0 | 3.2 | 1.6 | 0.9 |
| 1915–24 | 8,298 | 2,245 | 100.0 | 23.3 | 22.9 | 16.1 | 11.4 | 9.4 | 7.3 | 4.4 | 3.0 | 2.2 |
| 1905–14 | 6,602 | 1,570 | 100.0 | 17.7 | 18.8 | 14.0 | 13.8 | 11.4 | 8.7 | 7.2 | 3.7 | 4.7 |
| Prior to 1905 | 3,454 | 810 | 100.0 | 12.8 | 11.7 | 14.4 | 13.1 | 10.6 | 12.0 | 8.3 | 7.0 | 10.1 |

only 7.5 per cent of those in the other professions considered together so reported. Among college graduates work relief was reported by 18.3 per cent of the civil engineers and only 10.9 per cent of the mining and metallurgical engineers. For the other professional classes, the percentages were 9.3 for electrical engineers, 8.7 for mechanical and industrial engineers, and 6.6 for chemical and ceramic engineers.

In all professional classes, age was an important factor in the frequency of work relief. Table VII gives for the 3 professional classes civil, electrical, and mechanical engineers, the percentages of those receiving work relief, at any time during the 5 years, 1930–34, classified by age. The figures relate only to college graduates.

The median period of work relief was approximately 5 months, as shown in table VII for college graduates those graduating in 1930–32, and those graduating in 1933–34. Among the more recent graduates little difference is found between civil engineers and all other types of engineers, as regards work relief without unemployment. Of the 1,138 engineers graduating from college in 1933–34 and reporting some work relief, 333 reported no period of unemployment, that is, approximately a third of them appear to have entered directly into work relief. Among those graduating in 1930–32, 281 out of 1,747, or somewhat more than 1/6, reported such an

6. If it is correct to conclude that the major part of the work-relief experience came in the years 1933–34, the differences between the classes graduating in 1930–32 and those graduating earlier are not to be explained in terms of a longer period of eligibility for work relief. It may be pointed out that a shorter period in the case of the classes of 1930–32 is consistent with the earlier conclusion that recruitment was more extensive among this group of engineers than among the older ones. The still shorter period, which is indicated for those who graduated in 1933–34, may well be explained by the fact that they had a shorter period of eligibility for work relief.

experience. This may merely reflect a need for young engineers to staff minor supervisory positions on projects conceived to meet the needs of other groups.

In the case of those civil engineers who graduated in 1929 or earlier years, 242 of the 1,476 who reported work relief did not report a period of unemployment. There are too few cases in the other professional classes to warrant a breakdown, but among all engineers other than civil engineers graduating in 1929 or earlier, 110 out of 988 reported no period of unemployment. Two factors lead to the belief that some of those reporting a period of work relief but no period of unemployment should be separated from the unemployed: (1) It may be noted that this situation was commoner among civil engineers than among the other professional classes, undoubtedly because the training of civil engineers was more extensively required on work-relief projects than was the training of other types of engineer. (2) It seems probable that there was some misunderstanding by engineers replying to the questionnaire and that a few reported

**Table VII—Per Cent of Graduate Engineers, by Year of Graduation and Professional Class, Reporting Work Relief at Any Time, 1930–34, and Median Period of Work Relief**

| Year of Graduation | Per Cent Reporting Work Relief | | | Median Period (in Months) of Work Relief | | |
|---|---|---|---|---|---|---|
| | Civil | Electrical | Mechanical | Civil | Electrical | Mechanical |
| All years | 18.3 | 9.3 | 8.7 | 5.0 | 4.4 | 4.9 |
| 1933–34 | 26.4 | 12.5 | 10.2 | 4.1 | 3.8 | 4.1 |
| 1930–32 | 25.2 | 12.8 | 10.4 | 4.8 | 4.3 | 4.5 |
| 1915–29 | 15.9 | 6.2 | 7.4 | 5.6 | 4.6 | 5.7 |
| Prior to 1915 | 12.4 | 6.3 | 7.6 | 5.5 | 6.5 | 5.6 |

The civil engineers here tabulated do not include architectural and agricultural engineers, nor do the mechanical engineers include industrial.

public administrative employment in connection with work-relief projects as work relief rather than as public employment. It is possible that certain engineers reporting a period of work relief neglected to report a period of unemployment or merged the 2 figures in a single one of a period of work relief.

In general, a period of work relief was associated with a reported period of unemployment. This was true of more than 85 per cent of the engineers, without regard to professional classification, graduated in 1929 or earlier years, who secured work relief. For this group of college graduates, there is a clear relationship between the period of unemployment and entrance into work relief.[7] The percentages in table VIII represent the ratio of the total number of individuals receiving work relief after a given period of unemployment to the total number of unemployed persons who had at least as much as the shortest period of unemployment indicated. Thus, for example, 6 per cent of all civil engineers who reported any period of unemployment whatsoever were placed on work-relief projects after a period of less than 6 months of unemployment, etc.

During the 5-year period, placement on work-relief

**Table VIII—Per Cent of Unemployed Graduate Engineers on Work Relief After Specified Unemployment, 1930–34, by Years of Graduation**

| Year of Graduation | Per Cent of Engineers Who Received Work Relief After Specified Months of Unemployment | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | Less than 6 | 6–12 | 12–18 | 18–24 | 24–30 | 30–36 | 36–42 | 42–48 |
| All classes of engineers | 4.3 | 9.3 | 12.6 | 13.7 | 14.9 | 18.4 | 18.0 | 18.8 |
| Civil engineers | 6.0 | 11.9 | 15.7 | 17.9 | 18.1 | 22.1 | 21.2 | 24.6 |
| 1925–29 | 6.3 | 13.8 | 17.4 | 25.8 | 25.2 | 26.0 | 33.0 | 63.0 |
| 1915–24 | 7.2 | 13.5 | 19.5 | 20.9 | 19.8 | 36.0 | 28.0 | 27.0 |
| 1905–14 | 5.9 | 11.0 | 14.4 | 16.6 | 19.0 | 15.6 | 22.0 | 23.0 |
| Prior to 1905 | 1.8 | 6.4 | 9.0 | 8.5 | 10.6 | 16.8 | 13.0 | 18.0 |
| Other professional classes | 2.8 | 7.0 | 9.9 | 10.2 | 12.5 | 15.5 | 15.5 | 14.1 |
| 1925–29 | 2.5 | 7.4 | 10.6 | 11.2 | 13.5 | 19.6 | 20.0 | 20.0 |
| 1915–24 | 3.7 | 7.5 | 12.4 | 12.7 | 11.8 | 19.3 | 20.0 | 8.0 |
| 1905–14 | 2.8 | 7.1 | 8.5 | 9.1 | 15.2 | 14.0 | 10.0 | 19.0 |
| Prior to 1905 | 0.8 | 4.5 | 5.4 | 5.9 | 8.4 | 9.7 | 14.0 | 12.0 |

projects rose steadily as the period of unemployment was lengthened. This increase reflects the actual course of events in these 5 years, but the period was not homogeneous as regards the availability of work relief, which was first inaugurated on a large scale in 1933. Any person unemployed for as little as 6 months in 1931 had virtually no opportunity to secure work relief. On the other hand, a person who became unemployed in July 1931 probably would have found C.W.A. work, after the lapse of 30 months. Therefore, in interpreting the figures shown in table VIII, it must be remembered that longer periods of unemployment increase the probability of work relief merely by carrying over into a period in which work relief became available.

A further and more significant comparison may be made with reference to the availability of work relief to the members of the different groups of graduating classes. For this purpose, these classes should be interpreted as indicating not particularly differences between younger and older engineers, but more especially probable differences in the financial resources of the different groups. In the aggregate, those engineers who graduated prior to 1905 probably had substantially larger financial reserves than those who graduated from 1925 to 1929. In the case of civil engineers, the percentage on work relief was highest for those who graduated from 1925 to 1929. Among the other professional groups, this relationship was less well maintained, although there appeared to be a distinct demarcation between those who graduated prior to and after 1915. The strongest contrast was between those who graduated in the period 1925–29 and those who graduated prior to 1905.

7. For the correlation of the period of unemployment that antedates relief, the following information is available: The total period of unemployment, exclusive of work relief, and the total period of work relief. In order to simplify the presentation, the material is presented as though there were in all cases a sequence of an unbroken period of unemployment followed in certain instances by work relief. It is quite possible that in certain instances the total period of work relief is broken into several stretches interspersed with periods of work relief. In such a case, it would be incorrect to say that work relief followed after 12 months of unemployment if 12 months were the total reported period of unemployment exclusive of work relief. To distinguish several periods of unemployment would have required a greater refinement than it was possible to undertake by the questionnaire method. The extent of the error, which is implied in this assumption, is probably not great, but technically all that can be shown is a relationship between a certain aggregate period of unemployment, exclusive of work relief, and the existence of some period of work relief which may have preceded a period of unemployment or have broken into a period of unemployment.

# Switchboards for Boulder Power Plant

By L. N. McCLELLAN

**Switchboards for the power plant at Boulder Dam are unusual not alone for their size, but also for the combination in one plant of switchboard designs and methods that have been used individually but seldom together. The plan of the power plant and the switchboards and control equipment are described in this paper.**

THE Boulder Power Plant is unusual in many respects, and these unusual features are reflected in the switchboards. Mere "bigness" would not make the switchboards unusual, but other features resulting indirectly from such bigness introduce requirements in the switchboard design which are not commonly encountered. Among the well-known features of this plant are:

Generating units of 3,000, 40,000, and 82,000 kva

Transformer banks up to 165,000 kva and 287.5 kv

Ultimate capacity of 17 major generating units totaling approximately 1,300,000 kva

Among the lesser known or recognized features are:

The generators are disposed along the opposite sides of the river so that the power plant is in effect approximately 1,600 feet long, with the control room in the center. The farthest generator is approximately 700 feet from the control room.

The 287.5-kv substation or switch yard for the City of Los Angeles is approximately 1,500 feet from the control room.

The complete plant will involve 4 major systems, with transmission voltages from 132 kv up to 287.5 kv.

The Boulder Power Plant really represents several large generating stations, tying in with separate outside systems. The individual requirements of these systems must be taken care of with an over-all uniformity in operating practice and switchboard design. Standard, conventional switchboard design has been followed wherever possible. Nevertheless the very features previously mentioned necessitate the combination in one plant of switchboard designs and methods which have been used individually, but seldom together in the same plant.

The initial installation comprises 4 82,500-kva units for the City of Los Angeles, and 1 40,000-kva unit for the Southern Sierras Power Company. The plan adopted for these units will apply in general to the succeeding units. The general plan is to provide a separate switchboard or cubicle near each generator for manual control. There is also a centralized main control desk from which all the generators, transformers, and their related apparatus may be controlled automatically and remotely.

In brief, the City of Los Angeles system involves connecting 2 generators in parallel to a transformer bank, through suitable low-voltage circuit breakers. The transformers are located directly outside the generator room, and the low-voltage circuit breakers are located in suitable switch rooms, directly outside the main building, and as close to the respective generators and transformers as is possible. The high-voltage side of the transformer bank connects to a double-bus outdoor substation, from which are taken the Los Angeles lines. Each generator has 2 breakers in parallel so as to permit maintenance without interruption of service. Provisions are made for connecting a spare generator to a transfer bus, and energizing a transformer therefrom, in order to replace any generator that may be out of service.

## Generator Control Cubicles

The control system is arranged so that the generators may be operated from 2 locations, either the control room or the generator floor. Each generator control cubicle is located in a recess in the river wall of the power plant. It is provided with all the manual control and instrumentation usually associated with a water-wheel generator of like capacity such as circuit breaker, field, and governor controls. At this point the generator can be completely started even to synchronizing and connecting to the bus, controlled, and shut down. This permits and facilitates initial operation, testing, and maintenance, and provides emergency operation in case the main control desks should be out of service. Control is not provided for the high-voltage circuit breakers and disconnecting switches, but suitable signals indicate their connections. The voltage regulator, generator protective relays, and various graphic instruments are also located on this board.

This cubicle also serves as the transfer point for the control circuits coming from the main desk. Therefore, the interposing relays, interposing current transformers, automatic starting relays, and thermal converters for load control and totalizing are located here. A control-transfer switch determines whether the unit can be controlled locally or from the main control desk and thus prevents conflicting, contradictory, or incomplete control. This switch is provided with a cylinder lock to prevent unauthorized operation.

## Main Control Room

The contracts for power privileges established 2

A paper recommended for publication by the AIEE committee on power generation. Manuscript submitted July 11, 1936; released for publication October 16, 1936; revised to January 18, 1937.

L. N. McCLELLAN is chief electrical engineer of the United States Bureau of Reclamation, Denver, Colo.; A. J. A. PETERSON is switchboard engineer in the switchboard engineering department of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.; and C. P. GARMAN is assistant engineer of design, Bureau of Power and Light, City of Los Angeles, Calif.

principal lessees, the City of Los Angeles and the Southern California Edison Company, as the generating agents for generation of all power at Boulder Dam. The City of Los Angeles generates power for itself, the Metropolitan Water District, the cities of Pasadena, Glendale, and Burbank, and the states of Arizona and Nevada. The Southern California Edison Company generates power for itself, and the Southern Sierras Power Company. The main control room is divided into 2 sections to provide for separate operation by the 2 lessees. These rooms are located in the central portion of the power plant at an elevation approximately 70 feet above generator floor level. In the control room for the City of Los Angeles, the main control desk and the station service desk face each other from opposite sides of the room. The auxiliary control room boards are located on the other 2 sides of the room. The operator's desk, supervisory control benches, etc., are located in the center of the room, between the control desks. The equivalent equipment for the Southern Sierras Power Company is located in the adjoining room with provision for future equipment for the Southern California Edison Company.

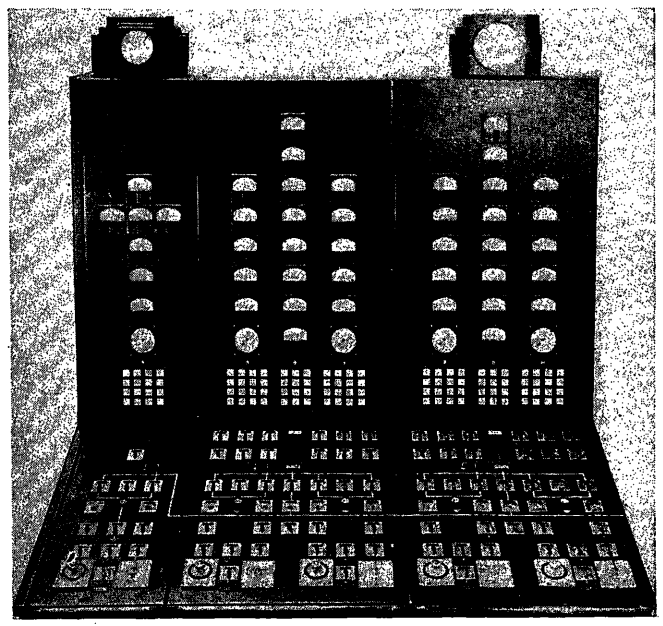

**Fig. 2. Main control desk, showing 3 panels with the control for 5 generators (one future) and 2 transformer banks**

## Main Control Desk

The main control desk centralizes the control of all the main generators, the power transformer banks, and the outgoing feeders. The desk for the City of Los Angeles comprises initially 3 fully equipped sections for the control of 5 generators, 2 transformer banks, and 2 outgoing lines. The initial desk for the Southern Sierras Power Company comprises a single section, mounted separately, for the control of 2 generators with their respective transformers and transmission lines. On account of the large number of units to be controlled, the desks are of the so-called "miniature" type, using Westinghouse type *K* indicating instruments 4 inches wide with scales $3^1/_2$ inches long, and control switches of the Minatrol type. With complete control and instrumentation including lamp indicators, miniature bus, governor controls, etc., the length of the Los Angeles section for the initial equipment of 5 generators, 2 transformers, and 2 lines is only 6 feet.

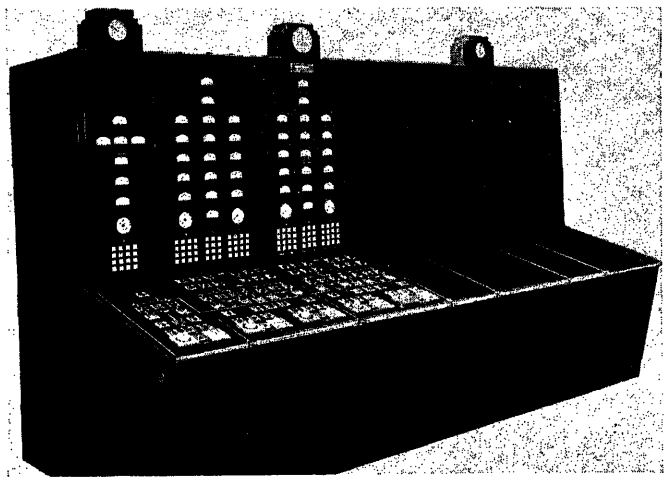

**Fig. 1. Complete main control desk**

Starting from the main control desk is almost completely automatic. The operator selects the breaker with which he plans to connect the generator to the bus, inserts the key for one of the 2 automatic synchronizers, and turns the master control switch to "start." Auxiliaries such as the bearing oil pressure pump, cooling water pump, etc., start automatically and when these are in operation, the turbine gates open. The generator then comes up to full speed, taking full voltage excitation, matches speed with the system and synchronizes, resulting finally in closing the preselected breaker. A synchronizer by-pass button is provided for manual synchronizing when the bus is dead or when the automatic synchronizer is out of service. This performance is carried out through a full complement of preventive interlocks and relays and continuous operation is safeguarded by means of protective relays operating as functions of electrical conditions in the main circuits, temperature, or in failures of the auxiliary devices. With one circuit breaker closed, the parallel breaker can be closed by the operator directly and immediately.

The high-voltage transformer or line circuit breakers can be handled manually, either after the generator has been put on the bus, or preset so that line connection is made on the low-voltage side automatically.

Once on the line, the operator can control the load, voltage, or regulated voltage level, etc., as in a conventional power plant. Shutdown can be made by the operator, or result from the operation of the protective relays. Most of the automatic and pro-

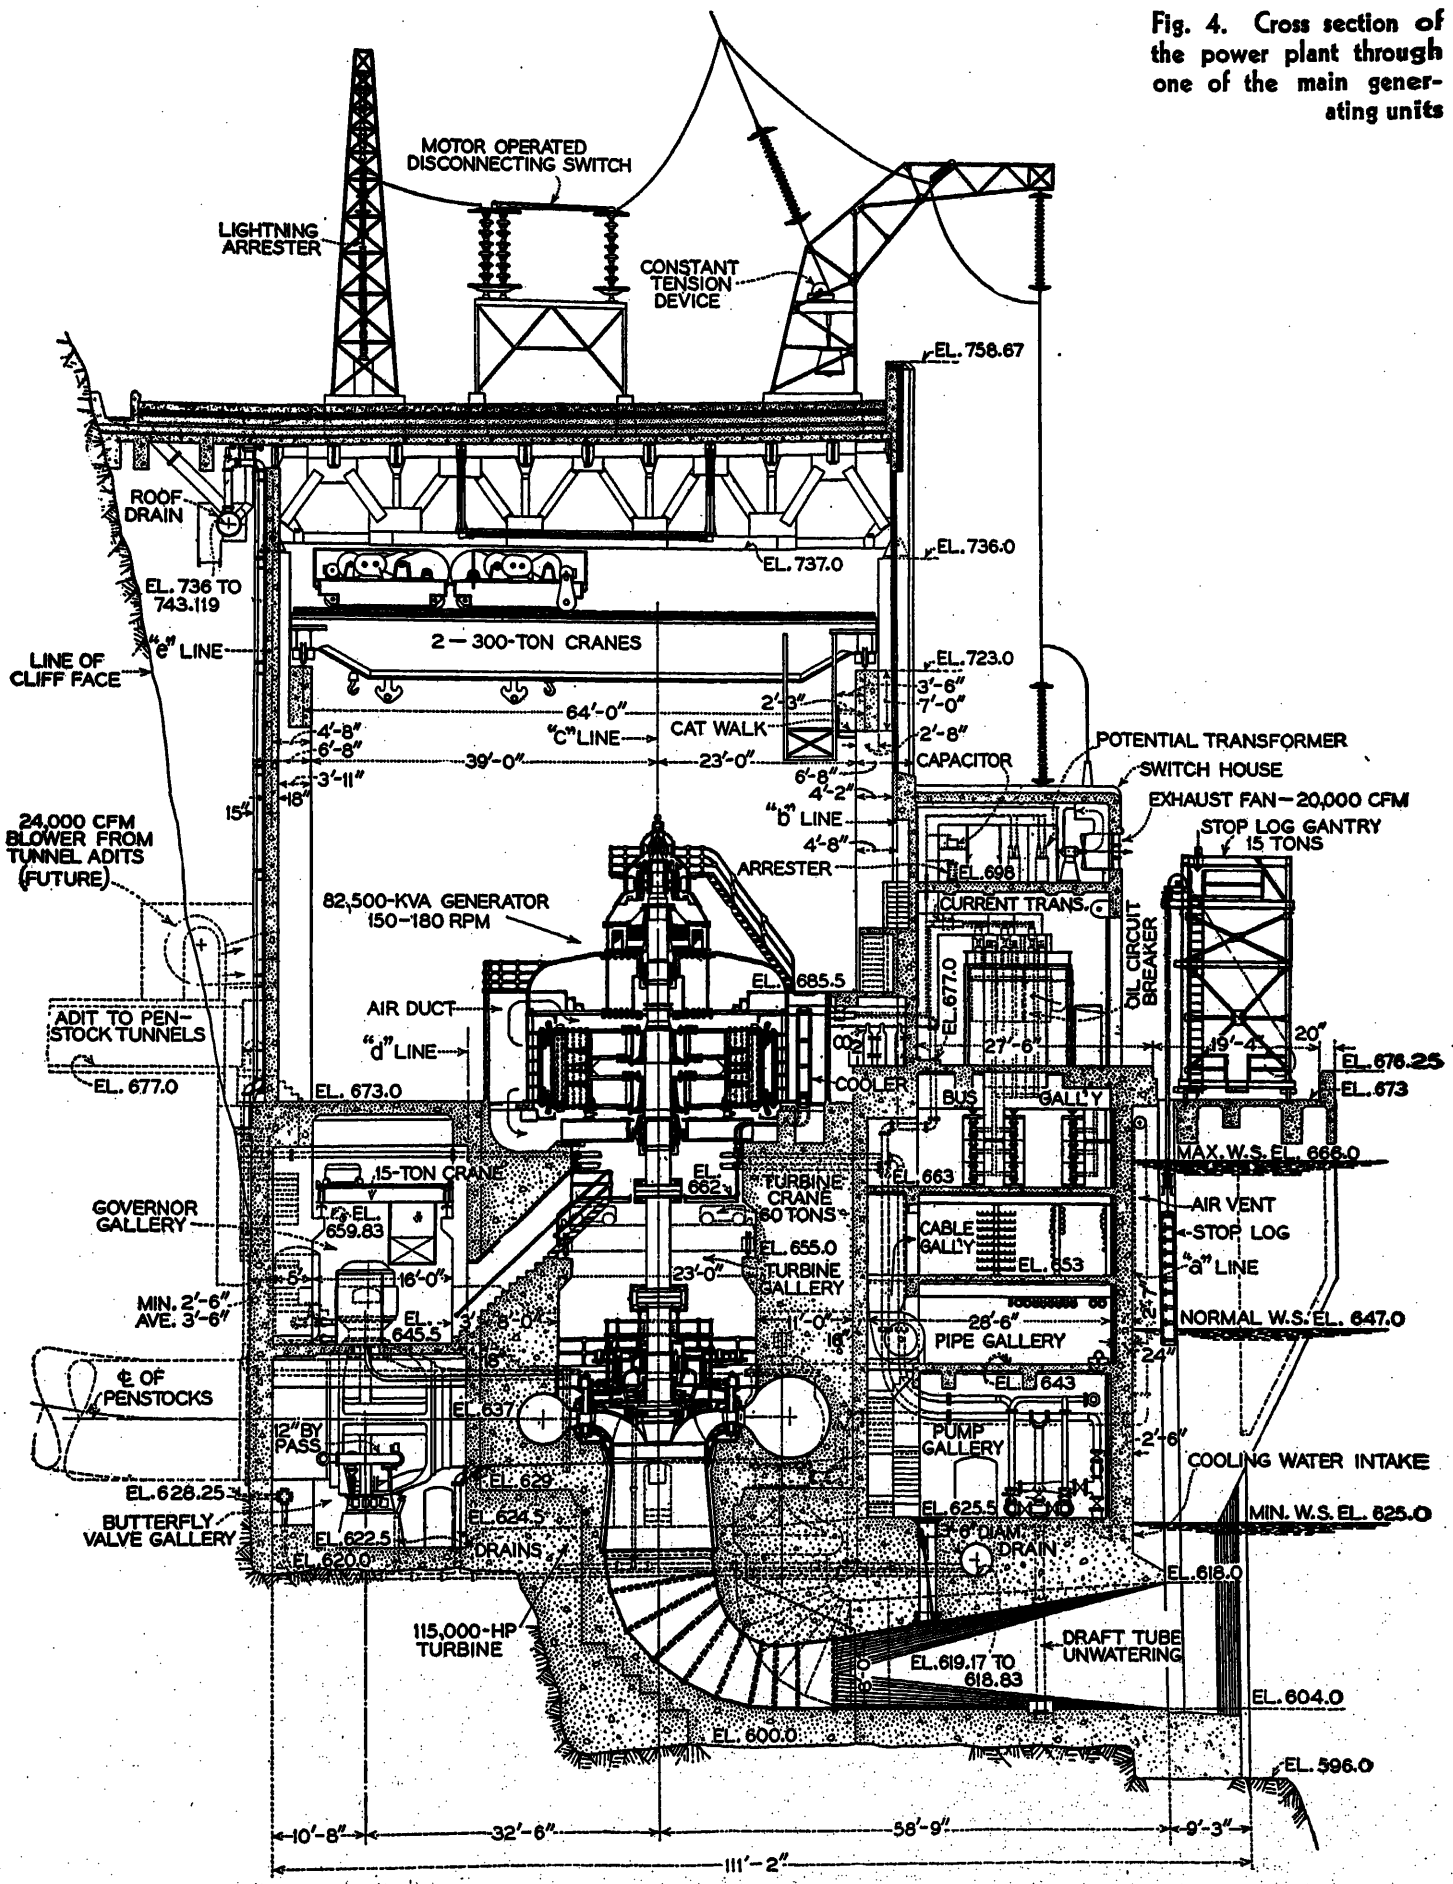

Fig. 4. Cross section of the power plant through one of the main generating units

tective features found only in an unattended station have been incorporated in this control in order to relieve the operator as far as possible from routine duty.

The control desk is constructed of "stretcher leveled" (smoothly finished) steel, with the back fully enclosed and provided with swinging doors. The front lower face is inclined toward the rear so as to facilitate approach to the desk and manipulation of the various controls thereon. Another unusual feature of this desk design is the arching of all internal cross members and corresponding placement of control conductors, so that an inspector can walk along the top of the terminal boards on the lower floor, and readily observe or adjust the apparatus and wiring on the under-inner side of the desk.

## Station Service Control Desk

The station service control desk is similar in construction and equipment to the main control desk. The 3 central sections are of full height, and are for the control of the 2 3,000-kva station service generators and the station service transformer bank. These sections are provided with complete instrumentation and control comparable to that provided for the main generators. Automatic starting, speed matching, and synchronizing are provided for these generators as is the case with the larger generators.

The control desk sections extending from each side of the center are of lower height, because of the relatively fewer instruments required thereon. These sections are for the control of the storage batteries and their charging generators, 2,300-volt feeders to various sections of the plant and to the 460-volt auxiliary transformers for station service. The outside sections, toward the Arizona and Nevada sides respectively, are provided with illuminated signals to indicate normal or abnormal conditions with respect to the various auxiliary services such as control supplies, cooling-water indications, bearing-oil indications, etc.

All controls from the main desk are at 125 volts direct current. These controls operate interposing relays located at their respective generator cubicles, or at the outdoor substation, translating to the heavier currents required for the various devices such as governor controls, and also to the 250-volt d-c control for the circuit breakers and similar apparatus.

For the various indicating and graphic instruments, potential is brought from the generator cubicles at full value of 110 volts. For the current instruments and similar devices, the normal 5-ampere secondary current is stepped down to 0.1 ampere by current transformers located at the generator cubicles or at the switch yard. By this means, the long control and instrument cables from the control desk to the generator cubicles or the switch yard are kept to a reasonable size, and excessive current-transformer burdens are avoided.

## Auxiliary Control Board

There are 2 auxiliary control boards each consisting of a double line of vertical panels, arranged back-to-back with a passageway between. These panels are equipped with the master automatic equipment used for the entire plant, that is, speed matchers and

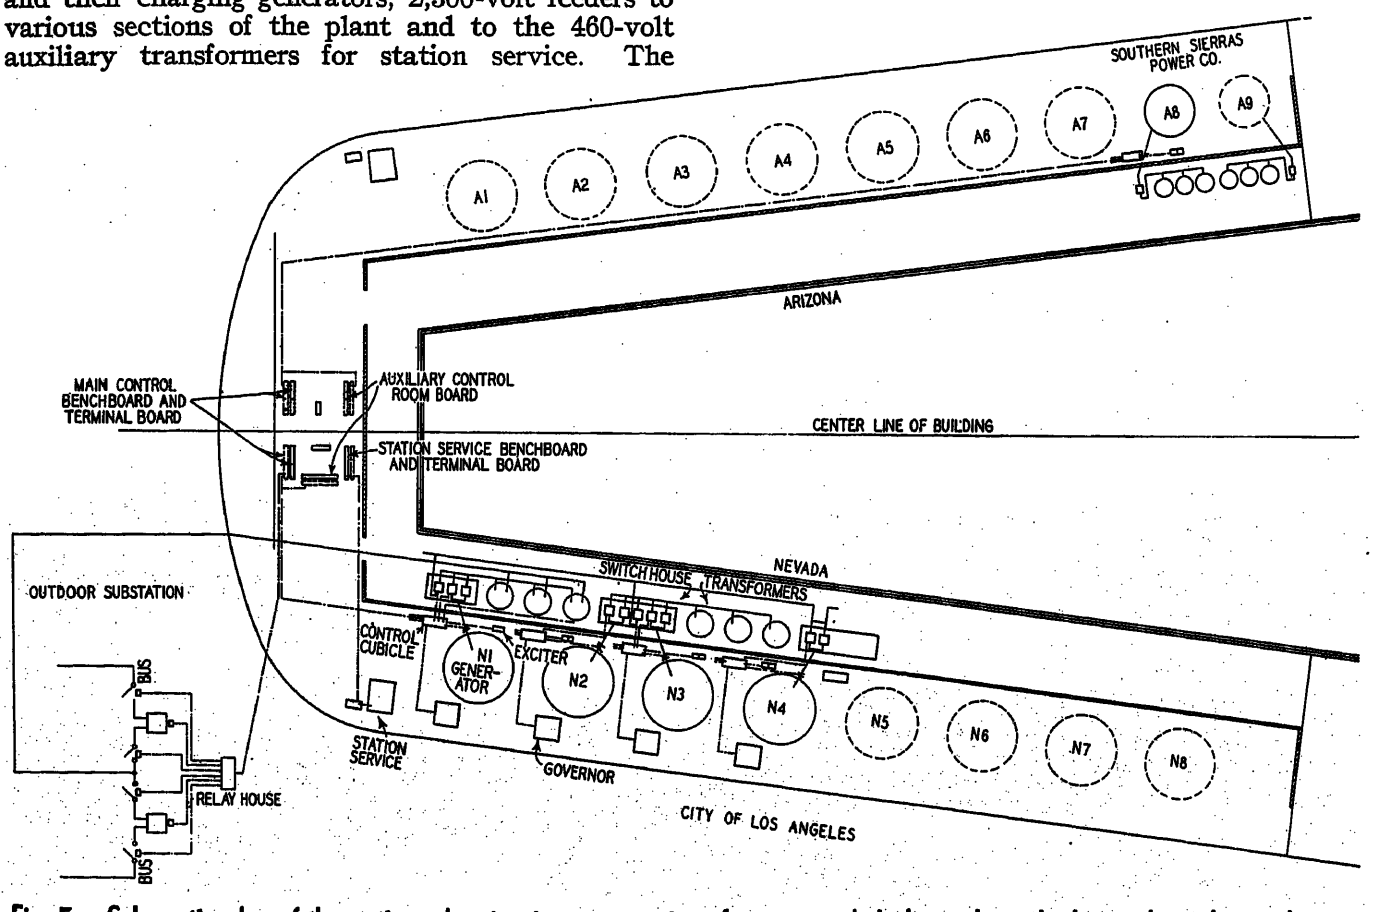

**Fig. 5. Schematic plan of the station, showing interconnections from control desk to the cubicles and outdoor substation**

synchronizers and frequency and load controls; with recording instruments for generator-armature and field-winding temperatures, bearing temperatures, and transformer temperatures; with frequency, totalizing, watt, and reactive kilovolt-ampere recording instruments; and with voltmeters for automatic recording of high voltage during faults.

## Terminal Boards

The control and instrument cables from the various cubicles, switch yard, station service switchgear, and station auxiliary switchgear are brought to terminal boards in a room below the main control room and located directly beneath the control desks or auxiliary boards which they serve. Vertical cables connect directly from the terminal blocks in the terminal boards to the terminal blocks in the switchboards above.

The terminal boards for the control desks are actually double units, mounted back-to-back, and running lengthwise under their respective desks, with a passageway between. Terminal blocks and test switches are mounted on one side, and small circuit breakers for the complete segregation of the 125-volt control circuit in the desks are mounted on the other side. The terminal boards for the auxiliary boards are similar, except that test switches and circuit breakers for control segregation are omitted.

## Control Supply

The control supply for the desks is provided by a 60-cell 125-volt storage battery, with suitable motor-generator charging equipment. The various circuits to the switchboard desk section are supplied through individual circuit breakers. Not only is the supply segregated for each main unit, but also for each distinct part of the unit. The completeness of this segregation may be indicated by the fact that 38 2-pole circuit breakers are required for the control circuits of one desk section controlling 2

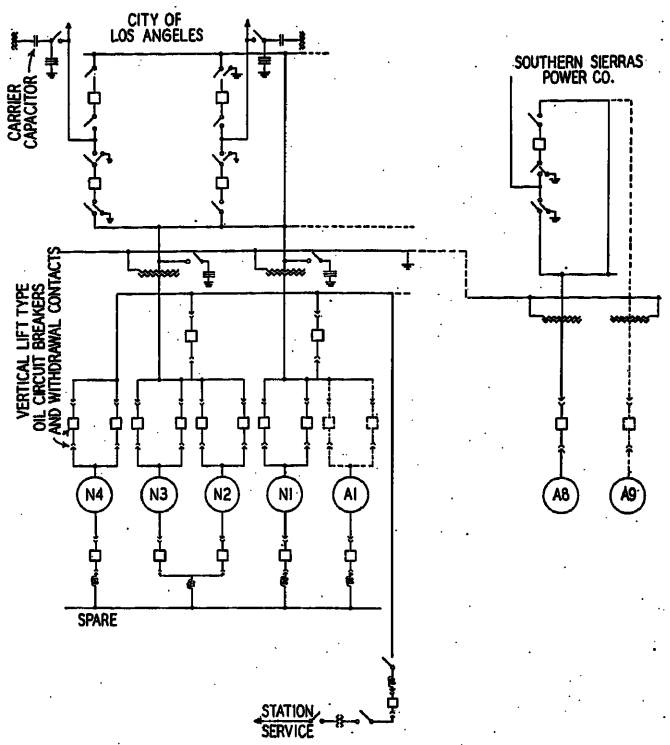

**Fig. 6. Simplified single-line diagram of present equipment**

generators and one transformer. This segregation permits of complete isolation automatically in case of a fault and manually for maintenance purposes. While these circuits are only 125 volts direct current their importance and the possibilities of high short-circuit currents led to the choice of Westinghouse type *AB* automatic thermal-trip circuit breakers of 250-volt d-c rating and 10,000-ampere rupturing capacity.

Oil circuit breakers and similar apparatus are operated from 120-cell 250-volt batteries, one for each wing of the power plant, and for the switch yard. These control circuits are similarly segregated, not

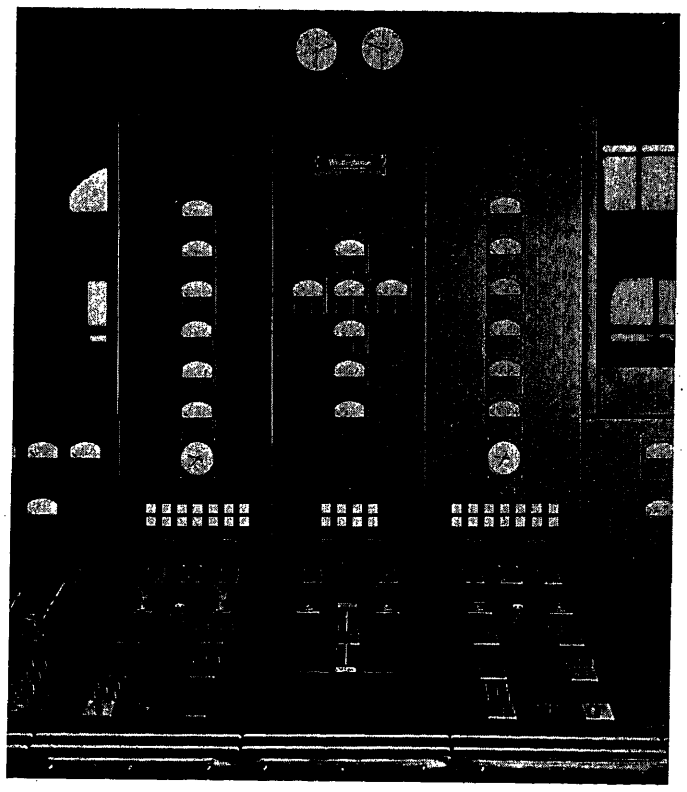

Fig. 9. Section of station service control desk

only for the individual generator or transformer units but also for the parts of the complete unit controlled. A combination of circuits is permitted only where multiple operation is required, as for the tripping of several circuit breakers from the operation of a single set of protective relays. Circuits from the 2 250-volt batteries are carried completely around the plant, so that control supply to the circuit breakers and other apparatus is always available.

Obviously, the control desk is of little value if either of the batteries is out of commission, so the usual circuit-breaker lamp indicators are connected so that a failure of either the 125-volt or the 250-volt storage battery source will put out the lights.

## High-Speed Differential Protection

High-speed clearance of internal transformer and generator faults is planned in order to maintain stability at the highest possible level and to limit the damaging effect of internal fault currents. Accordingly, the high-voltage oil circuit breakers on the 287-kv transformer bank will clear the fault in 3 cycles, and low-voltage breakers for the generators and the transfer bus will clear in 8 cycles. The differential relays for both the transformers and the generators will operate in approximately one cycle under fault conditions. These relays are of the balanced-beam type with low burden characteristics. The transformer relays are provided with self-contained voltage and timing interlocks so as to avoid operation and false tripping on the magnetizing-current rushes, either when the transformer banks are energized or as a result of recovery voltages following the clearance of an external fault, without introducing any delay in the event of a fault within the differential area.

The transformer differential relays will trip out all the circuit breakers feeding the transformer on both the high-voltage and low-voltage sides. The generator differential relays will trip not only the generator circuit breakers, but also the neutral and field breakers, shut down the water wheel, and release carbon dioxide into the generator housing. The low-voltage current transformers are located to provide overlapping protection zones, leaving no section unprotected.

Differential relay operation in one cycle introduces hazards of false tripping resulting from faults external to the protected zone. The balancing of dissimilar current transformers, unequal loading of transformers in parallel or divided power circuits, high ratio of fault to normal current, or slowly decaying d-c component of the external fault current may separately or jointly effect a saturation of the various current transformers, and thus unbalance the secondary currents to cause relay operation when no such operation should occur. The importance of these factors is evident when it is considered that the relays must determine whether the fault is within or beyond the transformer or generator and then operate in one cycle for an internal fault.

If the current transformers for the high-voltage side of the transformer are located in the circuit

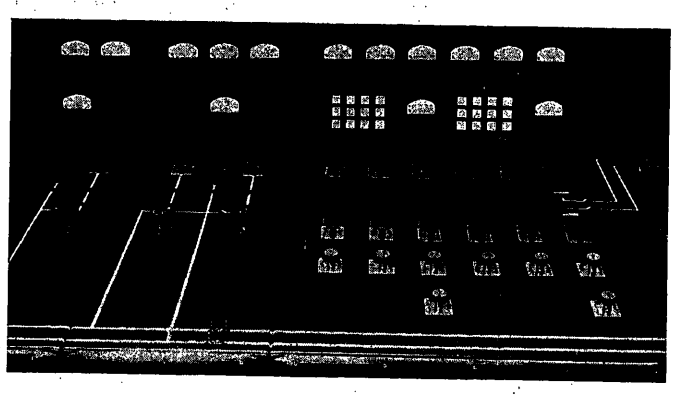

Fig. 10. Section of station service control desk

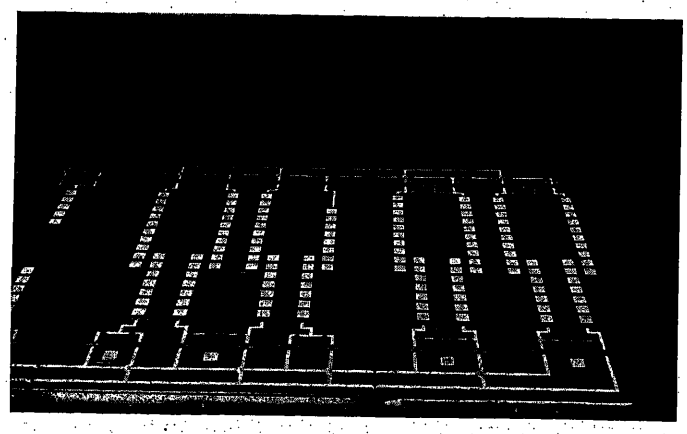

Fig. 11. Section of station service control desk

breakers of the double bus system, the current flowing in any given current transformer may be considerably larger or smaller than the current flowing through the transformer bank being protected because of current passing from one bus to the other. The restraint in the differential relay is very closely proportioned to the current flowing through the transformer bank, but the current tending to produce saturation in any given current transformer may be larger than this by the current flowing from one bus to the other through the transformer breakers. This would result in the current tending to produce saturation being much larger than the current to prevent the relay from operating.

The result of the d-c component of the short-circuit current and its low rate of change is to require a large total flux in the current transformer to transform this component from the primary to the secondary. If the flux required exceeds the saturation point for the current transformer, the latter will saturate during part of the short circuit, which in turn will cause the transformer to draw an excessive exciting current both for the d-c component

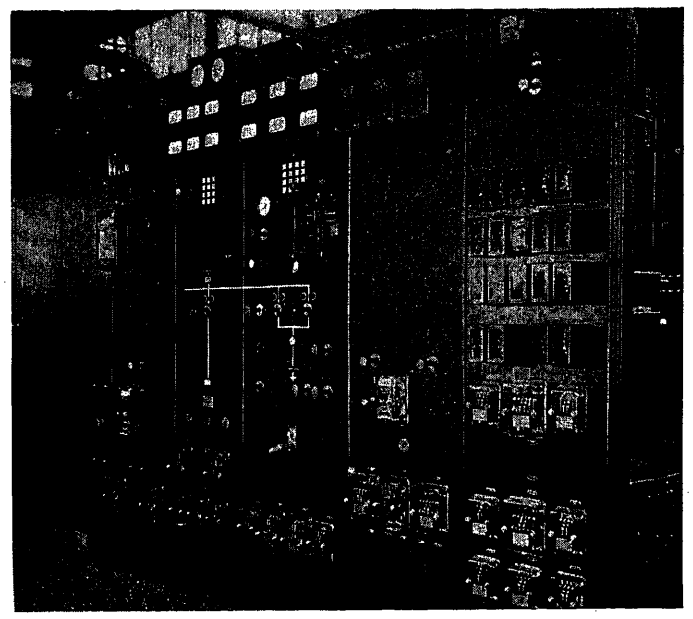

Fig. 13. Front view of cubicle of generator N–3

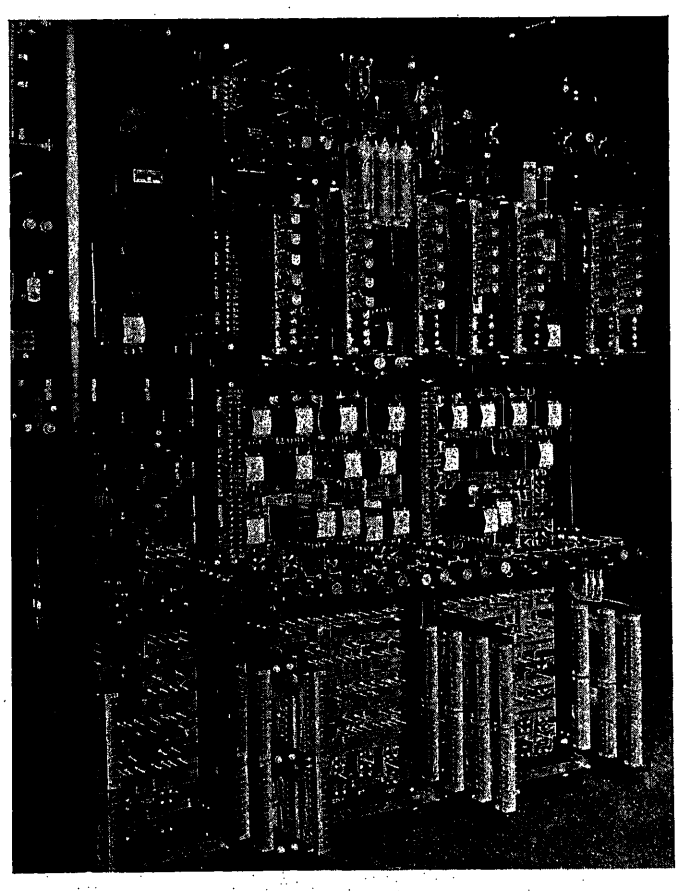

Fig. 12. Rear view of station service control desk

and for the a-c component being transformed at the same time. This results in a departure from ratio which can be very large in the most severe cases. Unless all the current transformers involved in the differential protection are affected in the same way and to proportionately the same extent, departure from ratio of one or more of the current transformers will result in current through the differential relay with some hazard of incorrect operation.

Referring particularly to the transformer protection, it is recognized that fully asymmetrical short circuits occur only infrequently, particularly on high-voltage faults, and likewise the worst short circuits occur only at rare intervals, and therefore the conditions which contribute to improper operation may be expected only at long intervals. However, the use of highly sensitive relays, and the presence of a slowly decaying d-c component emphasize the possibilities of such improper operation. Considering the relative importance to the City of Los Angeles of Boulder Dam power, it was desirable to eliminate this hazard as far as practically possible.

A complete theoretical analysis of the entire subject, supplemented by numerous oscillographic test data, indicated that the most practical solution would be obtained by 3 distinct steps. In the first place, the amount of iron in both the high-voltage and low-voltage current transformers was increased several times beyond normal. In the second place, the amount of copper in the current-transformer secondary windings, and in the connections from the transformers to the protective relays, was increased several times beyond normal in order to decrease the burdens. Lastly, the differential relays for the power transformers were located at the switch-yard rather than in the power plant, in order to shorten the runs and decrease the burden for high-voltage current transformers where the greatest unbalance might exist. All of these steps contribute to reduce the dangers of saturating, and thus tend to give proper current transformer performance within the limits of the differential relays under both steady-state and transient conditions.

In the case of the generator relays, the same type of problem exists, but the situation is more readily taken care of because of the similarity of design of

the current transformers co-operating in the differential protection scheme.

## Load and Frequency Control

Automatic load and frequency control of the most advanced and complete type will be provided for each of the initial power systems. Any of the City of Los Angeles generators can be placed on the following individual types of control regardless of the type of operation chosen for the remaining generators:

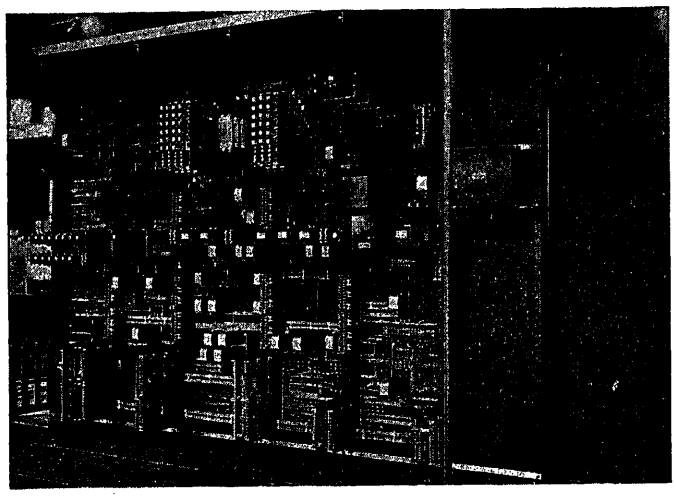

**Fig. 14. Rear view of cubicle of generator N–3**

1. Frequency control
2. Adjustable proportionate-load control
3. Independent base-load control

This equipment consists generally of a high-grade Warren Telechron type *E* master pendulum clock, a master frequency unit controller which can be switched to any generator unit at will, and a load controller for each unit. The master clock is separately mounted and the master frequency controller and the unit load controller together with their accessories, are mounted on the auxiliary control board. A combined system frequency and time error recorder is mounted on the auxiliary board, and a time-error indicator is mounted on the control desk. The unit load controllers are actuated by direct current obtained from "thermal converters" located at the generator cubicles.

While completely automatic load and frequency control is provided, manual control is also available, with suitable interlocking to prevent contradictory or conflicting operation and consequent "hunting" of control. In addition, the load and frequency control automatically trips off after an adjustable time delay on failure of the a-c or d-c supplies or when the frequency, unit load, or total load exceeds predetermined limits.

## Clock Supply Equipment

The complete plant will have approximately 300 synchronous motors operating various clocks, graphic instrument drives, etc. These clocks and graphic instruments should be kept operating regardless of the condition of the main power system, and particularly to obtain a graphic record under fault conditions and independent of the system under fault. Accordingly, a 115-volt 60-cycle frequency-regulated single-phase supply is obtained from 2 $7^1/_2$-kva generators, each driven by a d-c motor, energized from the main control storage battery. Either set can carry the entire load of clock supply.

The generators are regulated for voltage, which varies only under starting conditions, as the clock load is uniformly constant. Frequency is regulated by field control of the motors, taken from a standard frequency generator.

The standard frequency generator comprises an electrically maintained tuning fork, a vacuum-tube oscillator, duplicate amplifiers, etc. The tuning fork with its associated oscillator generates a small amount of constant-frequency current, which is amplified to operate standard clocks, used as monitors, and to energize the grids of hot-cathode mercury-vapor rectifier tubes, which serve in the field control of the motors to maintain constant speed.

While there is only a single master tuning fork and standard frequency supply, all tubes used therein are in parallel so as to insure continuity of operation and the field controls of the motors are independent.

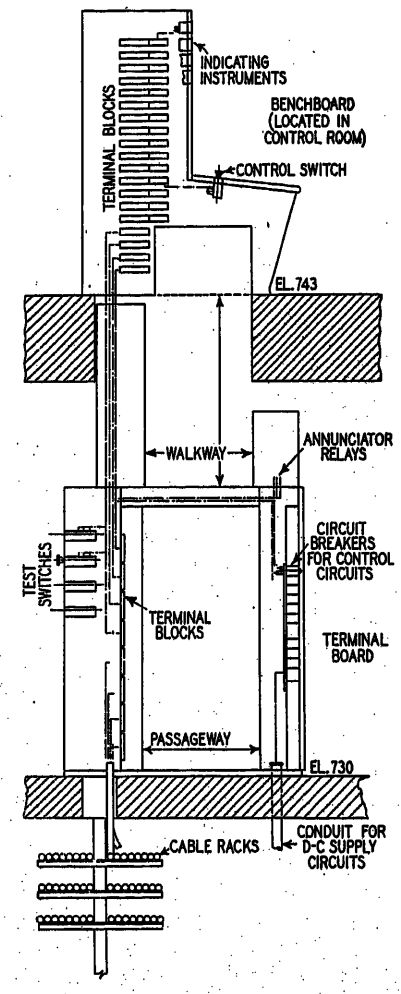

**Fig. 15. Cross section showing relation of terminal boards to control desk with their interconnections**

Suitable clocks are provided to check directly the output of the standard-frequency tuning-fork control, as well as the output of the motor generator set.

The equipment is expected to maintain a constant supply frequency with an error from standard time signals of less than one second per day. By checking with radio time signals, it should be possible to adjust so as to maintain the integrated time error very close to zero.

## Annunciator System

A very complete annunciator and signal system is required because of the large number of generating units, distances from each other and from the main control room, different operating floors, and the possibilities of operating the generators either from the main control desk or from the generator cubicles. The principal purposes are to provide communication between the main control room and the generator and governor floors, to call the operator's attention when a unit is being started or shut down, and likewise to call attention at the various points to any so-called "trouble" operation.

Dual telephone systems provide for the usual vocal communication.

For trouble indication, each of the generators and the transformers, including those for station service,

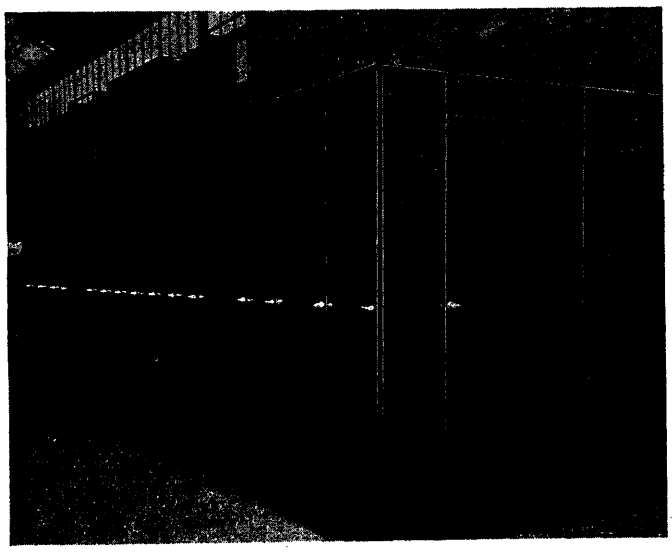

**Fig. 16. Terminal boards with doors closed**

is provided with an annunciator group at each of its control points. For instance, for generator $N$–1 there are provided an annunciator group on the main control desk, one on its generator cubicle, and one on the unit auxiliary control board in the governor gallery. In each of these groups is provided a lamp indicator to show

1. Low governor-oil pressure
2. Hot bearings
3. Generator-cooler failure
4. Hot generator windings
5. Generator cooling-water failure
6. Differential-relay operation
7. Overspeed
8. Overvoltage; direct current and several others

For each generator or transformer unit, the annunciator groups are identical, but the groups for the transformers and for the station service generators will differ slightly from those for the main generators, according to their respective needs.

Likewise on the feeder panels of the station service

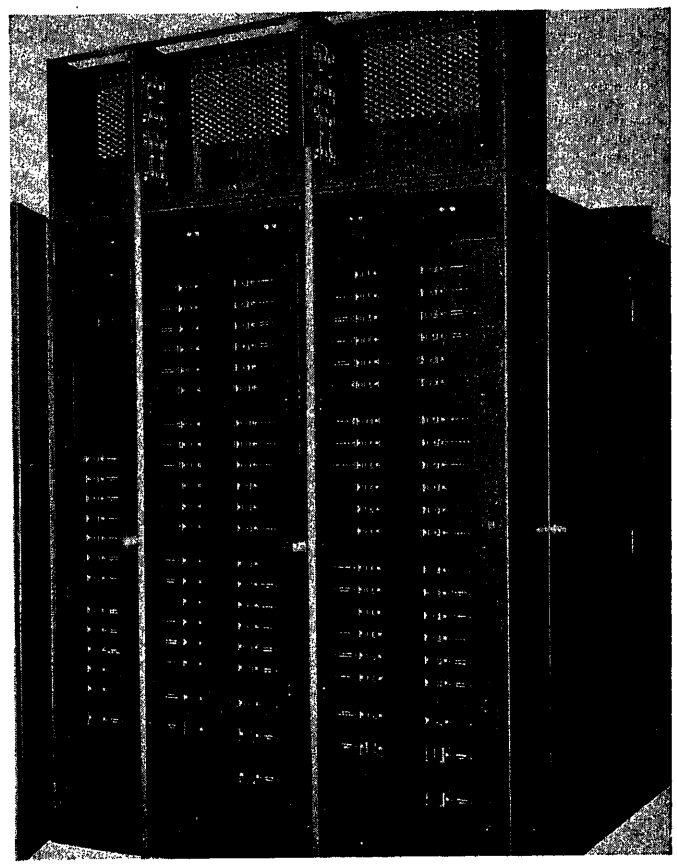

**Fig. 17. Front view of terminal boards with doors open, showing control distribution circuit breakers**

benchboard, there are similar annunciator groups to indicate, for instance, among others,

1. Ground on 250-volt battery number 1
2. Charger number 1 a-c supply circuit tripped
3. Nevada wing 250-volt feeder breaker tripped
4. Nevada canyon wall feeder trip
5. Feeder $A$ to switchyard tripped
6. Feeder to $N$–0 to $N$–6 600-kva transformer tripped

In each of the generator rooms there are provided large visual indicators on the generator balcony and on the governor gallery with numerals on 3 sides and visible at a distance of 300 feet to indicate at which unit the operator is required. Attention is called to these visual indicators by suitable audible signals, one to call the operator for standby service when starting up the unit, and the other in case of trouble.

Appropriate audible signals are also provided in the main control room, with bright lamp indicators to show the unit on which trouble occurs.

The annunciator system is operated by the protective relay which functions in cases of trouble; for instance, differential relays, low oil-pressure relays, high-temperature relays, etc. The trouble relays will usually maintain their contacts until the trouble has been corrected. When trouble occurs, the audible alarms will sound in the main control room and in the generator balcony and the governor gallery. These alarms will sound for approximately 10 seconds and then will reset automatically so as to be ready for the next trouble indication. At the same time, the large visual

indicators in the galleries will show the number of the unit on which trouble has occurred. One lamp indicator in each of the corresponding groups on the generator control board panel, the generator cubicle, and the unit auxiliary control panel in the governor galleries will be illuminated. After the trouble has been cleared, the annunciator indicator lamp can be extinguished by a reset push button at each group, but any attempt to do this before the trouble contacts have opened is futile. In addition, the operation or resetting of the annunciator indicator is not permitted to interfere with the automatic release of the audible alarms and their preparedness for further signals. The resetting of the annunciator indicator is done independently in each group, without affecting the indicator at another group. Likewise, resetting the alarm and annunciator indicators for one fault does not interfere in any way with the reception of signals and indication for subsequent faults.

On the end panels of the station service control desk are provided vertical rows of signal windows, to indicate the condition of the auxiliary control necessary for the generator units. For instance, for each main generator there are provided 10 lamp indicators for the a-c auxiliaries, including among others:

Transformer cooling water
Transformer-oil circulation
Fan indication
Generator cooling-water indication
Auxiliary control transformer
Governor oil-pump indication

and 7 signal windows for the d-c auxiliaries, including among others:

Generator bearing oil-pump indications
Generator field breakers
Generator differential-relay pilot lamp

Each signal window is about one inch square and is covered with a white translucent front on which designation of the equipment it represents is lettered in black, with a low-brilliancy lamp in back to indicate a normal condition.

It is obviously impossible to go into the detail of switchboard circuits and methods for a plant of this size. The foregoing description of a few of the problems gives a measure of the complexity of the over-all switchboard problem and some clue as to the completeness of the plans adopted.

Some further illustration of the problems may be obtained by considering that the electrical equipment in a plant of this size naturally represents many manufacturers. The main purpose of the switchboard is to control all of these electrical equipments, and to do so with a uniformity of methods that will facilitate operation and subsequent maintenance. For instance, the switchboards control oil circuit breakers of 3 manufacturers and air circuit breakers of 2 manufacturers. Each oil circuit breaker had originally its own control scheme, and while the distinctive features of each manufacturer have been retained, those different control schemes have been molded into an over-all uniform scheme.

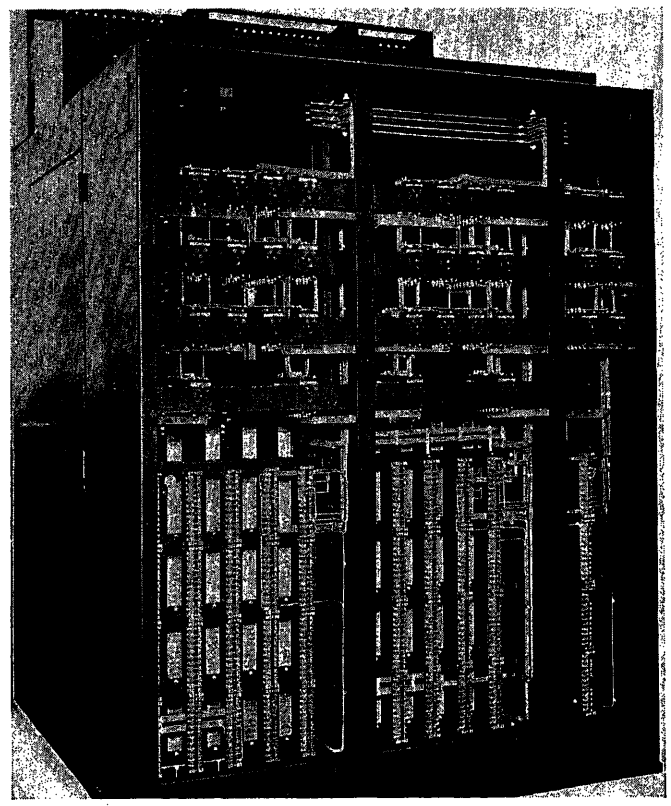

**Fig. 18. Rear view of terminal board with doors removed, showing terminal blocks and test switches**

Voltage regulators, load and frequency regulators, and automatic speed matcher and synchronizers are supplied by 3 different manufacturers. The switchboards provide mounting for graphic instruments from at least 2 manufacturers. All of these must be co-ordinated into a uniform and operating system.

While considerable emphasis has been given to the switchboards for the City of Los Angeles, because their 4 generating units are being controlled by the initial installation, the same features of design apply to the switchboards for the Southern Sierras Power Company.

It has been part of the fundamental plan to provide switchboards which will be complete in every detail, for every operating requirement of the best type of station, yet there is a simplicity, directness, and uniformity of design that will make operation and its attendant maintenance problems as simple as possible. The Boulder Dam switchboards are entirely modern and up to date, without departing from sound practice. They prove the feasibility of conventional switchboard design for a generating plant of this size and character.

# Electrical Water-Level Control and Recording Equipment for Model of Cape Cod Canal

By H. L. HAZEN
ASSOCIATE AIEE

**Control of water level according to a predetermined cycle and its automatic recording in a model of the Cape Cod Canal have been accomplished by electrical means which depend for operation upon the capacitances between the surface of the water and metal plates suspended above the water. The theory of operation and the apparatus are described in this paper.**

CAPE COD, which extends southeastward approximately 40 miles from the general coast line of Massachusetts, was cut by a canal some years ago to shorten coastwise shipping routes. In connection with the enlargement of this canal to facilitate the passage of large ocean vessels, certain problems arose that made it desirable to study the flow of water in the canal and in the adjoining portions of Cape Cod Bay and Buzzards Bay, using a hydraulic model. These model studies were undertaken as a co-operative project by the department of civil and sanitary engineering of the Massachusetts Institute of Technology, Prof. C. B. Breed in charge, and the Corps of Engineers, U.S. Army, Col. John J. Kingman, district engineer. The experimental work is being done at the River Hydraulic Laboratory at Massachusetts Institute of Technology under the direction of Prof. K. C. Reynolds.

Relatively high velocities of flow occur in the Cape Cod Canal, caused by the fact that the tidal range in Cape Cod Bay is somewhat more than twice that in Buzzards Bay, that is, the tides are more than twice as high, while the relative time phases are such that high water occurs in Buzzards Bay about 3 hours or a quarter-period before it occurs in Cape Cod Bay. In order to study by means of a hydraulic model the effect of enlarging the canal on these velocities, it is evidently necessary to reproduce in miniature the tidal water-level variations in the basins at the ends of the model canal. This requires automatic water-level control equipment. It is also necessary to obtain accurate water-level records at numerous stations along the canal and the adjoining waters of the model, as these readings constitute the useful data.

Both the automatic water-level controllers and the water-level recorders require a means of measuring the average water level over an area of a few square inches. Floats of any sort have proved unsatisfactory for this purpose because of the rather large and uncertain errors introduced by surface tension and by dynamic hydraulic forces. Floats also introduce an uncertain effect on flow in the model. Staff gauge water-level readings are subject to error because of surface waves which are unavoidable in this model. Because of these difficulties the electrical methods described in this paper were developed.

The model, built on a horizontal scale of 1 to 600 and a vertical scale of 1 to 60, represents the 8-mile canal together with $11\frac{1}{2}$ square miles of Buzzards Bay at its southern end and one square mile of Cape Cod Bay at its northern end. These areas of bay at either end are sufficient to extend to deep water where the tidal water levels can be assumed to be unaffected by any flow from the canal. By causing the water levels at these 2 deep-water ends of the model to follow any desired tidal cycle, the water levels and flows throughout the model are made to reproduce in miniature and to scale those occurring in nature. In this way the effects that any dredging will have on navigation, or the dredging profiles that are necessary to secure given depths of water, can be predetermined.

The water-level control problem is essentially that of making the water levels at the deep-water ends of the model bay areas rise and fall in accordance with the tides previously observed in nature. This water-level control is accomplished by 2 simultaneous adjustments. The first, or coarse, adjustment is obtained by a time-controlled flow of water into the deep-water end of each basin such that the tidal cycle would be reproduced to a first approximation without additional control. The second, or accurate, water-level adjustment is accomplished by automatically controlling the height of a discharge weir located at the deep-water end of each basin in accordance with the observed instantaneous error in water level near the weir.

In a basin covering a few hundred square feet, the rate of rise or fall of water level can be changed only slowly without causing serious waves. Therefore, a sensitive control device is required which will detect and correct an error in water level before it has become large enough to require a large change in weir discharge. Conversely, a sensitive control is subject to oscillation or hunting unless special care is taken to avoid it. Thus, the problem requires a compromise design based on a quantitative analysis of the dynamics of the entire system involved.

Attention is confined in this paper to the electrical control and recording equipment. The hydraulic aspects of the study are presented in an unpublished report by Prof. K. C. Reynolds.

A paper recommended for publication by the AIEE committee on automatic stations. Manuscript submitted June 15, 1936; released for publication September 3, 1936.

H. L. HAZEN is associate professor of electrical engineering at Massachusetts Institute of Technology, Cambridge.

The author acknowledges the aid others have given in this development; in particular, the enthusiastic co-operation of Prof. K. C. Reynolds, in charge of the River Hydraulic Laboratory at Massachusetts Institute of Technology, and of Prof. R. D. Bennett of the electrical engineering department.

## Layout of Water-Level Control System

As stated in the preceding section, the water levels in the 2 basins at the ends of the canal must be continuously adjusted so that the tidal levels observed in nature are correctly reproduced to scale in the model. This is done as follows:

A master "time" unit is used to control the sequence of all model tidal phenomena. This consists of an adjustable-speed d-c motor which is geared to a so-called Selsyn transmitter, and also to a valve-control shaft. The Selsyn transmitter drives 2 Selsyn synchronous motors, one near the weir of each basin. Each of these Selsyn motors is geared to a disk cam. The gearing and Selsyn units are so designed that the valve-control shaft and the 2 disk cams revolve synchronously at a speed of one revolution per tidal cycle. In nature the period of this cycle is about 12.42 hours, which is reduced to 9.63 minutes in the model. Each of the disk cams is essentially a polar plot of the tide-level curve for its basin. The problem then is to make the water level reproduce the tidal data given on the cam.

This is done by means of the apparatus shown schematically in figure 1. The cam continually adjusts the height of the "level unit" through the lever $L_1$. On this level unit is a plate $P$. Through the amplifier, weir motor, and rack and pinion, the weir is so controlled by the level unit that the water level tends to remain at a constant distance $D$ from plate $P$. As the cam is driven by the master time unit, the water level is made to reproduce the tidal curve. Lever $L_2$ provides damping in a manner explained in detail subsequently.

Evidently if this scheme alone were used to control the water level, enough water would have to be continuously supplied to the basin to raise the level at the most rapid rate called for by the tidal curve and to provide an excess for control by adjustable spillage over the weir. Also the weir would have to have a relatively large maximum spillage to lower the water at the maximum rate and discharge the inflow at the same time. To reduce the inflow of water required, and also to reduce the amount of controlling action imposed upon the weir, the simple expedient of controlling the water input to each basin by valves is used. Adjustable cranks on the valve-control shaft mentioned above operate ordinary gate valves through a lever system. Each gate valve controls the water supplied by gravity to one basin from a central constant-head tank. By suitably adjusting both the stroke and phase angle of these cranks, the amount of water-pump and weir capacity can be greatly reduced and the final level control made much more accurate. A separate valve-controlled water supply and weir-control unit is of course necessary for each of the 2 basins.

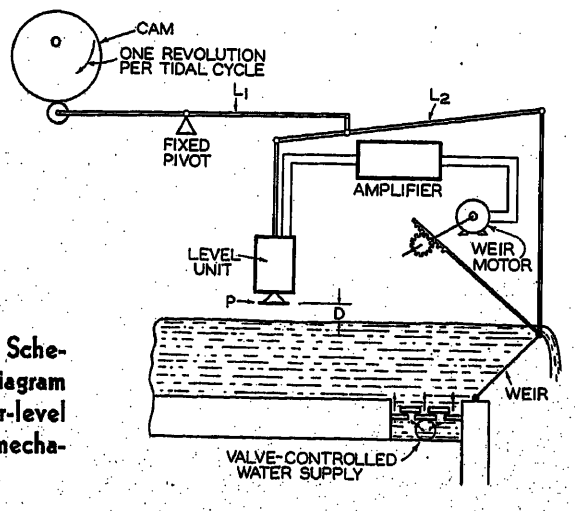

**Fig. 1. Schematic diagram of water-level control mechanism**

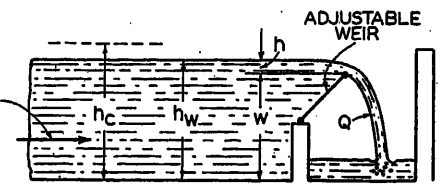

**Fig. 2. Diagram of a portion of a basin showing dimensions used in the analysis**

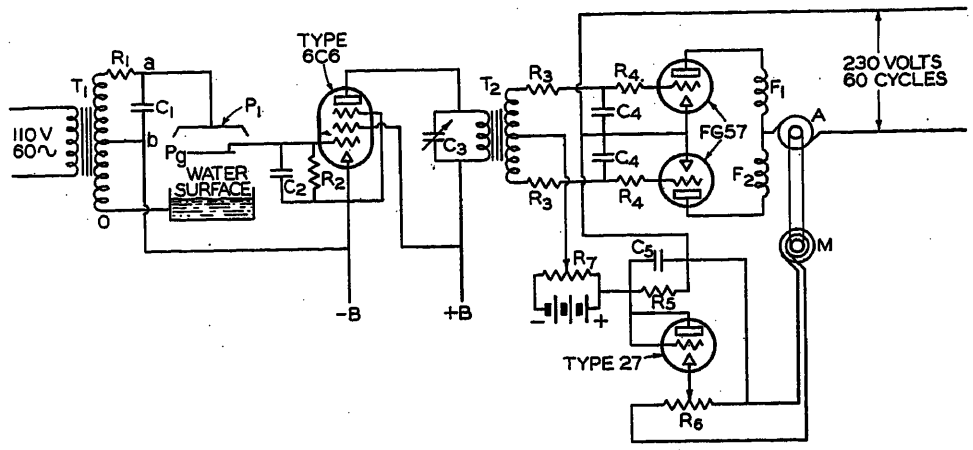
In the following section an analysis of the dynamic behavior of this water-level control system developed for the purpose of designing a stable and sufficiently accurate system is given.

## Analysis of Control System

Figure 2 shows schematically a portion of a basin representing the bay at one end of the canal for the purpose of indicating some of the hydraulic dimensions used in the control analysis. Three components of water flow affect the water level in this basin: first, the flow in and out from the canal; second, the flow in from the constant-head tank, controlled by the crank-operated gate valve; and third, the flow out over the weir. When the algebraic sum of these 3 components is correctly adjusted the water level in the basin will follow the prescribed tide-level curve. The first component is not subject to arbitrary control. The second component is an adjustable periodic function of time. Preliminary analysis showed that it should be such a function of time that the third component or weir discharge is approximately constant. This third component is then adjusted from instant to instant by the automatic control of the weir height to reduce the residual error in water level to a negligible value.

The analysis that follows applies to the action of the automatic weir-height control device. Let



$h_c$ = desired height of water at any instant (feet)
$h_w$ = actual height of water at any instant (feet)
$w$ = height of weir crest (feet)
$t$ = time (seconds)
$Q_o$ = net inflow to basin including flow from pump and canal (cubic feet per second)
$Q$ = weir discharge under head $h$ (cubic feet per second)
$h$ = head on weir (feet) = $h_w - w$
$h_o$ = average value of $h$ (a constant)
$l$ = length of weir (feet)
$A$ = area of basin (square feet)

All heights are measured from an arbitrary datum plane.

Two equations describe the motion of the system.

**Fig. 3. Water-level controller circuit**

$C_1$ = 0.01 microfarad
$R_1$ = 4,000 ohms
$C_2$ = 0.0001 microfarad
$R_2$ = 30 megohms
$C_3$ = 0.17 microfarad
$R_3$ = 1.0 megohm
$C_4$ = 0.003 microfarad
$R_4$ = 50,000 ohms
$C_5$ = 1.05 microfarad
$R_5$ = 50,000 ohms
$R_6$ = 1,500 ohms
$T_2$ = Audio transformer (Sampson type Y)

The first is the water-level equation

$$\frac{dh_w}{dt} = \frac{Q_o - Q}{A} \tag{1}$$

The second equation describes the control action exerted on the weir, which can be arbitrarily specified. Preliminary analysis indicated that this control system would operate properly if the weir speed were made to depend linearly on the sum of 2 quantities, the error in water level, and the departure of the head on the weir from its average value. The weir-height equation is then

$$\frac{dw}{dt} = g(h_c - h_w) + m(h_w - w - h_o) \tag{2}$$

in which $g$ and $m$ are constants. The right-hand term in equation 2 introduces required damping, as shown subsequently. The coefficients $g$ and $m$ are to be fixed by the given allowable error and the necessity for aperiodic operation.

Before combining equations 1 and 2, $Q$ must be expressed in terms of the head on the weir. The law assumed for the weir discharge was

$$Q = 3.33\, l h^{3/2} \tag{3}$$

which can be put into an approximate linear form in $(h - h_o)$ for heads near an average head $h_o$ by using the first 2 terms of a Taylor's expansion about $h_o$. Thus

$$Q = 3.33\, l h_o^{3/2} + 5.00\, l h_o^{1/2} (h - h_o)$$

within about 5 per cent for $0.7\, h_o < h < 1.5\, h_o$. Substituting this approximation in the right-hand term of equation 1 gives

$$\frac{Q_o - Q}{A} \approx q_o - q_1(h_w - w - h_o) \tag{4}$$

in which

$$q_o = \frac{Q_o - 3.33\, l h_o^{3/2}}{A} \tag{5}$$

and

$$q_1 = 5.00 \frac{l}{A} \sqrt{h_o}$$

$$= 5.00 \frac{l}{A} \sqrt[3]{\frac{Q_{ave}}{3.33\, l}} = \text{constant} \tag{6}$$

From equation 6 it may be seen that the average weir discharge $Q_{ave}$ fixes the constants $h_o$ and $q_1$. It also fixes the constant term of $q_o$.

Putting equation 4 in equation 1,

$$\frac{dh_w}{dt} = q_o - q_1(h_w - w - h_o) \tag{7}$$

Differentiating equation 7 with respect to time, substituting equation 2 in the result, writing $p$ for $\frac{d}{dt}$, and rearranging gives

$$p^2 h_w + q_1 p h_w + m p h_w + q_1 g h_w - q_1 g h_c - p\, q_o - m q_o = 0 \tag{8}$$

Since the error in water level is desired rather than the actual height of water, equation 8 is rewritten using a change of variable

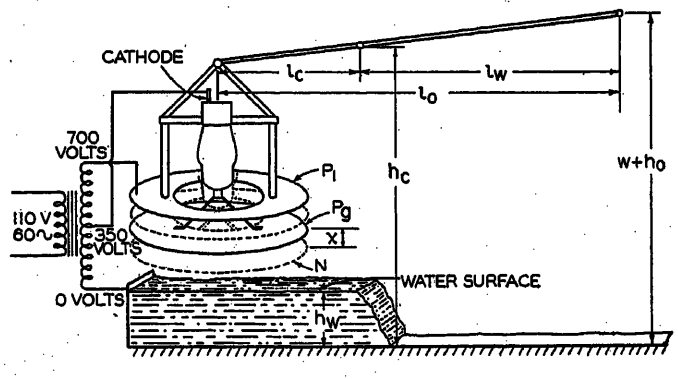


**Fig. 4. Diagram of damping lever**

*N* indicates position of $P_g$ for zero alternating potential on grid of tube

$$\delta = h_c - h_w \tag{9}$$

in which $\delta$ = error in water level in feet. Putting equation 9 in equation 8 and solving for $\delta$ gives

$$\delta = \frac{(p + q_1 + m)p h_c - (q + m)q_o}{p^2 + (q_1 + m)p + q_1 g} \tag{10}$$

In equation 10, $h_c$ and $q_o$ are time functions that can be determined from the tidal-level data, the valve-crank

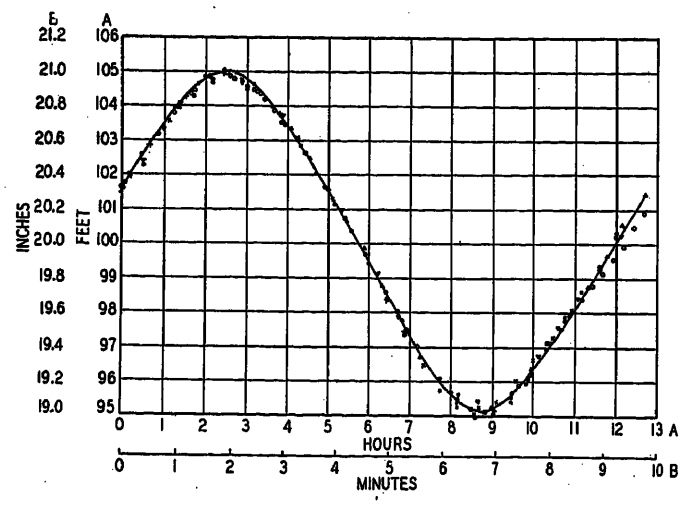

**Fig. 5. Typical level-controller performance**

Scales *A* for nature; scales *B* for model

Circles are actual tidal data obtained at Cape Cod Bay approach to canal. Solid curve is idealization of these data for model tide cycle. Other plotted points are typical water-level records taken in course of model studies

adjustments, and the dimensions of the basins; $q_1$ is a constant fixed by the constant component of weir spillage due to the average weir head $h_o$.

In order to determine $m$ and $g$, 2 additional conditions need to be imposed. The conditions selected are, first, that the operation must be aperiodic, and second, that the maximum value of the error $\delta$ shall not exceed a prescribed amount. For critical aperiodic operation, the denominator of equation 10 must have equal real roots, which imposes the condition

$$(q_1 + m)^2 = 4q_1g \tag{11}$$

The error condition is next imposed. A consideration of various features of the model study led to the selection of 0.0010 foot (equivalent to 0.06 foot in nature) as the maximum permissible value of $\delta$ which, preliminary calculations indicated, could be attained with reasonable apparatus.

It is subsequently shown that $q_1 << m$ and that therefore the numerator of equation 10 can be written with sufficient accuracy as

$$(p + m)(ph_c - q_o) \tag{12}$$

But $ph_c - q_o$ is the residual flow per unit of basin area which the automatic control must correct by adjustment of the weir, and can therefore be approximately described as a known function of time for either basin.

Thus far the analysis has been general, that is, it applies to any system of the type described. At this point it is desirable to insert actual numerical values, which necessitates considering a specific case. The end representing Buzzards Bay is arbitrarily chosen for the numerical work that follows.

Examination of the expected flow relations in the model of Buzzards Bay shows that this residual flow will impose on the automatic control a condition no more severe than that imposed by a sine-wave flow having an amplitude of 0.20 cubic foot per second and a period one-third that of the main tidal cycle. The main tidal period in the model is approximately 9.6 minutes. Therefore, for the basin of 900 square feet area the residual level variation to be corrected can be assumed for the purpose of design to have the form

$$ph_c - q_o = \Delta \sin 3 \frac{2\pi}{T} t \tag{13}$$

in which

$T$ = the period of the tidal cycle in model (seconds)
$\Delta$ = amplitude of assumed residual level error to be corrected by automatic control (feet)

Putting in the above numerical values,

$$ph_c - q_o = \frac{0.20}{900} \sin 3 \frac{2\pi}{9.6 \times 60} t$$

$$= 2.22 \times 10^{-4} \sin 0.0327t.$$

Replacing $p$ in equation 10 by $j\omega_3$ where $\omega_3$ is the angular velocity of the assumed residual level variation and $j = \sqrt{-1}$, and remembering that $q_1 << m$, gives

$$\frac{\delta}{\Delta} = \frac{m + j\omega_3}{-\omega_3^2 + mj\omega_3 + q_1g} \tag{14}$$

Using the simplified condition for critical damping

$$q_1g = \frac{m^2}{4} \tag{15}$$

in equation 14 gives

$$\frac{\delta}{\Delta} = \frac{m + j\omega_3}{\left(\frac{m}{2} + j\omega_3\right)^2} \tag{16}$$

Trial shows that $\omega_3 << m$, when equation 16 becomes

$$\frac{\delta}{\Delta} = \frac{4}{m}$$

Putting in numerical values gives

$$m = \frac{4 \times 2.22 \times 10^{-4}}{0.0010} = 0.89 \text{ foot of weir height per second for one foot departure of the weir head from } h_o$$

The quantity $q_1$ must now be evaluated. The average weir discharge for the conditions under which the auto-

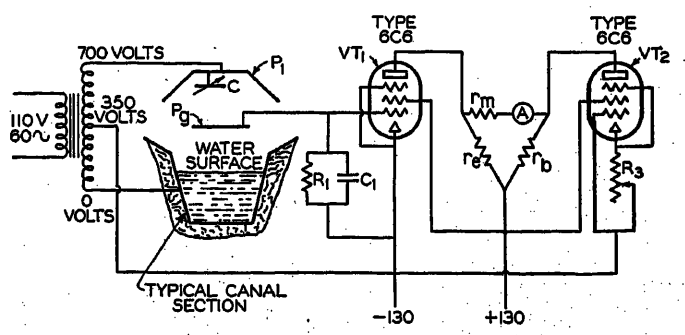

**Fig. 6. Circuit diagram of water-level recorder**

$R_1$ = 30 megohms $C_1$ = 0.0001 microfarad
$R_3$, $r_m$, $r_t$, and $r_b$ vary from unit to unit

matic control is to work is 0.7 cubic foot per second, which gives a value for the weir 12 feet long of

$$q_1 = \frac{5 \times 12}{900} \sqrt[3]{\frac{0.7}{3.33 \times 12}} = 0.0174 \text{ (dimensions same as for } m)$$

The assumptions $\omega_3 << m$ and $q_1 << m$ can now be checked. Thus

$\omega_3 = 0.0327$
$q_1 = 0.0174$
$m = 0.89$

which shows them to be justified within the accuracy justified by other data.

The constant $g$ can now be calculated from equation 15.

$$g = \frac{m^2}{4q_1} = \frac{0.89^2}{4 \times 0.0174} = 11.4 \text{ feet of weir height per second for one foot error in water level}$$

This completes the dynamic analysis, as all parameters are fixed.

## Design of Apparatus

Having determined the necessary numerical values of the damping coefficient $m$ and the level-restoring coefficient $g$, which are the 2 important dynamic parameters, the problem shifts to the design of apparatus that will be characterized by these values. This apparatus includes 3 essential parts: first, a level-measuring device; second, an amplifying device and motor to furnish power to operate the weir in accordance with the indications of the level indicator; and third, a suitable mechanism for inserting the damping described by the coefficient $m$. These parts will be described in order.

Figure 3 shows schematically the electrical features of the level indicator, amplifier, and weir-driving motor. The level indicator is essentially an electrostatic potential divider consisting of the water surface and the plate $P_1$ as its terminals between which the plate $P_g$ picks up electrostatically a potential intermediate between that of $P_1$ and the water. Plate $P_1$ is maintained at a 60-cycle alternating potential of 700 volts, effective value, above the potential of the water by the transformer $T_1$. The grid-to-cathode voltage of a type 6*C*6 pentode is the difference between the potential of plate $P_g$ and the midpoint of the 700-volt winding of $T_1$. The plates $P_1$ and $P_g$ are fixed mechanically with respect to each other and are moved as a unit by the water-level cam previously described. At some water level, $P_g$ and the midtap of $T_1$ will be at the same potential, and hence the grid-to-cathode voltage will be zero. If the water level is above this balance level, the grid will have impressed on it a 60-cycle voltage of a certain phase. If the level is below, the phase of the grid voltage will be displaced 180 degrees. Parts $R_1$ and $C_1$ constitute a phase-correcting circuit for making the voltage between $a$ and $b$ precisely in phase with the voltage between $b$ and $o$. This is required because the 2 secondary halves of $T_1$ are differently loaded.

Although the capacitance between $P_g$ and $P_1$ or $P_g$ and the water is only about 20 micromicrofarads, the circuit is very stable and requires practically no shielding. This is due in part to the excellent insulation of $P_g$, obtained by mounting it directly on the grid cap of the tube.

The amplifier consists of a type 6*C*6 pentode and 2 type *FG*57 thyratrons. The thyratrons are so biased by means of the resistance drop in $R_7$ that they fail to fire when no alternating current is present in the plate current of the pentode. Both have the same plate voltage but the a-c components of their grid voltages differ in phase by 180 degrees. The circuits are so adjusted by $C_3$, $R_3$, and $C_4$ that their grid and plate voltages are either in phase or 180 degrees out of phase. Consequently when the water level is above or below balance level, one or the other of the thyratrons fires, taking current from the 230-volt 60-cycle supply through the d-c motor armature $A$ and one motor field $F_1$ or $F_2$, thus driving the motor in one direction. To maintain correct phase relations this 230-volt supply must necessarily come from the same feeders as the 110-volt supply for $T_1$. If the other thyratron is fired, current flows through the motor armature and the other field, driving the motor in the opposite direction. The motor drives the hinged weir through a reduction gear and rack and pinion, as indicated in figure 1. Of course connections must be so made that a low water level raises the weir, and vice versa.

One other feature of the circuit will be mentioned. The motor (and weir) speed should be proportional to the indicated error in water level. The alternating voltage on the thyratron grids is proportional to this error. But the thyratrons are "on" and "off," that is, not smooth-control devices when used in this way. However, by driving an a-c magneto $M$ by the motor, rectifying its output, and charging capacitor $C_5$, which is shunted by a leak $R_5$, an additional d-c bias can be applied to the thyratrons. If this additional bias exceeds the peak value of the a-c grid voltage, it will cause the previously-firing tube to cease firing until the motor speed has de-

creased. Thus the average motor speed is kept very nearly proportional to the indicated error in water level.

Thus far no mention has been made of introducing damping. This important aspect will now be considered. Equation 2 can be written

$$\frac{dw}{dt} = (g - m)\left[\frac{g}{g - m} h_c - h_w - \frac{m}{g - m}(w + h_o)\right] \qquad (17)$$

in which the weir speed $(dw)/(dt)$ is a linear function of 3 heights—the desired water height $h_c$, the actual water height $h_w$, and the weir-crest height $w$, $h_o$ being a constant. This suggests the linkage shown in figure 4. The weir speed is proportional to the distance $x$, if $x$ is small, by which the plate system $P_1P_g$ is removed from its zero indication position, that is

$$\frac{dw}{dt} = kx$$

Since the water height is a directly additive (with negative sign) component in $x$, evidently $k = g - m$ and

$$x = \frac{g}{g - m} h_c - h_w - \frac{m}{g - m}(w + h_o) \qquad (18)$$

or

$$x + h_w = \frac{g}{g - m} h_c - \frac{m}{g - m}(w + h_o) \qquad (18a)$$

The linkage of figure 4 will produce this result if

$$\frac{l_o}{l_w} = \frac{g}{g - m}$$

Putting in the numerical values for the design for Buzzards Bay gives

$$\frac{l_o}{l_w} = \frac{11.4}{11.4 - 0.89} = 1.085$$

or

$$l_w = \frac{l_o}{1.085} = 0.92\, l_o$$

As mentioned earlier in the paper, all heights are measured from any common datum plane.

Final experimental adjustments of the constant $g$ were made by gear ratios and the values of $R_5$ and $C_5$ (see figure 3).

A similar calculation was made for the Cape Cod Bay basin controller which need not be repeated here, since it merely involves different numerical values.

## Practical Considerations

In the theoretical design given above, certain idealizations were made that are not realized in practice. One of the most serious of these is the tacit assumption that the water level changes at the same rate over the entire basin, following an adjustment of the weir height. Actually this is not so for 2 reasons. The first is that the weir displaces water when it is moved. This sets up a wave of higher or lower level, depending on whether the weir is raised or lowered, that propagates away from the weir over the basin at a finite rate. The second reason is that a lowering or raising of the weir also produces a local lowering or raising of the water level due to a changed discharge rate. This level change also propagates at a finite velocity.

If the water-level indicator for the controller is not very close to the weir, there is an appreciable time lag between the change in water level at the weir and the change of level at the level indicator. Such time delays in general

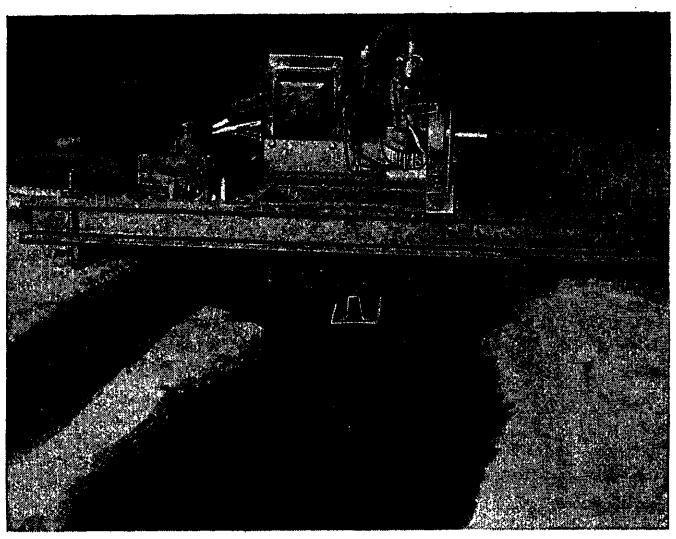

**Fig. 8. Level-recorder unit in place over canal**

Plate $P_g$ (figure 6) appears immediately above "bridge piers" in canal. Plate $P_1$ is the hood immediately above $P_g$. Tube $VT_3$ and resistor $R_8$ appear above framework

have the effect of introducing negative damping into any control system, that is, they tend to set up oscillation. In this installation this time lag was appreciable, which necessitated introducing somewhat more damping than that called for by the analysis. Final adjustment of the damping was made experimentally under actual operating conditions.

In the analysis it was assumed that the residual flow to be controlled by the automatic controller was made small by carefully adjusting the gate-valve cranks. In actual operation it proved more expedient to adjust these cranks only approximately and to make final adjustment of the tidal cycle by filing the control cams to a shape slightly different from the actual tidal curve. Since each tidal cycle is given a considerable amount of study, the time required to adjust the cams for each new cycle by filing is relatively unimportant. The advantage of making final adjustment by filing the cams is that there is a much more direct and easily-visualized relation between the residual water-level error and the change in the cam necessary to correct it than there is between this error and the corresponding corrective change in valve-crank setting. Once the cams are corrected, the tidal cycle repeats accurately thereafter, independent of any minor changes in the canal flow caused by trial modifications of the model.

## Controller Performance

After the adjustments described, together with certain minor circuit adjustments, were made, the controllers were put into operation in November 1935, and they have operated consistently since then with little attention. Errors in the water level of the 2 basins have been within the limits established as satisfactory for the studies to be made. Rough tests were made of the dynamic performance of the controller which showed that the device was operating in substantial accord with the design calculations. The significant test, however, is the performance of the controllers in accurately controlling the water levels under actual operating conditions. Typical performance data are shown in figure 5. In this figure the circles represent actual tidal data recorded at the Cape Cod Bay approach to the canal. The solid line is the slightly-idealized tidal cycle derived from these data to be reproduced in the model. The remaining plotted points are those obtained on the model during a series of typical runs.

## Water-Level Recorder

Attention is now turned to the other apparatus used on the canal model which is of interest to electrical engineers, namely, the water-level recorders.

As in the case of the water-level indicator for the water-level controller, floats were barred for level recorders because of the serious and uncertain errors introduced by surface tension and by dynamic forces caused by water currents. The general scheme adopted for the water-level recorder is similar to that described hereinbefore, that is, the water surface is used as one electrode of an electrostatic potential divider from which the grid potential of a pentode is derived. In the recorder, however, the variation in the d-c component of plate current rather than in the a-c component is used to indicate the water level. This d-c component is indicated by a d-c milliammeter. The simultaneous recording of the indications for the 9 water-level stations in the model is done photographically.

In figure 6 is shown the circuit of a recorder. The chief difference between this circuit and that of the first tube in figure 3 is the method of utilizing the output. In the recorder circuit, the fixed plates $P_1$ and $P_g$ are so placed, and the adjustable plate $C$ so set, that at the lowest water level the capacitance between the water and $P_g$ is slightly greater than that between $P_g$ and $P_1$, thus impressing sufficient alternating voltage on the grid to reduce the plate direct current slightly (about 10 per cent) below its value for equal capacitances. As the water level is raised, the capacitance unbalance and hence the grid alternating voltage become greater, decreasing the plate direct current. Thus the plate direct current is a measure of the water level. This is the general scheme of operation.

A number of refinements are necessary to reduce the errors. The goal for error was set at 0.5 millimeter probable error for level ranges up to about 4.5 centimeters. Plate $P_g$ is 2.5 centimeters or more from the high-water level to avoid difficulties resulting from splashing, while the canal section in some cases is only about 13 centimeters wide at the top. These conditions made it difficult to reach the desired accuracy with simple equipment.

Proper shaping and placing of plates $P_1$ and $P_g$ are important in order to obtain adequate sensitivity at low water when the capacitance of $P_g$ to the canal walls is much larger than its capacitance to the water surface, and when the rate of change of the latter capacitance with respect to water level is small. Conversely, at high water the rate of change of this capacitance with water level is relatively high. A reasonably linear calibration curve was obtained by using the steepest part of the curve for grid alternating voltage versus plate direct current at low water, and the flatter part at high water. Typical calibration curves are shown in figure 7. Because some grid alternating voltage is necessary even at low water, no phase-correcting circuit was required on the 350–700-volt half of the a-c high-voltage supply for a level-recorder unit.

Another aspect that must be given careful attention is the error resulting from variations in screen voltage. Unless some form of compensation is used, this error can easily become as much as 2 or 3 millimeters of water level per volt change in screen voltage at 130 volts for the 6*C*6 tubes used. By using a second 6*C*6 tube $VT_2$ with fixed grid voltage (see figure 6), this sensitivity to changes in screen voltage is considerably reduced and at the same time a convenient means is provided for suppressing the zero of the d-c plate milliammeter $A$. The screens and heaters of both tubes are supplied from the same sources. By suitably adjusting the values of the resistances $r_m$, $r_l$, and $r_b$ in the milliammeter mesh, the milliammeter reading can be made to range over any desired fraction of

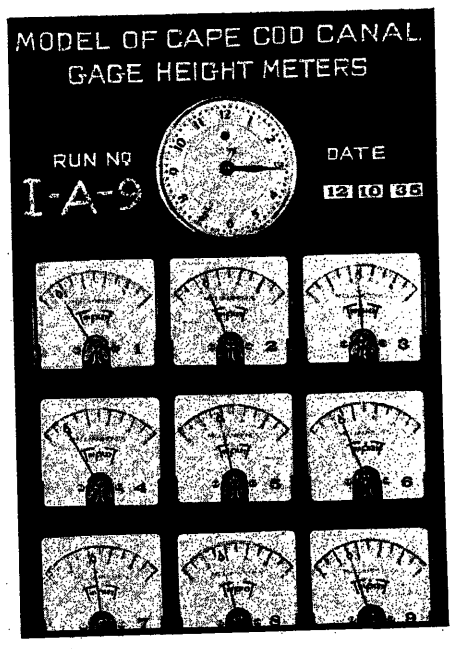

**Fig. 9. Instrument panel for water-level recorder**

The 9 milliammeters indicate water levels at 9 stations in model. Water levels are obtained from calibration curves

full scale for any given range of water-level variation. By adjusting the resistance $R_s$, these readings can be centered on the meter scale. The resistance $r_m$ is made large enough so that the temperature error due to copper in the milliammeter is made negligible. This feature is pertinent because of the rather wide fluctuations in temperature occurring in the building in which the model is located.

The best shape of calibration curve for water level versus milliammeter reading is obtained by properly shaping and placing the $P_1$ and $P_g$ plates, and finally by adjusting the low-water grid alternating voltage with the small auxiliary capacitor plate $C$.

Both alternating and continuous voltage regulators are used in the power-supply circuits because of the high degree of consistency required of the tubes and circuits. By this means the cathode temperature, the grid alternating voltage, and the screen voltages are maintained within the necessary close limits.

Figure 8 is a view of an assembled level-recorder unit in place over a section of the model canal. The instrument panel containing the 9 milliammeters, a clock, and a place for data pertaining to a run is shown in figure 9. This is photographed at intervals of 20 seconds throughout a tidal cycle lasting 9.63 minutes by means of a 35-millimeter motion-picture camera. After the film is developed the meters and clock are read from the projected image of the negative. Figure 9, in fact, is reproduced from one of the photographs taken in routine recording.

## Performance of Water-Level Recorder

The recorders have been in operation practically continuously since November 1935. With them level measurements have been consistently obtained that utilize the full hydraulic accuracy of the model.

In general the uncertainty of a current reading has been found to be of the order of 0.005 milliampere in a recorder-current range of about 0.8 milliampere. In terms of water level this represents an uncertainty of from 0.12 to 0.25 millimeter. Using the vertical scale factor of 1 to 60 between model and nature, this uncertainty is seen to represent from about 0.025 to 0.05 foot in nature, the larger figure being associated with the larger tidal ranges.

To achieve this precision requires careful calibration at intervals of 2 or 3 weeks. Other operating precautions are also necessary, such as careful control of all voltages, and allowing a warming-up period of about half an hour previous to taking readings. As stated hereinbefore, both alternating and continuous voltages are automatically controlled by voltage regulators whose settings are checked by manual adjustment. Good-grade portable voltmeters have sufficient accuracy for use in this checking and adjustment.

The principal cause for frequent calibration is the gradual change in the mutual conductance of tubes with use. Because of this change it is occasionally necessary to readjust the resistance $r_m$, shown in figure 6, in order to maintain a working range of 0.8 to 0.9 of full scale on the meter for the working range of water level. This is done before a calibration and occasions little inconvenience.

## Summary

The electrical equipment described in this paper has made possible the successful reproduction of tidal cycles and accurate recording of water levels in a hydraulic model. The equipment is relatively simple and inexpensive. Although requiring some care in operation, it has proved entirely serviceable and has been in practically continuous use since the installation was completed in November 1935. Ordinary adjustments are made by engineers with little electrical training. The results obtained with this electrical equipment are sufficiently accurate to make the hydraulic errors the controlling factor in the over-all accuracy of the model studies.

# Lightning Currents in 132-Kv Lines

By PHILIP SPORN
FELLOW AIEE

I. W. GROSS
ASSOCIATE AIEE

**Data pertaining to lightning currents actually measured in tower structures, counterpoises, and ground wires on 132-kv lines during 1933–36 are presented in this paper. It is concluded that stroke currents rarely exceed 150,000 amperes, although 220,000 amperes has been indicated, and that currents as high as 60,000 amperes measured in the overhead ground wires indicate the necessity of adequate shielding of the line at station entrances.**

THE organized field and laboratory investigations on the effects of lightning on electric systems and apparatus, started some 10 years ago, have uncovered many of the mysteries of lightning affecting line performance and equipment protection. Voltage magnitudes and polarity have been measured, wave shapes determined with some degree of completeness and certainty, and frequency and severity of lightning disturbances observed.

As various theories of the mechanism by which lightning produced its disturbing effect on electric systems were put forth, discussed, and checked against the field operating experience, it became apparent that a fuller knowledge of the currents in the lightning stroke itself, and their distribution in the various parts of the electric system subject to its influence, were urgently needed to help solve the problems of lightning protection to lines and equipment.

Having actively entered into the very early investigation work mentioned above, and having recognized the value of this work in bringing about better service to electricity consumers and greater protection to apparatus, the authors have continued without interruption the field investigation work first started some 10 years ago. However, during the past 4 years their research has centered about the problem of determining lightning currents in strokes themselves, and in various parts of the transmission network. This investigation has been conducted on the properties of the American Gas and Electric Company and in co-operation with the General Electric Company.

In this paper there will be presented in a summarized form the high points of the field data obtained during the period 1933 to 1936, inclusive. Particular emphasis will be laid on the lightning currents actually measured in lightning strokes, tower structures, counterpoise wires, and ground wires. Correlation of line performance with these data will be given to the extent warranted by the data. However, the authors believe that, in view of the large volume of field data secured in this investigation of the past 4 years, it will be best to use available space to present the maximum amount of pertinent data, interpreting and correlating only the most important parts of those data.

The investigation was carried out on 2 132-kv lines forming part of the American Gas and Electric Company network, and on one line constructed for 132-kv but operated at 66-kv. These lines are the Glenlyn-Roanoke in Virginia, Philo-Canton in Ohio, and Deepwater-Pleasantville in New Jersey, respectively. Their general design characteristics and past performance record have been previously presented.[1] The major part of the field measurements was obtained on the Glenlyn-Roanoke line where instruments were located to record lightning currents in tower structures, tower arms, counterpoise wires, ground wires, and tower-top lightning rods. The impulse flashover characteristics of insulator assemblies on this line are approximately 910 and 750 kv on the 1x5 and $1^1/_2$x40 impulse waves, respectively. On the Philo-Canton and Deepwater-Pleasantville lines, measurements were recorded in tower-top lightning rods only.

To make most effective use of the available equipment, measuring instruments were concentrated at line locations which from past experience appeared to be the most heavily lightning-infested sections of the line. The degree of instrument coverage in per cent of total line length on which investigation was carried out throughout the 4 years (1933 to 1936) was 7.3 per cent of the Philo-Canton line, 5.3 per cent of the Deepwater-Pleasantville line, and 100 per cent of the Glenlyn-Roanoke line in 1933–34 and 1935, and 23 per cent in 1936. Summarizing this on the basis that would have existed if the entire work had been carried out in one year, the field setup to record lightning currents appears as follows:

| | Length of Line Investigated (Miles) |
|---|---|
| Tower-top lightning rods | 70 |
| Counterpoises | 28 |
| Tower arms | 88 |
| Tower legs | 218 |
| Ground wires | 29 |

In evaluating the extent of line covered as shown by the above tabulation, it must be remembered the 4-years' work gave a diversity of lightning severity not possible with a single-year's investigation.

## Determination of Lightning Currents

All lightning currents reported here were determined by the surge-crest ammeter in the field. The surge-crest

A paper recommended for publication by the AIEE committee on power transmission and distribution. Manuscript submitted December 12, 1936; released for publication January 4, 1937.

PHILIP SPORN is vice-president and chief engineer of the American Gas and Electric Company, New York, N. Y. I. W. GROSS is electrical research engineer with the same company.

1. For all numbered references see list at end of paper.

ammeter[2] consists essentially of small laminated cobalt-iron magnets approximately $1^1/_2$ inches long by 0.1 square inch in cross section placed in a definite position in the magnetic field of the conductor in which the current is to be measured. By measuring the residual magnetism left in the magnet after the passage of current the crest value of the current is determined and in some cases its oscillatory characteristics as well.

The field setup of these magnetic links on a typical tower as installed in 1936 is shown in figure 1. Similar installations were in service during 1933, 1934, and 1935, although all towers at which field setups were made did not provide for measurements at all points of the tower structure shown in figure 1.

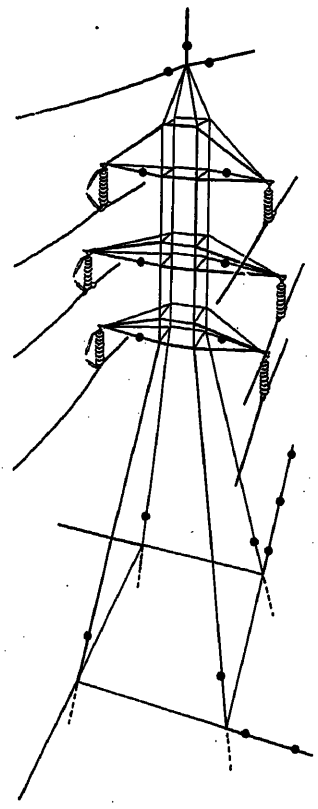

**Fig. 1. Arrangement of magnetic links of surge-crest ammeter on a typical tower in 1936**

The number of surge link installations and their locations for the 4 years herewith reported are shown in table I. Previous to 1936 currents were measured in quite a few towers by the use of one surge link installation on one leg only of the tower, the total tower current being subsequently obtained by multiplying the reading recorded in one leg by 4. Although this method of measurement seemed to give reasonably accurate results, the more precise method of using separate link installations on each tower leg was followed in 1936 when the investigation was concentrated on particularly heavy lightning infested line sections.

In the attempt to determine the flow of lightning current in the tower structure, several cases were encountered in the past where the absence of any current indication in certain locations caused some doubt as to the interpretation to be placed on the results. In such cases it is necessary to consider both the maximum and minimum currents the surge-crest ammeter, as set up, is capable of measuring. The range of measurements for the different types of field installations is shown in table II, these values being for unidirectional surges. Currents of the oscillatory type can be measured in a slightly higher range by suitable calibration of the surge-crest ammeter. This was done in some cases.

## Field Measurements of Current

Although the field records are too numerous to present completely here, some of the outstanding data and a summary will be given for currents measured in tower legs, tower-top lightning rods, tower arms, counterpoises, and ground wires, and the 4-years' data condensed and correlated so far as space permits.

A knowledge of lightning currents, both in the stroke itself and in the tower structures, was early recognized as most valuable as an aid to the study of lightning performance of lines. Therefore, the field setup was planned to obtain current readings in the lightning stroke by various means and in the tower structures by measurements in the tower legs close to the ground line.

### Currents in Tower Legs and Lightning Stroke

A summary of currents obtained in legs on single towers for the 4 years is given in table III. It may be observed that over 150 observations of currents in excess of 10,000 amperes, 14 in excess of 50,000 amperes, and 2 between 90,000 and 100,000 amperes were made. Such data have been used in the past in combination with individual tower-footing resistances to indicate the maximum potential of the tower, and from that the possibility of flashover under lightning conditions has been predicted and in many cases verified.

In determining the lightning current in the stroke itself, 3 different methods of attack have been used. The first consisted of a summation of lightning currents in

† Measurements on one leg.

adjacent towers which appeared to be affected by one lightning disturbance. A summary of these data for the 4 years is shown in table IV. Here 31 stroke currents in excess of 50,000 amperes, 12 in excess of 100,000 amperes, and a maximum of 220,000 amperes for the stroke are indicated. The second method of determining current in the lightning stroke was by direct measurement in the tower-top lightning rod mounted at the tower top with suitable measuring instruments. Here the current in the stroke is measured directly. Data for the 4 years obtained in this way are shown in table V. The currents by this method of determination run much lower, the maximum current recorded being 50,000 amperes. The third and partially direct method, although not carrying with it the certainty of the direct measurement in the lightning rod but still probably having more justification than the addition of currents in the adjacent tower legs, is the method of adding current readings in a ground wire section as recorded at adjacent towers under conditions where the lightning stroke appears to have hit the ground wire in mid-span and has flowed in both directions to adjacent towers. Adding these currents at each end of the affected spans gives a value of the total lightning-stroke current. These data are given in table VI. These in a single year's observation on one line show 7 records in excess of 50,000 amperes and 1 in excess of 100,000 amperes, the maximum being 110,000 amperes. The stroke currents obtained by each of these 3 methods have been plotted in curve form in figure 2. A curve representing the average of these 3 methods of determining stroke current has been plotted here also and another showing the single tower currents tabulated in table III. It is particularly interesting to compare the last curve with the curve of average total stroke current.

## Lightning Currents in Counterpoises

The indicated benefits of counterpoises both by theory and, to some extent, by practice has led to a search for actual field data to show what was taking place in these buried conductors under lightning conditions. Field setups were therefore made to measure currents at various points along the counterpoise length. The particular counterpoises used on the Glenlyn-Roanoke line consisted of 2 long (150 feet) buried wires parallel to the line and 2 40-foot buried wires at right angles to the line. Current measurements on the long counterpoise were made on both ends and in the middle, and on the short counterpoise at both ends (see figure 1). The current distribution in these counterpoises is shown in figure 3, in percentage of the current measured in the long counterpoise at the point close to where connected to the tower. Figure 3 shows that the long counterpoise carries on the average approximately 4 times as much current as the short counterpoise as measured at the tower leg. At a distance of 40 feet which, in this case, is the end of the short counterpoise, the long counterpoise is carrying 6 times the current measured in the short counterpoise. It will also be noted that the current on the end of the short counterpoise is approximately the same, on the average, as that at the end of the long 150-foot counter-

poise, although in 3 cases the current at the far end of the long counterpoise is in excess of that entering the short counterpoise at the tower. The greater effectiveness of the long counterpoise in discharging current to ground is indicated clearly by the data.

It was expected in the initial field instrument setup that a relation would be found between the currents measured in the tower legs and those measured in counterpoises. Currents measured in counterpoises and the tower leg to which they were attached have been plotted as frequency-magnitude curves in figure 4. The surprising features shown by these data, are, first, that the current in the long counterpoise is apparently greater than that in its tower leg; the current in the short counterpoise is more along the expected lines, being less than that in its tower leg. This may be partially explained by the fact that measurements in tower legs were made in the main legs of the tower and the cross lattice bracing may have shunted some appreciable part of the tower current past the measuring instrument. If this explanation for the larger current in the counterpoise than in the tower leg is correct then the individual tower leg currents shown in figure 2 would be considerably greater than indicated, which would bring that curve even closer to the curve of average lightning stroke currents in figure 2.

Typical data on current values in tower legs and counterpoises are given in table VII. These data show that although the ratio of currents in tower legs and counterpoises is remarkably constant in some cases from year to year or between one observation and the next one, there

*C*—Bottom arms (57 records)
*D*—Arms with flashover (66 records)
*E*—Arms with no flashover (124 records)

are nevertheless many cases where a wide range of ratios exists. Thus, the table which gives the records at 9 towers which were subjected to a lightning disturbance from 2 to 4 times in the 3 years during which the observations were made, it will be seen that at tower 18*R*, for example, the ratio of current in long counterpoise to that in tower leg varied only from 1.65 to 1.47. At tower 21*G* the variation was from 1.09 to 1.39. Conversely, at tower 10*G* the variation ran from 0.55 to 2.28. Although it may be suggested that counterpoise and even tower leg resistances may have changed within a period of 2 years, it is, however, significant that ratios of from 2 to 1 for the long counterpoise current to tower leg currents, and from 3 to 1 for ratios of short counterpoise currents to tower leg currents have been obtained in the same year at the last mentioned tower, that is, 10*G*. It is suggested that these different ratios of current division between tower leg and counterpoise at a given location may be due to some extent to the difference of wave shape of the initiating lightning surge.

To aid further, an analysis of the current distribution in tower legs and counterpoises the data in figure 5 are presented. Here the ratio of current in the counterpoise to that in its tower leg has been plotted against the ratio of conductance of the same counterpoise to the same tower leg. The conductance of the tower leg has been calculated from the tower footing resistance measured before counterpoises were installed, (the tower, of course, being disconnected from the ground wire) on the assumption that the resistance of each tower leg footing was equal, that is, the resistance of one tower leg was 4 times the measured resistance of the 4 legs of the towers. The "shotgun" diagram of figure 5 does not permit drawing curves with any high degree of certainty. However, a characteristic trend is definitely indicated both for the long counterpoise and the short counterpoise.

If it is assumed that the current distribution in the ground at the foot of the tower is on the basis of measured resistance only, then the current division should be proportional to the conductance of tower leg and counterpoise. Such a distribution of current is shown by the dotted curve in figure 5. An examination of that curve

and of the 2 others in figure 5 seems to indicate that the short counterpoise apparently behaves very closely along the lines expected from a straight d-c characteristic, but that the long counterpoise carries considerably more current than can be explained from the standpoint of a d-c characteristic. It is recognized that the data shown in figure 5 are perhaps too erratic to permit definite conclusions, but the general trend seems to be indicated.

### Tower Potential

In the past in analyzing field records of currents in towers, a procedure of multiplying tower current by the tower resistance was frequently employed to indicate potentials which could be compared with line insulation flashover and thus determine whether or not insulator assemblies should have been expected to flashover under the conditions encountered. In the authors' investigation work, in general, high tower potentials obtained in this way have almost, without exception, correlated with flashovers at towers carrying these high potentials. There are on record, however, a few cases where flashover marks have been found on insulator assemblies and high tower potentials were not obtained by the method of calculated *IR* drop outlined here.

With the values of tower footing resistances and counterpoise resistances known, it is possible from the data obtained to make a comparison between the *IR* drop in the tower footing and the *IR* drop in long counterpoise and short counterpoise. This interesting comparison is given in table VIII. Columns 9, 10, and 11 give the voltage comparisons by these 3 methods of analysis. It may be noted that there is no regular consistency in the tower voltages indicated, although frequently there is very good agreement between the readings obtained by 2 methods, but the third method is distinctly out of line. There are, of course, a number of variables which cannot be evaluated readily and it seems that some of these will have to be investigated further before any general agreement can be reached as to the accuracy of determining tower potentials by any of these 3 methods.

### Tower Arm Currents

At the start of this work in 1933, in concentrating on the measurement of lightning currents, the surge-crest ammeter was recognized as a device which, when located on tower arms, had the possibility of indicating whether or not insulator assembly flashover had taken place.

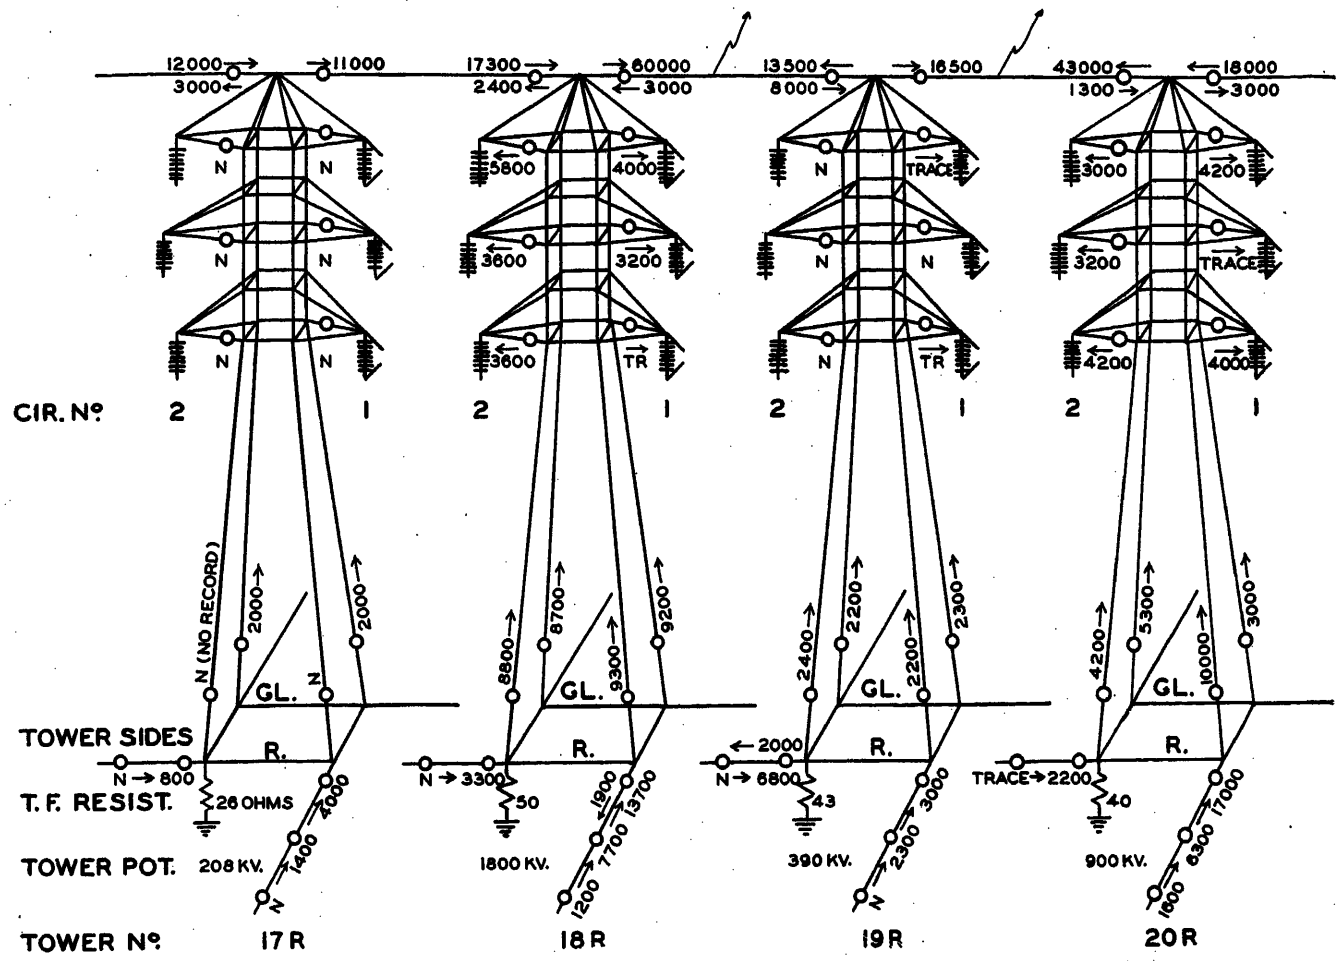

**Fig. 8. Lightning currents measured in towers of 132-kv Glenlyn-Roanoke line, August 31–September 16, 1936**

The original application was made primarily for this purpose. As the work progressed, however, it appeared that it was possible to obtain calibrated current readings, and the records have been gone over and correlated on this basis. The summarized data on current readings in tower arms are shown in figure 6. The outstanding point brought out by this group of curves is that the currents in the top tower arms were the highest, in the lower arms the lowest, and in the middle arms slightly greater than in the bottom arm but considerably less than

in the top arm. It may also be noted that the solid curve of figure 6, which shows arm currents where flashovers of insulator assemblies were known to have occurred, accounts for currents as high as 26,000 amperes and as low as 4,000 amperes.

It is definitely known that tower-arm currents as low as from 3,000 to 5,000 amperes have been recorded in the field both with and without indication of insulator flashover. These can be accounted for even without line flashover, on the basis that the tower leg at the arm location is shunted by the arm and its hanger bar. This consideration leaves somewhat uncertain the interpretation of tower arm currents. High arm currents, in the order of from 10,000 to 26,000 amperes, were recorded in 1936 in only 5 cases, of which 2 instances were on flat-top towers without ground wires (of which there were 4 on the line). It is believed the remaining 3 cases were caused by direct strokes to the line conductors. This interpretation of tower-arm currents indicates a high degree of shielding afforded by the single conventional ground wire.

### Ground Wire Currents

Measurements in the ground wire itself at each side of a tower were first obtained this year. Typical readings of currents in the ground wire are shown in table VIII, column 8. Currents above 20,000 amperes and their distribution have been tabulated separately in table IX. The highest current measured in the ground wire, it may be seen, was 66,000 amperes but there are 25 records of currents above 20,000 amperes. If currents of this magnitude are to be expected in wires of a transmission system subject to lightning, serious consideration must be given to keeping currents of such magnitude out of stations if station apparatus is to be protected. Also, consideration must obviously be given to the ability of protective devices to handle lightning currents of this magnitude, since these are considerably in excess of what has ordinarily been considered possible to reach a station where pre-station voltage limitation is provided for by steel tower construction and limited insulation for a reasonable distance beyond the station. Again, currents of this order, if they are to be taken as traveling waves associated with line surge impedance, indicate voltages far in excess of values which could exist on the line without flashover. There is room, therefore, in this connection for further research.

### Typical Field Records

Typical field records showing currents obtained in tower legs, arms, ground wires, lightning rods, etc., have been charted in figures 7 and 8, and a close study of these, it is believed, will prove fruitful. It is from records of this type that the data summarized, presented, and discussed in this paper have been obtained. The double-reading indications on the ground wires in both figures are obtained from a proper calibration of the surge-crest-ammeter records; the reverse directions of current flow apparently indicate reflections of current. In general, such current oscillations are absent or of small magnitude in tower legs, arms, and in counterpoise readings except in the last where they are sometimes encountered in combination with high current values.

## Summary and Conclusions

Based on the field data obtained on lightning currents during the past 4 years, part of which has been presented in this paper, the following conclusions seem definitely warranted:

1. Although lightning stroke currents as high as 220,000 amperes have been indicated, it appears that the maximum stroke currents

# Tooth-Frequency Eddy-Current Loss

By PAUL NARBUTOVSKIH
ASSOCIATE AIEE

**A method of recording, by means of an oscillograph, the eddy currents in various parts of the cross section of a squirrel-cage-rotor bar is presented in this paper. From such records the magnitude of the power loss caused by eddy currents, and its variation with load, may be determined. A series of tests of this nature has been made; the results, which the author believes to be correct in general, show that the change of eddy-current loss with load is negligible, thus simplifying the determination of the composite stray-load loss of a squirrel-cage induction motor.**

THE eddy currents in a squirrel-cage rotor bar may be measured by a method that occurred to the author some time ago; the method permits recording by means of an oscillograph the current flowing at any particular point of a conductor cross section, if the cross section and the distribution of the current density in it remain substantially uniform throughout the portion of the conductor length along which the current flow is studied. A bar of a squirrel-cage rotor essentially satisfies these requirements, being of a uniform cross section, and having a uniform distribution of the current density, at least through the stacked-iron length of the bar.

At normal operating conditions the frequency of the fundamental working current in the bar is so low that the effect of the fundamental-frequency leakage flux upon the distribution of the current density throughout the bar cross section is negligible; that is, the main current is distributed almost uniformly throughout the cross section of the bar. This main current, however, is not by any means the only current flowing in the bars. Part of the fundamental air-gap flux passes through the slots, and hence through the conductors, and the pattern of this slot leakage flux pulsates at the frequency of the passing stator teeth.[1,2] As a result of this, tooth-frequency eddy currents are produced in the rotor bars, the amplitudes reaching a very substantial value in some parts of the bar cross section, as shown by observation. The method of recording such currents by means of an oscillograph, to be described later, provides a means of studying the current distribution in the bars and an experimental measurement of the attendant power loss. The determination of this power loss, its variation with load, and the study of factors causing its variation with load constitute the subject of this paper.

## Results and Conclusions

The machine used for the experiments was a squirrel-cage motor, rated at 10 horsepower, 220 volts, 60 cycles, 1,200 rpm. The number of teeth in the stator was 72; the number of teeth in the rotor, 37. The shape of the rotor and stator punchings is given in figure 1, together with the dimensions of the rotor-bar section.

As should have been expected on the basis of A. B. Field's[3] and J. J. Thomson's[4] theories, the amplitude of the eddy currents was found to be a maximum on the surface of the bar (nearest to the air gap), decreasing rapidly with distance from the surface in the interior bar. The maximum amplitude of the tooth-frequency eddy-current density on the surface was several times greater than the main working current density. In spite of this, the power loss caused by the tooth-frequency eddy currents was found to be considerably less than the copper loss caused by the fundamental working current, because the region of the high eddy-current density is limited to a comparatively thin surface layer of the conductor facing the air gap.

The actual magnitude of power loss caused by tooth-frequency eddy currents, based on oscillographic records, was 27 watts. The copper loss caused by the main current, using the amplitude obtained from the oscillographic records, was computed to be 87 watts; as obtained from slip measurement, it was 85 watts. The values of the fundamental current loss were computed as a check upon the correctness of results obtained from the oscillograms.

The magnitudes of the tooth-frequency power loss just given remained substantially unchanged as the load was applied. If any change with load was observed in the particular motor tested, it was a decrease instead of an increase. Considering that the total power input to the motor at full load was approximately 10 kw, the tooth-frequency eddy-current loss constituted about 0.3 per cent of the power input at full load. Though this quantity itself is not entirely negligible, any observed change of it with load was much too small to be of any practical importance. The significance of this conclusion is obvious, for no convenient method of testing a motor for the change of this item with load is available. A possibility of neglecting it simplifies the problem of testing for the stray-load loss.

Though no experimental data on other motors is

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted September 14, 1936; released for publication November 6, 1936.

PAUL NARBUTOVSKIH is a teaching assistant in electrical engineering at Stanford University, Calif.

1. For all numbered references, see list at end of paper.

available, this conclusion very likely applies to all motors in general. There is every reason to believe that the tooth-frequency eddy-current loss in other motors has a relatively lower value than in the motor tested, for the latter had very thin rotor-tooth shoulders, and shallow slots, with a consequent large area of bar surface facing the air gap, where the eddy current density is particularly large.

## Method of Measurement

The method of recording the current flowing at any point of the bar cross section, can be explained

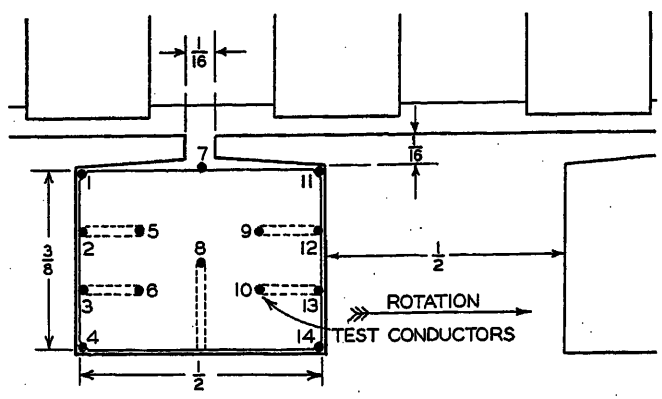

**Fig. 1. Diagram showing dimensions of stator and rotor teeth and location of test conductors**

Dimensions are in inches

with reference to figure 2. It requires placing an insulated test conductor $a$—$b$, within the bar material, and at that point of the bar cross section where the current to be recorded flows. One end of the test conductor $a$ is connected directly to the oscillograph, and the other end is connected to the rotor bar at point $c$. Point $d$ of the bar is the terminal of the other lead to the oscillograph. The instantaneous voltage appearing between leads $a$ and $d$ can be shown to represent correctly the density of the instantaneous bar current flowing along path $a$—$b$, that is,

$$e_{ad} = K\delta_{ab}$$

where $e_{ad}$ is the voltage between leads $a$ and $d$ and $\delta_{ab}$ is the instantaneous current density along path $a$—$b$. This follows from consideration of the equation giving the total electric potential between points $a$ and $d$

$$e_{ad} = \int_{abcd} \left[ K_\varphi \frac{\partial B}{\partial t} \sin \beta + \delta\rho \cos \gamma \right] dl$$

where

$B$ = magnetic flux density along the path of integration
$\beta$ = angle between the direction of the magnetic flux and the path of integration
$\delta$ = current density along the path of integration
$\gamma$ = angle between the direction of current flow and the path of integration
$\rho$ = resistivity of the material

The subscript below the integral sign indicates the path along which the integral is taken. This integral can be divided into 2 parts:

$$e_{ad} = \int_{abc} [X]dl + \int_{cd} [X]dl \tag{1}$$

in which $X$ denotes the quantity inside the brackets in the previous equation. The first term is taken along the test conductor and the second along some path within the bar. The path $c$—$d$, being arbitrary, can be taken along the surface of the conductor from $c$ to $b'$, then alongside the test conductor from $b'$ to $a'$, and on the surface from $a'$ to $d$. The end surfaces of the bar are outside any magnetic influence and the current density along them is zero; therefore, all points of these surfaces are at the same magnetic potential. Hence, the integral along these surfaces will disappear, and

$$\int_{cd} [X]dl = \int_{b'a'} [X]dl$$

taken in the immediate vicinity of the test conductor in the bar material.

Considering now equation 1 again

$$e_{ad} = \int_{abc} [X]dl + \int_{b'a'} [X]dl$$

$$= \int_{abc} K_\varphi \frac{\partial B}{\partial t} \sin \beta dl + \int_{abc} \rho\delta \cos \gamma dl +$$

$$\int_{b'a'} K_\varphi \frac{\partial B}{\partial t} \sin \beta dl + \int_{b'a'} \rho\delta \cos \gamma dl \tag{2}$$

Since the paths $a$—$b$ and $b'$—$a'$ are in the immediate vicinity, and neglecting the integral along $b$—$c$,

$$\int_{ab} K_\varphi \frac{\partial B}{\partial t} \sin \beta \cdot dl + \int_{b'a'} K_\varphi \frac{\partial B}{\partial t} \sin \beta dl = 0 \tag{3}$$

Also, if the circuit of the test conductor is linear, with impedance $Z$, and current $i$ taken by the oscillograph,

$$\int_{ab} \rho\delta \cos \gamma dl = -iZ \tag{4}$$

The use of equations 4 and 3 reduces equation 2 to

$$e_{ad} = -iZ + \int_{b'a'} \rho\delta \cos \gamma dl$$

When the distribution of current density is uniform along the bar, $\delta$ is constant, $\gamma = 0$, and this expression reduces to

$$e_{ad} = -iZ + \rho\, \delta_{b'a'} l \tag{5}$$

$\delta_{b'a'}$ being the current density in the bar along the test conductor. The condition of uniformity of the distribution of current density is fulfilled along the

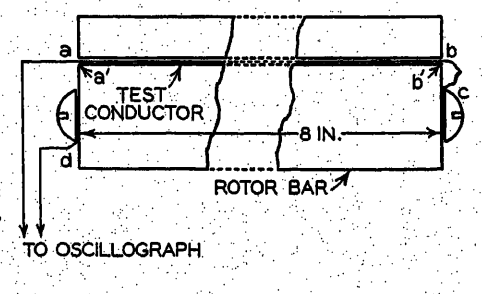

**Fig. 2. Sketch of the device used to detect eddy currents in various parts of the cross section of a rotor bar**

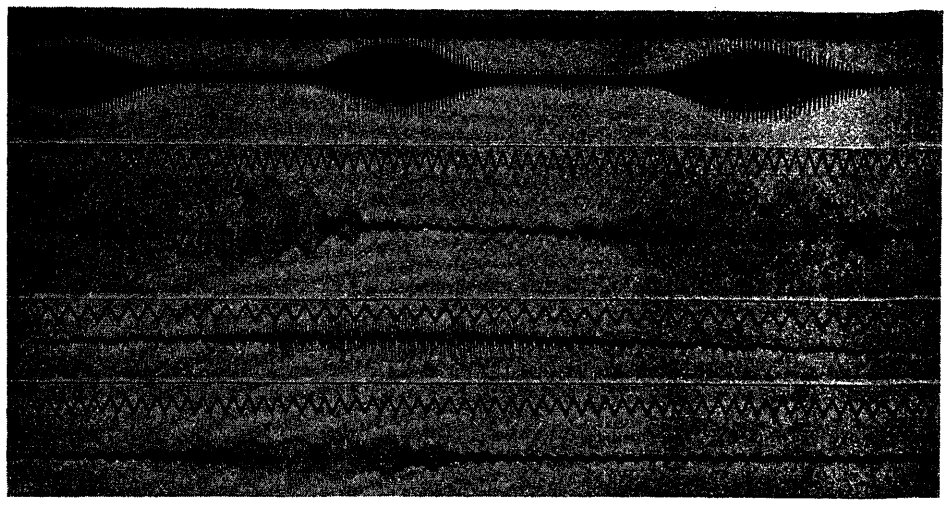

**Fig. 4. Oscillograms of tooth-frequency eddy currents in the trailing outer corner of a rotor bar for various conditions of operation**

*D*—Motor load with bar disconnected

major part of the bar length. The ends of the bar near and beyond the length of stacked iron undoubtedly introduce a slight irregularity in the resultant voltage, but the effect of this irregularity cannot be important practically.

The use of a vacuum-tube amplifier was found to be necessary to record the voltage $a$—$d$ on the oscillograph. This further simplified equation 5, for $i = 0$ and

$$e_{ad} = \rho\delta b' a' l$$

This equation merely states that the voltage between points $a$ and $d$ is proportional to the current density in the bar along $a$—$b$.

For the purpose of the present study 14 conductors were placed in one rotor bar, 9 of which were located at different points on the surface, and 5 inside of the bar. The location of the test conductors is given on figure 1.

To place the conductors inside the bar, slots 25 mils wide were milled as indicated by the dotted lines on figure 1 to the depth at which the test conductors were to be placed. A steel piano wire of a diameter slightly larger than number 26 enamel-insulated copper wire, used for the test conductors, was then placed at the bottom of the slots, and the slots were filled with sheet copper, soldered to the walls of the slots. After pulling out the steel wire, very fine canals were formed parallel to the axis of the bar, just large enough to place the test conductors inside without injuring the insulation. This method of placing the test conductors inside of the bar impares somewhat the homogeneity of the bar material. It is doubtful, however, that the effect can be appreciable, for the layers of solder introduced were extremely thin.

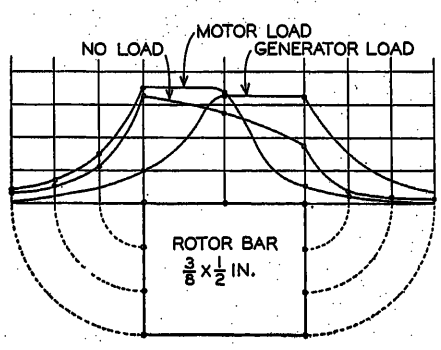

**Fig. 3. Diagram showing distribution of the amplitude of tooth-frequency eddy currents on the surface of a rotor bar**

The scale of amplitude is in hundredths of an inch

With the 14 test conductors a series of oscillograms was taken, one set of 3 different conditions of operation for each of the test conductors. These conditions of operation were:

1. No load, motor idling on a line at rated voltage.
2. Approximately full motor load at rated voltage.
3. Generator load at rated voltage, with the slip the same as for the second test.

The general character of the eddy current wave can be obtained from the reproductions of some of the oscillograms given in figure 4.

## Effect of Load

Before considering the power loss caused by the tooth-frequency eddy currents, it seems advisable to understand the factors producing a change in this loss as the motor is loaded. The only factor producing the tooth-frequency flux pulsation in the rotor slots at no load is the tooth-frequency component in the permeance distribution along the stator periphery. When the motor is loaded, the load currents produce an additional component of the tooth-frequency flux, because of the tooth-frequency component in the distribution of the magnetizing force along the stator periphery. As a result, the amplitude of the tooth-frequency pulsations may be expected to increase with load.

Actually the situation is considerably complicated by the effect of saturation of the rotor-tooth shoulders, produced by the combined effect of the rotor leakage flux and the main air-gap flux of the machine. The observed distribution of the eddy-current density for different load conditions can be seen from the oscillograms of figure 4 and also from figure 3, which gives the distribution of the eddy-current density on the surface of the bar, obtained from the oscillograms. An almost symmetrical distribution for no load becomes greatly distorted when the machine is loaded either as a motor or as a generator, but the character of distortion is different in the 2 cases. For motor operation, the amplitude of the tooth-frequency eddy current is increased in the region of the trailing

corner of the bar and greatly decreased in the leading corner. For generator operation, the effect is reversed: the amplitude is greatly decreased in the trailing corner of the bar, and increased in the leading corner. This difference between motor and generator operation immediately suggests the explanation of the phenomenon, which can be readily understood with reference to figure 5. This illustration shows the relative direction of the main flux and rotor-leakage flux in the rotor-tooth shoulders. As can be seen from figure 5*a*, when the machine is operated as a motor the leading (with respect to the center of the bar) tooth shoulder operates at a lower flux density than does the trailing tooth shoulder, for the main and rotor leakage fluxes here oppose each other. As a result of this low flux density, the leading tooth shoulder acts as an effective magnetic shield, reducing the influence of the tooth-harmonic flux in the leading

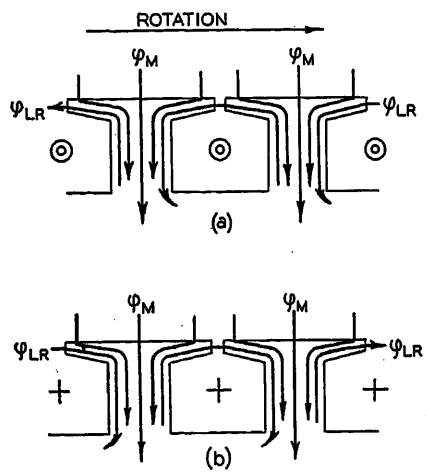

**Fig. 5. Diagrams illustrating the effect of rotor leakage flux and main flux upon the magnetic saturation in the rotor-tooth shoulders**

(*a*)—Machine operating as a motor
(*b*)—Machine operating as a generator
$\phi_M$—Main flux
$\phi_{LR}$—Rotor leakage flux

corner of the bar. The trailing tooth shoulder, on the contrary, operates at a high flux density and therefore produces little or no shielding effect. When the machine is operated as a generator the direction of the leakage flux reverses with the resultant reversal of the effect in the leading and the trailing corners of the bar. A conclusive proof of the origin of the redistribution of eddy-current density with load is obtained by operating the machine with the test bar disconnected from the short-circuiting ring at one end, thus preventing the main current from flowing. Under this condition the effect was found to disappear, because the leakage flux had been largely eliminated.

For the particular motor used the effect of saturation in the tooth shoulders was pronounced, as can be seen from figures 3 and 4. The net change of power loss produced by the effect may be either an increase or a decrease, depending upon the design of the punchings and the conditions of operation. Without attempting a rigorous analysis, the design of the punchings and the conditions of operation may be said to affect the eddy-current redistribution in the following way: When the shoulders are operated at a fairly high fundamental flux density, so that their shielding effect is small, the addition of the leakage flux may be expected to result in a decrease of the total eddy-current loss. This result may be expected because the increase of flux density in one of the shoulders will not reduce its shielding effect appreciably, being small already. On the contrary, a decrease in the flux density in the other tooth shoulder may bring it to a point of high permeability, and hence increase the shielding effect of the shoulder more than enough to offset the decreased shielding effect in the other shoulder in their common effect upon the eddy-current losses. The opposite result may be expected, if the main flux alone does not saturate the shoulders. The eddy current loss in the conductors remains low at all times, if the shoulders provide effective shielding at all loads, that is, when no saturation is caused even by the combined action of the main and the leakage fluxes.

## Method of Computation

For the purpose of computing the tooth-frequency eddy current loss in the rotor, using the observed current amplitude distribution, Field's equation, giving the distribution of the eddy current density inside of a solid piece of conducting material in terms of the current density on the surface, was employed:

$$\delta_x' = e^{-mx}\delta_s' \sin(\omega t - mx) \tag{6}$$

where

$\delta_x'$ = instantaneous current density at a distance $x$ from the surface along a normal
$\delta_s'$ = current density on the surface

$$m = 2\pi\, 10^{-4}\sqrt{\frac{\mu f}{10\rho}}$$

$\mu$ = permeability of the material
$f$ = frequency of the eddy currents
$\rho$ = resistivity of the material

This equation states that the eddy-current density distribution along distance $x$ normal to the surface has a character of an attenuated wave. For the purpose of this analysis, only the total amplitude variation with $x$, instead of the instantaneous value of $\delta_x'$ is of importance. This is obtained by dropping the function $\sin(\omega t - mx)$, which reduces equation 6 to

$$\delta_x = \delta_s\, e^{-mx} \tag{7}$$

where $\delta_x$ and $\delta_s$ denote the total amplitudes of the eddy currents at a depth $x$, and at the surface, respectively.

Equation 6 is developed for the following conditions: (1) uniform phase and amplitude of $\delta$ on a plane surface; and (2) a piece of material thick enough to allow the eddy-current wave to disappear largely before it reaches another boundary surface, that is, there is an absence of reflections of the wave within the conductor.

The first of these 2 conditions is not realized in the actual case observed. This fact is accounted for later in the application of equation 6. The second condition is sufficiently realized for the observed eddy current amplitude attenuates with sufficient rapidity to obviate any appreciable effect of reflections. In

# Reactance of End Connections

By J. F. H. DOUGLAS
MEMBER AIEE

**Use of image conductors in iron, of Rayleigh insulating partitions, and of images of conductors in these partitions is shown in this paper to afford one possible line of attack on the problem of the reactance of the end connections of electrical machinery. The use of 2 other methods to reduce the field in the end zone to a basis where Ampere's equation may be correctly applied is also suggested.**

THE PURPOSE of this paper is to suggest certain lines of attack upon the problem of end-connection reactance, which it is hoped will lead to more accurate formulas than are available at present. No completed solutions are given, because it is felt that the proposals should be discussed thoroughly before the details are filled in by calculation. In this way the path will be clearer for further research.

There are 2 methods of approach at present to the subject of end-connection reactance. The first consists in supposing the poles, armature, iron, and slot conductors removed, and the end-connections joined. On this basis, Ampere's equation may be applied and formulas for the specific permeance of self-induction per centimeter of end turn found. These expressions are of the type

$$P' = 0.2 \log_e \frac{D}{r} + C \qquad (1)$$

In this equation $D$ is the diameter of a circular or the side of a square end-connection, $r$ is the geometric mean radius of the coil, and $C$ is a constant depending on the form of the coil and may be approximately from $-0.05$ to $-0.10$.

A second line of approach is to assume a potential function over the surface of the end-connections of the form

$$V = M \sin (\pi x/A) \cos (\pi y/B) e^{-Cz} \qquad (2)$$

In this equation $A$ is the pole pitch, $B$ is the axial length of both end connections, and $C$ is chosen to satisfy Laplace's equation. The $x$ co-ordinate is measured parallel to the circumference, $y$ parallel to the shaft, and $z$ along a radial line. The origin is at the intersection of the armature surface, the point of reversal of magnetomotive force, and a plane perpendicular to the shaft and flush with the pole ends.[1]

It will appear from the discussion that both of these lines of approach are equivalent to an erroneous placement of a Rayleigh flux partition perpendicular to the shaft and flush with the pole ends. The second equation also implies a Rayleigh conducting partition placed perpendicular to the shaft and at the ends of the armature winding.

The assumptions made in this paper are as follows: Ampere's law may be applied to determine end-connection fields, provided image conductors are assumed in certain Rayleigh conducting and insulating partitions. When a plane iron surface is slotted, and there is a difference of magnetic potential across the gap thus formed, the gap may be closed with a fictitious conductor carrying current opposite to the currents establishing that difference of potential. The Schwarz - Christoffel theorem may be used to transform certain known fields into other new and useful fields with different boundary shapes. Rayleigh insulating partitions may be placed perpendicular to the shaft only so as to join the edges of the pole in the interpolar regions. Radial Rayleigh insulating partitions may be placed at the edges of the poles so as to divide the end zones into polar and interpolar regions.

## Inductance and D-C Machines

Figure 1 shows several examples of conductors near iron. The symbol $S$ is used to denote stator iron, $R$ rotor iron, $P$ polar iron, $Y$ yoke iron, and $A$ armature

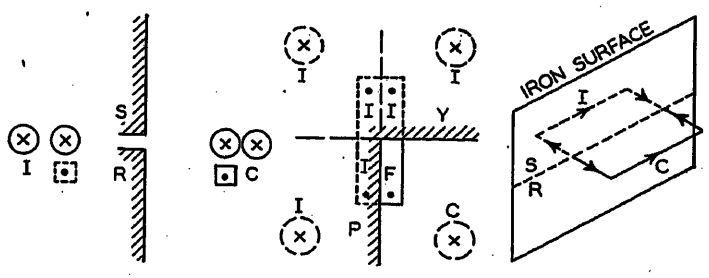

**Fig. 1. Image coils in iron**

iron. The symbol $C$ denotes an armature end conductor, and $F$ a field coil. By placing the image conductors $I$ as shown the iron surfaces may be eliminated because of the symmetry. The figure shows several important cases. At the left is shown a basis for the leakage inductance of an induction motor, in the center a basis for the inductance of a coil of a d-c machine undergoing commutation, and at the right the means in part for estimating open-circuit reactance of an induction motor. So far as these fields are 2-dimensional, reference may be made to

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted July 29, 1936; released for publication October 1, 1936.

J. F. H. DOUGLAS is associate professor of electrical engineering at Marquette University, Milwaukee, Wis.

1. For all numbered references see list at end of paper.

Hague,[2] who has developed the idea of image conductors in a number of cases.

Several examples of the use of a fictitious conductor *FC* to close an air gap and establish a required potential difference across the gap are shown in figure 2. The current must be equal and opposite to that in the other coil. There are image conductors in this case also, but for simplicity they are not shown. They are governed by the same rules as in figure 1. At the left in figure 2 is a basis, in part, for the estimation of the open circuit inductance of an induction motor; in the center is a basis for estimating pole-end leakage from a d-c machine; and at the right there is combined the left-hand picture of figure 2 with the right-hand picture of figure 1 as the complete picture of 2 coils co-operating to establish 2 iron surfaces at a definite difference of potential.

Figure 3 shows a conductor *C* in the corner between 2 perpendicular Rayleigh partitions. The plane *RI* is an insulating plane, while *RC* is a conducting plane. This gives rise to the image conductors as shown, and the inductance of this field may be found by Ampere's equation. The Schwarz-Christoffel[3] equation may be used to transform the field in the quadrant to that in the infinite half plane shown at the right. The equations applying to this case are

$$dz/dt = S\sqrt{t} \qquad t/a = (z/a)^2 \tag{3}$$

where $(z = x + jy)$ is the co-ordinates of any point in the $Z$ plane or left-hand figure, and $(t = q + js)$ is the co-ordinates of the corresponding point in the $T$ plane or right-hand figure. The inductances of the 2 fields are the same. The radius of the conductor is doubled, and the angle $\theta$ doubled in the right-hand figure. This boundary condition is useful in estimating inductance of end connections in one of the zones into which the field may be divided.

Figure 4 shows 2 current elements symmetrically located on either side of a plane surface. The figure shows the elements, a point $P$ on the plane of symmetry, the radii vectors from the elements to the point $P$, and the angle between the elements and the radii vectors, all in orthographic projection. Two cases are shown establishing conditions for the plane of symmetry being respectively a Rayleigh insulating and a Rayleigh conducting plane. It is the basis for establishing image conductors for the 3-dimensional case.

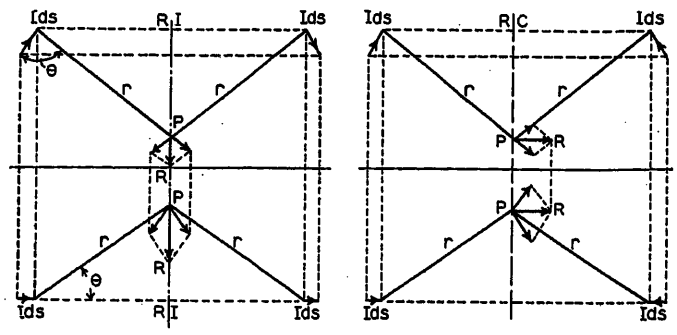

**Fig. 4. Ampere's law and Rayleigh planes**

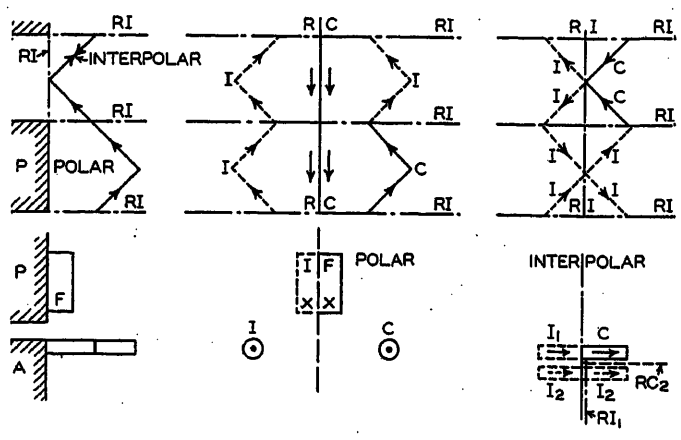

**Fig. 5. Image conductors, direct reaction**

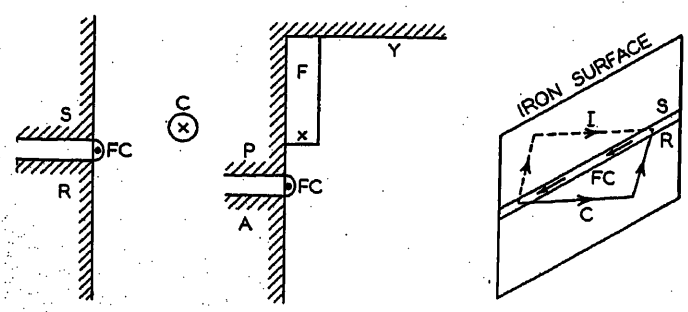

**Fig. 2. Fictitious conductor closing gap**

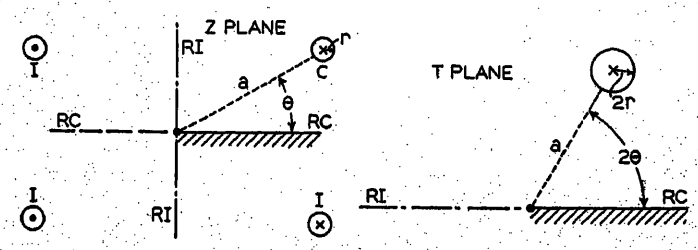

**Fig. 3. Rayleigh planes and conformally transformed field**

## Synchronous Machines

In figures 5 and 6 the end connection field of a synchronous machine is analyzed and methods of computing inductance are established. In figure 5 directly magnetizing conditions are shown, and in figure 6 transversely magnetizing conditions are shown. At the left of both figures the poles, the interpolar spaces, and the armature iron, as well as the field and armature coils, are shown in orthographic projection. Also shown are assumed insulating Rayleigh partitions, dividing the end connection zone from the zone over the armature surface, and dividing the end-zone into 2 regions, namely a polar zone, opposite the polar iron, and an interpolar zone opposite the interpolar regions. Although these assumed planes cramp the flux, it is believed that less error results from them than from those used as the basis of present formulas. The insulating Rayleigh planes are designated by the symbol *RI*. The iron surfaces constitute Rayleigh conducting planes.

In the center and right-hand parts of figure 5 the Rayleigh partitions, the coils of the armature and

All iron surfaces are made of insulation in model

field designated by $C$ and $F$, and their images are shown. In the center figure the image system for the polar zone is shown, and in the right-hand figure the image system for the interpolar zone. In the elevation view of the interpolar zone an inconsistency may be noted, caused by the vertical plane being in part an insulating, and in part a conducting plane. This may be resolved in 2 ways. If the line $RI$ is assumed to be drawn adjacent to the armature too small an inductance is obtained, but there is the image system $I_1$ which can be calculated. On the contrary, if a Rayleigh conducting plane $RC_2$ is placed just under the armature conductors, the image system $I_1$ and $I_2$ is obtained which gives an inductance approximately twice as great as the former, and which is too large. A compromise value will therefore be subject to an uncertainty of 33 per cent. It is hoped that discussion may show the way to a better solution of this particular zone.

In figure 6 there is at the left the orthographic projection of the machine structure, together with assumed Rayleigh insulating partitions. In the center is the image system in the polar zone and in the right hand part is the image system in the interpolar zone. In this case, in the polar zone, it is necessary to introduce the artifice of the fictitious conductor for closing the gap and establishing the needed difference of potential across the gap, between the polar and armature iron. In the elevation at the right it may be noticed that the image of $C$ is either $I_1$ or $I_2$ according to whether the line $RI$ or $RC$ is taken for forming the image. This case is really the Rieman surface which was resolved in the discussion of figure 3.

If the basic assumptions indicated here should prove valid, a program of research would include the evaluation of the inductance of single coils, groups of coils, and the effect of mutual inductance. This would be built up into combined coefficients for the 3 symmetrical components of current and for both the steady and the transient states.

The effect of variations in the boundary conditions such as those caused by the proximity of iron of the frame, housing, and shaft may in some cases be resolved by the Schwarz-Christoffel transformation, but the greatest promise is offered by the use of an experimental method devised by Mullner.[4] In figure 7 is shown a diagram of a water tank in which the conjugate field of end connections may be set up, in the form of an electrokinetic analogue. The experimental arrangements include a brush electrode for a field coil, a circular rod for the armature coil, and the use of copper on the boundary for Rayleigh insulating partitions and of insulation on the boundary for Rayleigh conducting partitions.

A solution of the problem of end connection inductance is to be desired not only for its own sake, but also as an aid in estimating of losses caused by such fields in nearby metal.

## Lightning Currents in 132-Kv Lines

(*Continued from page 252*)

rarely exceed about 150,000 amperes. Only 10 per cent of the measured currents were in the range above 70,000 to 100,000 amperes.

2. Single-tower currents showed 100,000 amperes as a maximum, with 10 per cent of them above 45,000 amperes. Apparently fairly definite relationships between current magnitude and frequency of occurrence exist. Such data used in combination with tower-footing resistances are helpful in predicting the lightning performance of transmission lines.

3. Counterpoises in the order of 40 feet long are far less effective in discharging lightning currents to ground than longer counterpoises of say 150-foot length, the ratio of currents being in the order of 1 to 4 respectively at the point of attachment to the tower.

4. The short counterpoise not coupled with the line discharges

lightning currents in a manner closely following its expected performance from the standpoint of its ohmic conductance to ground. The long counterpoise, coupled with the line (underlying it), discharges currents of the order of twice this value, on the average.

5. Currents recorded in tower arms have yielded no conclusive data. It would appear that in view of the fact that only 3 records of currents were obtained in 1936 in excess of 10,000 amperes, under conditions attributable to direct strokes to line wires, that the present typical construction with one ground wire of the Glenlyn-Roanoke line is giving a high degree of shielding of the line wires. Two similar records were obtained at one point on the line, where for structural reasons the ground wire was absent.

6. The high currents measured in the ground wires (66,000 amperes maximum) indicate the necessity of adequate shielding of the line at station entrances. They also clearly show the need of knowing more definitely the characteristics of lightning-protective devices, in view of the possibility of much higher currents through these devices than have been considered in the past.

7. Previous field investigation work on lightning effects on electrical lines and equipment has yielded many valuable data which are useful in evaluating the factors affecting the operating performance of such equipment under lightning conditions.

The breaking down of the over-all picture of lightning on a line into its component parts, to determine the currents in the various parts of the electric circuit as covered by the planned investigation work presented in this paper, is beginning to give a clearer understanding of what is actually taking place in the various parts of the entire lightning circuit. The situation is steadily being approached where lightning currents in the electric system can be predetermined with some degree of assurance, which should be of paramount value in providing protection to lines and equipment and determining the duty on protective equipment. However, a great deal of the unknown remains to be explored.

## Tooth-Frequency Eddy-Current Loss

(*Continued from page 256*)

fact, it decays faster than is predicted by equation 6, which is probably a result of the phase difference between eddy currents at different points of the bar surface. It follows from this observation that the eddy-current loss computed on the basis of equation 6 will not be less than the actual value.

Using equation 7, the power loss per unit area of the conductor surface is

$$\frac{P}{bl} = \int_0^\infty \rho \left(\frac{\delta_x}{2\sqrt{2}}\right)^2 dx = \frac{1}{8}\rho\delta_s^2 \int_0^\infty e^{-2mx} dx = \frac{\rho\delta_s^2}{16m} \qquad (8)$$

where $b$ and $l$ are the width and length, respectively, of the conductor surface at which power loss $P$ takes place, and $\delta_s/(2\sqrt{2})$ is the effective value of the current density at distance $x$ from the surface. This equation requires 2 modifications before it can be applied to this analysis: (1) to account for the variation of the eddy-current amplitude that takes place at the frequency of the fundamental rotor current and its multiples; and (2) to account for the nonuniformity of the eddy-current amplitude on the surface of the conductor as given by figure 3.

The first of these conditions can be met approximately by assuming that the shape of the eddy-current wave is a pure sine wave, 100 per cent modulated by a fundamental-frequency sine wave given by a function

$$\delta = \delta_m \sin \omega_t t \cdot (1 - \sin \omega_r t)$$

$\omega_t$ being the angular velocity of the tooth ripple, and $\omega_r$ being that of the fundamental rotor current. This assumption introduces a factor into equation 8 equal to a ratio of power loss with modulated and unmodulated waves. The value of this factor is then

$$K = \frac{\frac{\omega_r}{2\pi}\int_0^{\frac{2\pi}{\omega_r}} \rho\delta_m^2 \sin^2 \omega_t t\,(1 - \sin \omega_r t)^2 dt}{\frac{\omega_t}{2\pi}\int_0^{\frac{2\pi}{\omega_t}} \rho\delta_m^2 \sin \omega_t t dt}$$

On the assumptions that the value of the ratio $\omega_t/\omega_r$ is large and is an integer, both of which are reasonable since the value of $\omega_t/\omega_r$ is of the order of 1,000 or greater, the value of $K$ reduces to

$$K = 0.113/0.5$$

To overcome the difficulty caused by nonuniformity of the distribution of current density on the surface, as an approximation the distribution of the eddy-current amplitude along any normal to the bar surface may be assumed to comply with equation 7. Measurements show that the amplitude within the bar is less than that given by equation 7; hence, the actual power loss is less than that computed on the basis of equation 7. Equation 8 therefore may be written in the form

$$\frac{d\left(\frac{P}{l}\right)}{db} = K\frac{\rho\delta_s^2}{16m}$$

The power loss per unit length of the bar will be

$$\frac{P}{l} = \int_0^b \frac{0.113\rho\delta_{sm}^2}{0.5 \times 16m}\, db$$

This integral was evaluated by numerical integration, using values of $\delta_{sm}$ obtained from figure 3. The result obtained, 27 watts for all the bars in the rotor at no load, probably is greater than the true value.

# First Report of Power System Stability

**The AIEE subcommittee on interconnection and stability factors* presents herein the first comprehensive review by an AIEE committee of the subject of stability, or successful parallel operation of a-c machines transmitting large blocks of power without loss of synchronism. A summary of principal installations made during the past 10 years which gives data on the various stability measures employed and a comprehensive bibliography are included.**

STABILITY, in the sense employed in this report, is concerned with the successful parallel operation of a-c machines as affected by the magnitude of power transmitted. While this problem has existed since the beginning of parallel operation, it is only within the past 10 to 15 years that it has assumed a position of major concern. During this period stability has received a great deal of attention in papers before the AIEE and in the technical press. The development of analytical methods for predicting power system performance has been followed by methods for improving stability. However, during this period the general subject of stability has not been comprehensively reviewed by any AIEE committee. Hence, this "First Report on Power System Stability" has been prepared for the purpose of reviewing the developments and of summarizing in so far as appears practicable the present status of the art in this field.

## Historical Review

The early problems of parallel operation were concerned principally with the phenomenon known as hunting. Prior to 1890 parallel operation of synchronous machines was accomplished in isolated instances. The problem did not assume importance until after the change from belted machines to engine-driven machines and from smooth to slotted armature construction. At about this time the necessity for parallel operation became general and the hunting problem approached serious magnitude. The cause was not well understood. It was variously ascribed to the presence of harmonic circulating currents, to the pulsating torque of the prime-movers, to the correspondence of the electro-mechanical period of the power system and the periodicity of the impulses of the prime-movers and to the improper design or functioning of prime-mover governors. Considering the complexity of these problems, particularly during the transient conditions involved in the hunting phenomena, it is not surprising that the state of the art at the time made exceedingly difficult the determination of the true cause of hunting. Probably the most successful method for minimizing hunting was the introduction of the damper winding proposed by LeBlanc in France in connection with alternators and independently by Lamme in the United States in connection with synchronous converters. Gradually the essential factors of the problem were understood and the question of harmonic circulating currents eliminated. In the first decade of the present century the problem ceased to be one of serious importance. The principal reason for this change in the situation was the introduction on a large scale of constant-torque type prime-movers in hydro-electric and steam turbines. The great increase in the size of the power systems made them inherently more stable and less subject to disturbances arising from the peculiar characteristics of an individual machine or application. However, the problem still existed in connection with special applications, such as those involving gas engine prime-movers or synchronous motor-driven compressors. It was also found that hunting was likely to be encountered with synchronous converters if the supply lines had a resistance drop of more than 15 per cent. During the last 20 years hunting has not been a serious problem considering the operation of power systems as a whole.

Another type of the general problem of parallel operation is one involving the ability to maintain synchronism both during steady-state or normal circuit conditions and during transient conditions, such as those arising from sudden increase in load, change in circuit condition, or occurrence of a short circuit with its subsequent clearing. This problem, commonly called the stability problem, is concerned with power limits and is distinct from the hunting problem which is characterized by periodic phenomena. In the early days it was recognized that synchronous and induction motors had very definite power limits. However, this was viewed as a machine problem; the corresponding system problem did not at this time receive consideration.

The methods for controlling voltage regulation were not well developed; the automatic tap changer under load, the feeder voltage regulator, the automatic generator voltage regulator, the use of synchronous condensers for voltage control were either not employed at all or not to the degree to which they are today. Consequently, the effort was directed to provide systems of good inherent regulation which was obtained generally by making lines and apparatus of low impedance. This practice to achieve good voltage regulation and the use of multiple circuits to minimize interruptions of service resulted in systems capable of transmitting relatively large amounts

A paper recommended for publication by the AIEE committees on power transmission and distribution, electrical machinery, power generation, and protective devices. Manuscript submitted November 2, 1936; released for publication December 2, 1936.

* Personnel of the AIEE Subcommittee on Interconnection and Stability Factors: R. D. Evans (*chairman*), S. B. Crary, A. P. Hayward, J. A. Koontz, A. A. Kroneberg, H. J. Scholz, F. V. Smith, and H. R. Stewart.

of synchronizing power with corresponding high power limits under normal operating conditions.

With the advent of the automatic voltage regulator and its application to condensers at the receiving end of long transmission lines it became possible to obtain good local regulation from a system which had high reactance and low synchronizing power. Thus it became practical to operate systems much closer to their steady-state stability limits. While this combination solved the voltage regulation problem, its exploitation in the course of time led to the transmission of large blocks of power per circuit and consequently to the stability problem.

Parallel with this development of long-distance straight-away transmission, interconnections of large power systems for economic and emergency purposes led to a different form of the stability problem. The character of the operation in this case depended very largely upon the properties of the tie line. Frequently these lines operated quite satisfactorily for steady-state conditions but in the event of a disturbance on either system, if the tie line were incapable of transmitting sufficient synchronizing power, instability would be inevitable. However, it was found that no difficulty was encountered except during severe faults if the systems were tied solidly together through tie lines designed to carry a large amount of load. Troubles were for the most part encountered on systems which were connected through fringes or through so-called "shoe string" lines. Interconnection to reduce cost and improve service reliability thus became a factor in the problem.

Concurrently, consideration was being given to the use of generator and bus reactors for the purpose of limiting the interrupting capacity required of circuit breakers. These layouts also affect system stability by decreasing the synchronizing power under conditions before and after the fault is cleared and by reducing the severity of the disturbances themselves during the fault condition.

About 1920 the work on the power circle diagram in connection with long distance power transmission focused attention to the margin of power between the operating point and the theoretical stability limit. This led to exhaustive tests, both in the laboratory and in the field, for establishing the characteristics of power systems under steady-state conditions and during transient disturbances. In 1925 a case of instability occurred on a long-distance high-capacity transmission system in which the system was operating under steady-state conditions while portions of the paralleling line were out of service for maintenance and repair. While the possibility of pull-out had been recognized before this experience, its occurrence nevertheless did stimulate further careful investigation of stability limits of long transmission systems. As a result of the interest in the subject and the development in the methods of calculating electrical systems, it was found that system oscillations during disturbances could be predicted with satisfactory accuracy by step-by-step methods. This has been substantiated by the data on power system oscillations obtained during (1) scheduled tests and (2) normal operation by means of automatic transient recording apparatus.

Attention was then directed toward methods for improving system stability including consideration of the power system layout and operation as well as features of the apparatus. As a result of this work a number of important changes in practice came about, concerning particularly the reactance of synchronous machines, the speed of response of excitation systems, and characteristics of automatic voltage regulators. The most successful modification of practice in order to improve stability has been the recent developments of high-speed circuit breakers and relays. Consideration has also been given to the control of all factors in the problem with a view to co-ordinating them to give the maximum improvement in stability at a minimum cost.

## Methods of Analysis

Parallel with the recognition of the importance of the stability problem the necessity arose for the development of methods for calculation. Thus about 1922 engineers seriously undertook to determine the stability limits of power systems; they set about the task of predicting the time variation of angle, power, and voltage quantities for all types of transient disturbances. Prior to this time the basic ideas relating the power, angle, and voltages of simple systems were understood but it was necessary to extend these basic concepts for the more complicated problems under consideration. An example of these extensions is the power circle diagram which was developed to include distributed capacity and general networks. The analytical work back of the circle diagram was extended, covering not only the case of 2 machines but 4 or more machine cases for which the circle diagram is not applicable.

The power circle diagram was early found to be of considerable value in pointing out maximum power limits and requirements in reactive kilovolt-amperes to maintain system voltages. It was also helpful in obtaining power-angle relations between 2 ends of a long line, particularly between points of maintained voltage.

Since the stability problem is so closely related to the characteristics of machines the next development was the extension of the Blondel 2-reaction method to include the transient performance of machines with salient-pole rotor construction.

Undoubtedly the most important analytical development in the general field of unbalanced polyphase problems is that of "symmetrical components." Applied to the stability problem, it became possible to calculate the distribution of current and voltage throughout the system during periods of unbalanced faults and also to determine the equivalent balanced positive-sequence impedance that should be placed at the point of fault to completely simulate in its action upon machine performance the particular unbalanced fault. In this connection it was necessary to develop methods of calculation and of test for the phase-sequence constants of lines and apparatus.

An interesting development of this period was the mechanical analogue, a mechanical equivalent of the actual electro-mechanical system, in which the principal generating units are replaced by small flywheels and the

system reactances by springs. By properly proportioning the elements of this system the angle-time variation of this equivalent will exactly duplicate the system performance quantitatively as well as qualitatively, thus indicating stability or instability for different kinds of faults. While the mechanical analogue has been used to some extent for the purpose of calculating system performance, its principal value has been its unique facility for visualizing the essential factors in the stability problem.

A very tedious and irksome part of the early stability calculations was the reduction of the actual system into an approximately equivalent network of a more manageable form, such as 2- or 3-machine problem. The construction and use of the network analyzer or a-c calculating board has eliminated much of this labor. By means of the a-c calculating board the entire system impedance diagram including the generating sources can be set up, thus representing in miniature the equivalent of the actual system. From this duplicate system the necessary constants may be obtained which will reduce a given system to the simplest number of impedance branches. The problem may be solved by a step-by-step method, either analytically or by the calculating board, using small intervals of time and adjusting by steps the phase position and magnitudes of the machine voltages as dictated by the simultaneous solution, considering the acceleration and inertia of all the machines. Mention should also be made of the integraph which has been employed in the production of general curves which have been used in the solution of specific stability problems.

The development of automatic recording equipment has provided an important source of information on power system performance. This equipment, which is of the oscillographic type, is capable of recording instantaneous variations in voltage, current, power, and phase angle quantities—including both phase quantities and their sequence components. The data obtained in this manner are useful in determining the margins in stability under operating conditions. These records are valuable in checking relay and circuit-breaker performance, and also in determining the character and location of the fault.

The most recent development affecting methods of analysis has to do with the determination of the machine constants to be used. It has been shown that saturation affects transient reactance and also certain other reactances used in transient stability calculations. Recently, work has also been done toward the determination of the appropriate values of reactance to use in steady-state stability calculations. The results of this work are being reviewed by a subcommittee of the AIEE electrical machinery committee.

In summarizing this review of the methods of analysis, it can be stated that the available methods are now considered to be satisfactory for determining the stability of a system under any assumed set of conditions. It is recognized, however, that for certain types of systems the present methods require analysis by a relatively large number of independent machines and this requires a considerable amount of work to cover a reasonable range of operating conditions.

## General Discussion of Factors Affecting Stability

In this report the stability terms are used in accordance with the following definitions:*

"Stability, when used with reference to a power system, is that quality of the system or part of the system which enables it to develop restoring forces between these elements equal to or greater than the disturbing forces so as to restore a state of equilibrium between the elements.

"Steady-state stability exists in a power system if it operates with stability when there is no aperiodic disturbance on the system.

"Transient stability exists in a power system if, after an aperiodic disturbance has taken place, the system regains steady-state stability.

"If automatic devices are used to aid stability their use should be indicated by the following phrases:

Steady-state stability with automatic devices.
Transient stability with automatic devices.

"The term, automatic devices, includes only those devices which are operating to increase stability during the period preceding and following a disturbance as well as during the disturbance. Thus relays and circuit breakers are excluded from this classification and all forms of voltage regulators included. Devices for inserting and removing shunt or series impedance may or may not come within this classification depending upon whether or not they are operating during the periods preceding and following the disturbance."

These definitions of stability terms recognize a distinction between stability with automatic devices, and stability by inherent action. While the general term includes both effects, it is the intention that mention should be made of automatic devices when used.

It is recognized that the definitions of stability are based upon viewing the problem as essentially one of equilibrium. In each synchronous machine there is a problem of equilibrium between the mechanical forces acting on machine shafts and the electrical forces acting on the machine windings. Thus in the synchronous generator there are the mechanical forces due to the prime-mover tending to accelerate the rotor and the electrical forces due to electrical output and losses tending to decelerate the rotor. In the synchronous motor there is the corresponding problem of equilibrium between the electrical input and the mechanical output and losses. If, in the process of maintaining equilibrium, synchronism is not lost, stability results.

The factors affecting the stability problem, therefore, include any which will affect the mechanical input (or output) and the electrical output (or input). Among the mechanical factors are the prime-mover input, the governor characteristics and inertia of rotating parts, and among the electrical factors are the characteristics of circuits including switching operations and apparatus including excitation systems and their voltage regulators, and load circuits including induction motors as well as static apparatus.

The above discussion indicates that there are many factors entering into the stability problem. Also, there are many ways in which these factors may be controlled to secure stability. The extent to which any of these

* These definitions are taken from the report of the subject committee on definitions of terms used in power system studies, presented at the AIEE winter convention, New York, N. Y., January 22, 1932.

factors are beneficial in improving stability is dependent upon the particular system under consideration.

This report is principally concerned with stability as affecting the operation of synchronous machines, such as a combination of a generator and a motor or 2 groups of synchronous generators with an intervening transmission line. The report is also principally concerned with the usual type of power system where parallel circuits are employed and a relatively high standard of service is required.

In general, the transient stability limit of a system is considerably lower than the steady-state stability limit. Hence, the transient stability limit is more important for the service and layout conditions normally encountered. In general, the basis of system design from the stability standpoint is predicated on the successful clearing of a particular type of fault in any line section. The type of fault considered is usually the double line-to-ground fault on transmission systems. However, single line-to-ground faults are sometimes considered for transmission systems and 3-phase faults for metropolitan systems. In a few situations single-circuit lines may be employed because service conditions permit the interruption of supply to the load or because the system layout is such as to permit the loss of an entire station output. In these situations the steady-state stability limit, of course, becomes of greater importance. However, even in such cases secondary circuit faults or abrupt load changes are likely to make the controlling stability limit a transient limit.

## Discussion of Specific Factors in the Stability Problem

A discussion will now be made of the effect of various specific factors in the stability problem. For convenience these will be arranged under 2 principal headings of (1) power system layout and operation and (2) characteristics of apparatus.

### Power System Layout and Operation

The stability characteristics of power system layouts should be analyzed for the 3 circuit conditions associated with the fault, *viz.*:

1. **Before the fault.**
2. **During the fault.**
3. **After the fault.**

Some features of layout are beneficial to stability for all 3 circuit conditions while other features are beneficial for one condition and detrimental for another; hence, the many features of power system layout must be weighed individually in connection with each circuit condition.

#### *Series Reactance*

The most obvious method of increasing the stability limit of a system is to reduce the transfer reactance or "through reactance" between synchronous machines as this directly increases the synchronizing power that may be interchanged between them. The reactance of a transmission line may be reduced by reducing the conductor spacing. Usually, however, the spacing is controlled by other features, such as lightning protection and minimum clearance to prevent an arc from one phase involving another phase. Another method of reducing line reactance is to increase the conductor diameter by using material of low conductivity or by hollow cores. Usually, however, the characteristics of the conductors are fixed by economic conditions quite apart from stability. The split-conductor has been considered for a number of cases as a measure for decreasing line reactance but objections from a mechanical point of view have prevented its use on any major project.

The transformer reactance should be kept as low as practical. While some variation from normal reactance is permissible, economic considerations usually prevent much departure from the normal value.

The series capacitor provides another means for decreasing the "series" reactance of transmission systems. However, at times of system faults the current through the capacitor raises the voltage across it to a value much in excess of its normal value. Hence, to protect the capacitor against puncture the usual practice is to use a normal voltage capacitor with means to short circuit it during excess current conditions. The series capacitor as proposed is thus rendered ineffective at just the time when it is most desired. The alternative is to use capacitors capable of withstanding the high voltages arising under fault conditions. In no major project in America has the series capacitor received serious consideration.

The usual ways of reducing transmission circuit reactance drops are to use additional parallel lines or circuits of higher voltage. Comparisons at times are made

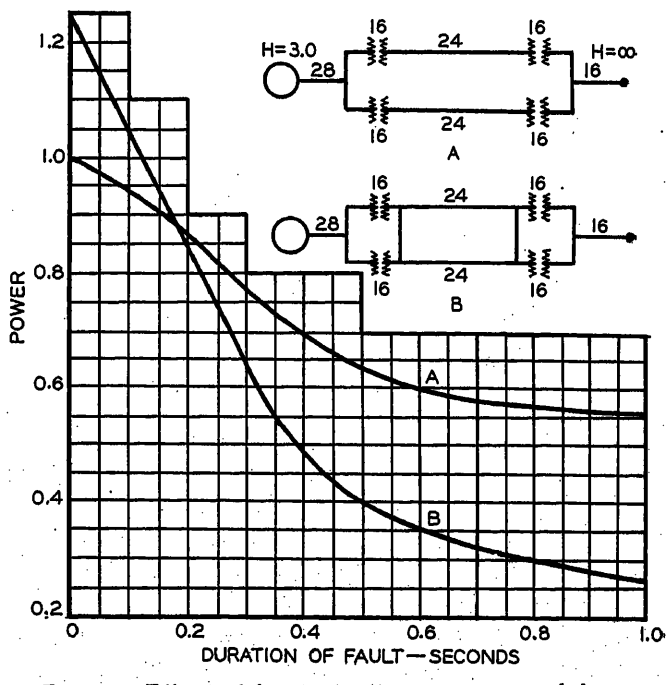

**Fig. 1. Effect of bussing arrangement on stability limits; double line-to-ground fault at sending end**

*A*—Low-voltage bussing *B*—High-voltage bussing
System reactance shown in per cent; inertia constant $H$ = kilowatt-seconds/kilovolt-ampere

between a larger number of low voltage circuits and a small number of high voltage circuits. In these cases it must be borne in mind that the switching out of a circuit produces a relatively greater reduction in the power limit of the layout with the smaller number of circuits than with the larger number.

*Bussing Arrangements*

The method of paralleling lines or apparatus, or the bussing arrangements, may have an important bearing on system stability. The use of high-voltage busses at the ends of transmission lines or at intermediate points results in smaller reduction in the "through reactance" at the time of the isolation of a faulted transmission line section than for the case with low-voltage bussing, since the latter involves the loss not only of the line but also of the associated transformers. During the faulted condition the shock to the system is greater with the high-voltage bus than with a low-voltage bus. It is impossible to generalize on the relative merits of high- and low-voltage bussing arrangements as the result in any particular case is dependent upon the relative reactance proportions of the system, the type and duration of the fault, and the character of system grounding. The results of calculations on a particular system with alternative bussing arrangements are illustrated in figure 1. It will be observed that for the faults of short duration the change in the "through impedance" of the system after the fault is cleared is more important than the shock to the system during the fault, and, therefore, the high-voltage bussing arrangement gives higher stability limits; while for faults of longer duration, the shock to the system is more important and the converse regarding layout is true. By using reactors between the high-voltage busses, it is possible to obtain characteristics intermediate between those for high- and low-voltage bussing, approaching either to any degree desired. Figure 2 shows the results of the study in a particular case of the effect of varying the number of intermediate switching stations on a long transmission line.

Another method of bussing is incorporated in the scheme known as "synchronizing at the load" as applied to metropolitan type power systems. By metropolitan system is meant the type of system that exists in large cities and is characterized by large turbogenerating units located close together with short transmission distances. With this scheme there are no direct ties between synchronous machine busses but only indirect ties through a multiplicity of connections at secondary or utilization voltages. With this layout secondary faults will not have a severe effect upon the system and can be "burned clear." Faults on a particular generator bus will require disconnection of that unit but the remaining units while subjected to a substantially greater shock, will accelerate or decelerate as a unit. Of course, the shock to the connected load will be decreased as the speed of circuit breakers and relays is increased.

While "synchronizing at the load" was developed for supplying power to metropolitan areas, the underlying general principle has been considered in connection with long-distance transmission projects. The modification of the scheme for this application is characterized by the

bussing of the system only on the low-voltage side at the receiving end. On such a system transmission-line faults result in the disconnection of an entire unit consisting of a generator, sending transformer, transmission line, and receiving transformer. Since the plan of operation contemplates the disconnection of a unit for every fault on

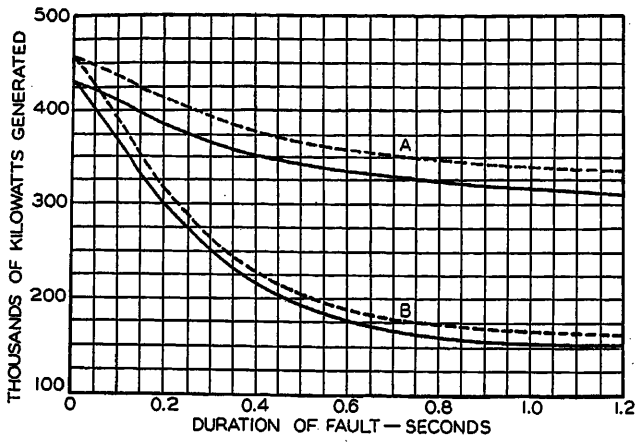

**Fig. 4. Effect of generator reactance upon stability**

the transmission line or its associated apparatus, each circuit may be operated relatively close to its steady-state power limit. Faults on the low-voltage bus at the receiving end will probably be controlling in determining the transient power limits. These connections are similar to those employed on early systems where transmission lines from separate hydroelectric plants were paralleled only at the receiver.

The same general principles of system connection have also been employed in circuits employing 2-winding generators and 4-winding transformers. These schemes improve stability by limiting the severity of short circuit and by distributing the stress among the remaining units. An important advantage of the double-winding generator arises from the fact that in the event of a fault on one winding the sound winding can carry load and thus minimize the disturbance to the system which would result from the disconnection of the faulted machine and the readjustment of load on the remaining units.

Another method of bussing is the "loose-linked" system which consists of a number of power areas normally operated in parallel, being loosely connected for purposes of synchronizing and interchange of power. The plan of operation is such that in any power area the largest generator or the interlinking ties may be lost without leaving a load in an area in excess of the ability to carry it. In the event of a serious disturbance within a power area, that area including its load and sources of power is isolated from other power areas by opening of the ties at appropriate points.

*Grounding*

In America it is common practice on high voltage systems to ground the neutral solidly and on moderate-voltage systems to ground the neutral solidly or through a resistance. For certain types of high-voltage systems there has been recently an increase in the tendency to provide transformers with sufficient insulation in the neutral to permit grounding through a moderate impedance. The Petersen scheme of power system grounding using reactors tuned with the capacitance to ground at fundamental frequency has not been generally accepted though it has been used successfully in a few locations. These schemes also have arc-suppression characteristics as discussed in a subsequent section. The introduction of neutral impedances, by limiting the severity of the fault, increases the stability limits. Two effects may be present. If the impedance is a pure reactance, the current is limited and the synchronizing power is increased thereby; if the impedance is a resistance, power is absorbed in it and the generator output increased and its acceleration is correspondingly retarded. The effects of these factors are illustrated in figure 3, which shows the stability limit as

$WR^2$ = moment of inertia in pounds per foot²

a function of the duration of the fault and the connection of the neutral impedance for single and double line-to-ground faults on the high-voltage line at both the sending and receiving ends of a typical system. These curves show conclusively that neutral impedances, preferably resistance at the sending end and reactance at the receiving end, are beneficial in maintaining stability. The importance of the method of grounding in relation to power system stability has been minimized by the development of high-speed breakers and relays and the trend in the direction of basing system design upon the more severe types of faults. In general, however, factors such as lightning protection and relaying, and cost affected by insulation and interconnection with other systems, rather than stability, determine particular methods of grounding to be employed.

*Power System Operation*

Power system operation is often as great a factor as proper system design to insure system stability. The allocation of generator capacity in relation to the system load and circuit conditions is of considerable importance, particularly under abnormal circuit conditions. The stability problem may be accentuated by interconnection and is complicated by the related problems which arise when frequency control is applied or when the location of generating capacity is determined by maximum economy requirements rather than system load requirements.

Most power systems are designed for adequate stability under steady-state conditions. There are, however, many systems where a stability problem is encountered as a result of a fault and for economic reasons it is not always possible to eliminate this condition.

A consideration of certain basic operating principles will prevent exceeding the steady-state limits and insure prompt recovery following a fault.

Adequate spinning reserve capacity either in the form

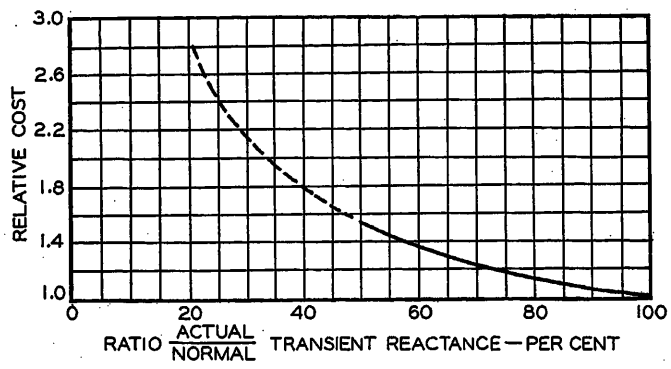

**Fig. 5. Approximate cost of decreasing the transient reactance of salient-pole synchronous generators**

of spare generators or reliable interconnections must be available in each load area to insure a steady-state limit in excess of the power and reactive kilovolt-ampere requirements in event of loss of a generating unit or loss of excitation.

The method of supplying excitation to a system has an important effect on stability. The choice of the value of bus voltages to be maintained or compensated for load and circuit changes may be of great importance. Voltage regulators tend to improve stability conditions by automatically changing the excitation in accordance with loads. They are capable of sustaining system voltages within safe limits for the loss of excitation on one of the units. They also tend to keep the field strength of individual units within reasonable limits, thereby preventing the cascading of trouble following the initial disturbance. Other characteristics of excitation systems and their control in relation to stability are discussed in a subsequent section.

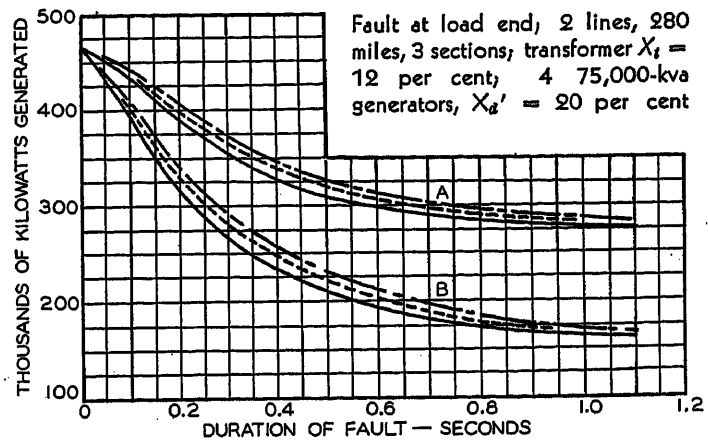

**Fig. 6. Effect of generator inertia upon system stability**

*A*—Single line-to-ground fault
*B*—Double line-to-ground fault

——— Minimum $WR^2$ (31 × $10^6$ pound-feet$^2$)
- - - - - 50 per cent additional $WR^2$
— - — 100 per cent additional $WR^2$

The increasing use of automatic devices, such as refrigerators, water heaters, water pumps, etc., which are not locked out following an outage, results in excess power requirements when service is restored. A recent outage resulted in a peak following restoration of service which was approximately 45 per cent in excess of the load interrupted.

Provision must be made for excess generator capacity for a short period following restoration of service or the service restored slowly to limit the temporary load until its diversity becomes normal.

The spinning reserve capacity for best results should be distributed in the several load areas so that its availability is not restricted by tie-line limitations.

The use of automatic load control on interconnecting tie lines has increased the practical load limits of these lines by preventing the usual drift in the tie-line load, thereby holding the scheduled load well below the tie-line limits. These devices are of no value for transient conditions.

Co-ordination of stability studies and operating instructions for abnormal conditions is a matter of considerable importance for insuring the maintenance of stability or avoidance of service interruption.

When synchronism is lost on a system having synchronous condensers, a state of equilibrium may be reached under which the system will neither accelerate nor retard until conditions are changed by switching operations, or by removal of synchronous condensers. The removal of synchronous condensers, either manually or by underspeed relays, relieves the system of superimposed low frequencies, due to condenser excitation, and permits a more rapid restoration of service.

## Characteristics of Apparatus

### *Synchronous Machines*

The characteristics of synchronous machines which are important from the standpoint of stability are substantially the same in the generator, motor, or condenser. In general, the characteristics of generators are of much more importance because they constitute the largest percentage of the total connected synchronous capacity and because they have such an important bearing on the overall system angles. The following discussion will be given in terms of synchronous generators with the understanding

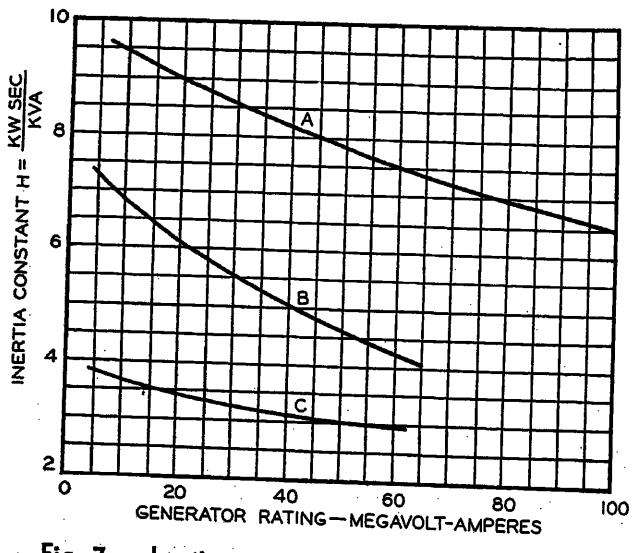

**Fig. 7a. Inertia constants of large turbogenerators, turbine included**

*A*—1,800 rpm condensing
*B*—3,600 rpm condensing
*C*—3,600 rpm noncondensing

that for synchronous condensers and motors the general features are the same but generally of relatively less importance.

The best criterion of generator performance under conditions in which system stability is determined chiefly by the transient characteristics is its transient reactance or more definitely, the direct axis component commonly designated as $X_d'$. The value of this reactance is affected to some extent by the saturation characteristics of the machine. The appropriate value to be used in a stability analysis also varies with the location and severity of the fault. From the standpoint of calculation it is usually impracticable to consider more than one value of transient reactance, which value should be selected considering the condition both during the fault and immediately after its isolation. The effect of decreasing the transient reactance of generators upon increasing the stability limits for a particular study is shown in the curve of figure 4. The normal values of the constants of various types of synchronous machines are shown in table I. The effect of decreasing the transient reactance upon the cost of a machine is indicated in a general way by the curves of figure 5. In a number of installations it has been found desirable to employ generators of less than normal transient reactance.

For a few present-day systems, steady-state stability limits will be found important. With increased application of faster breakers and relays and the logical attempt to increase the load carried on these circuits, the steady-

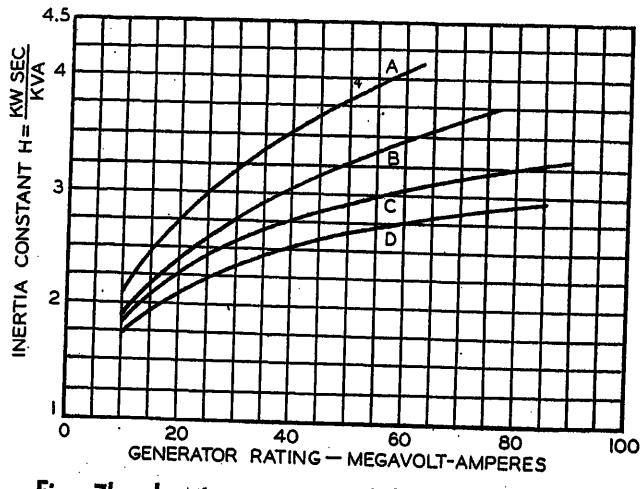

**Fig. 7b. Inertia constants of large vertical-type water-wheel generators, including allowance of 15 per cent for water-wheels**

*A*—450–514 rpm
*B*—200–400 rpm
*C*—138–180 rpm
*D*— 80–120 rpm

state stability limitations will become increasingly important. The best criterion of machine performance with reference to steady-state stability is equivalent synchronous reactance. This reactance differs from the ordinary synchronous reactance defined by the AIEE since it has been adjusted for the operating conditions in order to include the effects of saturation according to the load currents and excitation requirements.

Short-circuit ratio is in itself not directly a measure of the characteristics of the machine from the standpoint of stability. It is, however, of value as an approximate measure of the size of machine. Its value in this case depends upon the fact that to a considerable extent any reduction of reactance in a machine below its normal value is obtained by derating a larger machine and modi-

fying the current-carrying parts to meet the reduced values.

The inertia of a synchronous generator or motor is also a factor in the stability problem since it affects the natural period of system oscillation, or the time required to reach a point beyond which recovery would be impossible. Figure 6 shows the results of calculation for various values of generator inertia upon the stability limits for a particular system. The normal values of inertia constants of the various types of synchronous machines are indicated in table II. The curves of figure 7 show the inertia constants for steam turbine generators and vertical water-wheel generators. The effect of increasing the inertia of generators upon the cost is illustrated by the curves of

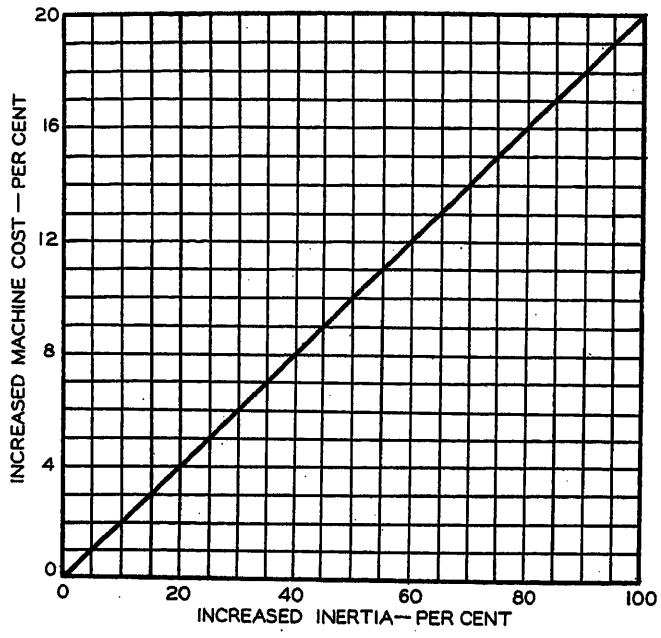

**Fig. 8. Approximate cost of increasing the inertia of large vertical-type water-wheel generators**

figure 8. In a few cases, where calculations have indicated that a particular system would operate relatively close to the stability limits, generators of higher than normal inertia have been installed.

The severity of unsymmetrical system faults is affected by the negative-sequence impedance of the connected machines. Amortisseurs or damper windings affect both the real and reactive components of this impedance. Machines without damper windings possess the highest negative-sequence reactance and from this viewpoint are the most desirable but on the other hand machines with high-resistance damper windings possess the highest negative-sequence resistance. The curves in figure 9 show the combined effect of the damper material upon the stability limit of a typical system for line-to-line and double line-to-ground faults on the high-voltage bus at the generator end. It will be observed that the improvement with high-resistance dampers is quite appreciable for faults of long duration but for faults of a duration comparable with that which can be obtained at present with high-speed breakers, the improvement is very much less. In the event of system oscillations low-resistance copper damper windings produce the greatest damping of the mechanical movement. However, this effect is unimportant during and following a system fault except in the rather rare case in which the system is so constituted that pull-out takes place as a result of compound oscillations following a disturbance. To obtain the partial

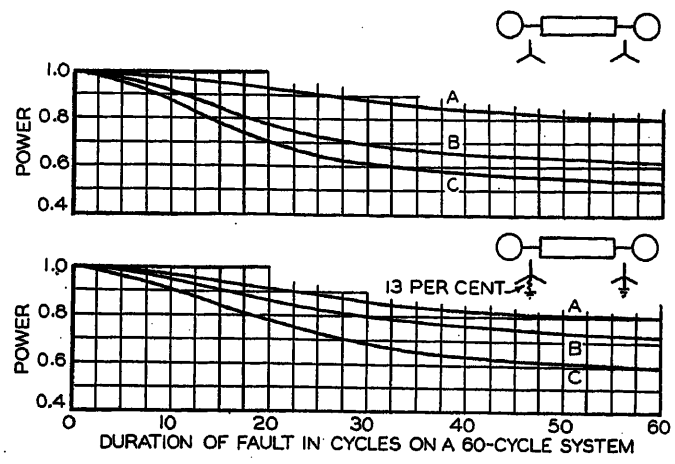

**Fig. 9. Effect of damper winding material upon stability limits**

System same as figure 3C

*A*—High resistance *B*—No dampers C—Copper
Upper curves for line-to-line fault
Lower curves for double line-to-ground fault

advantage of the high loss associated with high-resistance dampers at times of unbalanced faults and the damping of oscillations associated with low-resistance dampers, the generators for one installation were supplied with a new type of damper winding which consists of a double cage arrangement in which the outer row of bars is made of high-resistance material and the inner row of bars is made of a low-resistance material imbedded in the iron. For the double frequency associated with negative-sequence the copper bars possess a high reactance and, therefore, force most of the current through the high-resistance bars, but for the low-frequency associated with the system oscillations the current varies inversely with the resistance of the damper bars in which case most of the current flows through the copper winding. The benefits from high-resistance damper windings will be decreased as the fault duration is decreased by the use of faster breakers and relays. Damper windings also have characteristics which tend to suppress spontaneous hunting and to reduce system voltages and recovery rates arising from short circuits; in these respects, low-resistance copper dampers are somewhat more effective than high-resistance dampers.

With the increase in size of generator units, the greater concentration of power on a single bus has increased the duty on circuit breakers and the area affected by a fault on or near the bus. These effects have been greatly

minimized by the advent of the 2-winding generators in which the 2 armature windings are connected only through their mutual coupling which may be controlled by suitable design. Generators of this character lend themselves to incorporation as units in the system layout known as "synchronizing at the load" or its variations as described previously.

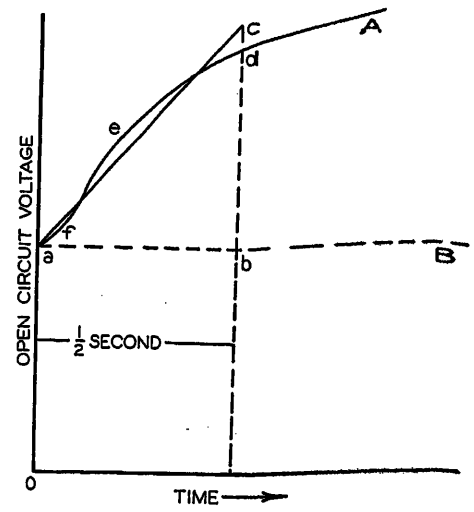
*Excitation Systems*

Control of the excitation system on synchronous machines provides a means for improving stability limits for transient conditions and also for steady-state conditions. Such systems operate to increase stability, (1) by overcoming partially the demagnetizing effect within a machine or (2) by positively increasing the machine fluxes and terminal voltages. Excitation systems that are effective from the standpoint of stability are commonly termed quick-response excitation systems, the principal features of which are:

1. Exciter of high rate of build up and of high "ceiling" voltage.
2. A reliable source of power to the exciter.
3. Quick-responding regulator.

Exciter response is the rate of build up or build down of the main exciter voltage when resistance is suddenly removed from or inserted in the main exciter field circuit by the action of the voltage regulator. The response of an exciter may be expressed as either volts per second or the ratio of the volts per second to some other designated value, e.g., the nominal collector ring voltage. In order to obtain the benefits of a high rate of response, it is necessary for the exciter to have a high ceiling voltage, i.e., a high ratio of maximum to normal operating voltage. The actual response depends upon the excitation system as a unit, on the initial value of the exciter voltage, and on the characteristics of the field and armature circuits of the main machine, and in general varies appreciably during the build-up and build-down process. Because of this variation, it has been found desirable to establish a definite basis for discussion, guarantees, and tests as defined under nominal exciter response.

The nominal exciter response is defined as the ratio to the nominal collector ring voltage of the slope, in volts per second, of that straight line voltage-time curve which begins at nominal collector ring voltage and continues for one-half second, under which the area is the same as under the no-load voltage time build-up curve of the exciter starting at the same initial voltage, and continuing for the same length of time.



Note: Nominal collector ring voltage is the voltage across the collector rings required to generate rated kilovolt-amperes in the main machine, at rated voltage, speed, frequency, and power factor with the field winding at a temperature of 75 degrees centigrade.

Figure 10 illustrates how exciter response is determined.

The exciters for quick-response excitation systems are built so that the field circuits have low time constants usually obtained by subdividing the fields and using external resistances in series with them together with other changes in design proportions. Generally, it is found most practicable to provide a pilot exciter operating with resistance in series with the field circuits of the main exciter so that the short-circuiting of these resistances will quickly apply increased voltage to the main machine field. This combination is of further advantage in eliminating the necessity for main field rheostats. The requirement for a high ceiling voltage makes it necessary to supply exciters of more liberal design than was the case with slow-response excitation systems heretofore in common use. With quick-response excitation systems it is more important than with previous excitation systems to have a reliable source of power for the exciter, sufficiently ample to supply the heavy demands that are required when a fault occurs.

**Fig. 10. Determination of nominal exciter response**

*A*—Actual build-up curve
*B*—Nominal collector-ring voltage
Area *abc* = area *afedb*

$$\text{Nominal response} = \frac{\text{slope of straight line } ac \text{ in volts per second}}{\text{nominal collector-ring voltage}} = \frac{2bc}{Oa}$$

The voltage regulator characteristics desirable with quick-response excitation systems do not differ radically from some of the types heretofore available. The principal feature of the new regulator has been the introduction of means which make the regulator respond to a sort of average voltage of the different phases instead of from a single phase which was prior practice. This change was made because of the fact that on the occurrence of certain types of unbalanced faults the voltage of a particular phase may rise though the voltage on the remaining phases drops. Thus the old type of regulator connected to this phase would introduce a change in the excitation in the wrong direction from the standpoint of system stability. This feature has been incorporated in commercial regulators in several different forms operating from different quantities. The original form used a network for supplying positive-sequence voltage to the regulator. Subsequently, this result was approximated by the substitution of a torque motor, a polyphase motor, which develops a torque proportional to the difference of the squares of the positive- and negative-sequence voltages. More recently rectifying means giving the average of the 3 phase-voltages have been employed to give corresponding action.

Quick-response excitation systems today are commonly

controlled by the exciter rheostatic type regulator provided with special auxiliary means for momentarily increasing the excitation in case a severe system disturbance is indicated. The exciter rheostatic regulator has the advantage over the vibrating type of being "at rest" for a large percentage of the time in comparison with the vibrating type, which principle will result in reduced maintenance.

Quick-response excitation systems tend to improve stability limits of power systems in 3 ways.

1. Maintaining or increasing machine flux against demagnetizing action of fault currents.
2. Supplying deficiency in system excitation due to loss of other sources of excitation.
3. Increasing steady-state stability limits.

Quick-response excitation provided one of the earliest methods used for improving the transient stability limits of systems. Its importance in this respect has, however, been minimized by the developments of high-speed circuit

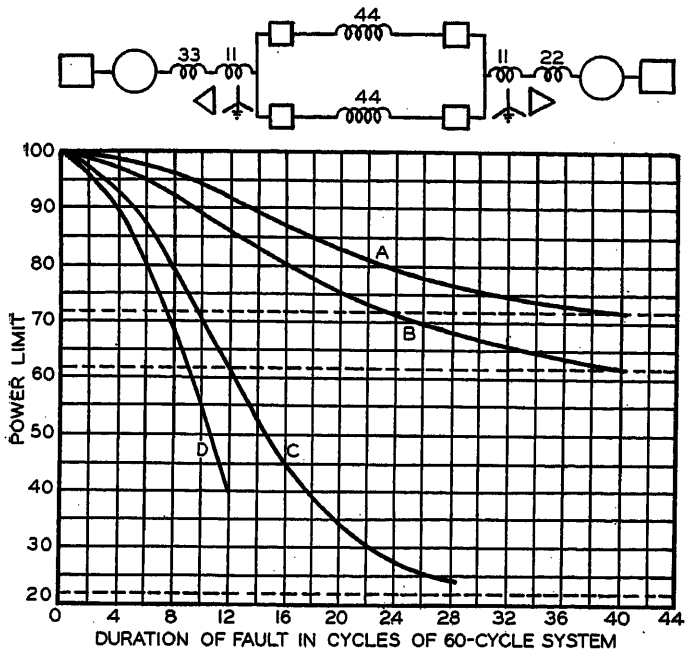


**Fig. 11. Effect of duration of fault on power limits for different kinds of faults**

*B*—Line-to-line fault
*C*—Double line-to-ground fault
*D*—Three-phase fault

System reactance shown in per cent

breakers and relays which limit the duration of fault currents and their demagnetizing effects.

Another feature of quick-response excitation systems is the ability to increase the excitation to meet the requirements of a system arising from the loss of other sources of excitation as from the disconnection of a generator or condenser. This feature cannot, of course, be supplied by means of high-speed circuit breakers. In order to be effective in this respect a quick-response excitation system must have a relatively high ratio of ceiling to normal operating voltage and the regulating equipment must be such as to permit operation under these conditions for the length of time necessary for some readjustment in the system to be brought about.

Quick-response excitation systems also provide means for increasing the steady-state stability limits. Laboratory tests on miniature systems have indicated that quite large increases in the steady-state limits over the values possible with fixed excitation can be secured by the application of a suitable regulator and exciter. These increases vary from 300 per cent for a generator and a synchronous motor directly connected down to 25 per cent for the condition simulating the transmission power over a 200-mile line at 220 kv. The effect of the excitation system in this connection may be viewed as tending to make the steady-state stability limits depend upon transient instead of synchronous reactances. In general, however, since the steady-state limits are higher than the transient limits the use of a regulator to increase the steady-state limits has been without real significance. There is also a question as to the desirability of having the operation of a station at its rated load being dependent upon the functioning of a regulator. Consequently, the choice of regulator has been determined from its performance under transient conditions and its maintenance under ordinary operation. In these respects the exciter rheostatic regulator possesses advantage over the vibrating type though the latter would appear to be superior in improving dynamic steady-state limits.

*High-Speed Circuit Breakers and Relays*

The duration of a fault condition has a very important effect on the stability of a system. The fault condition reduces synchronizing power (1) directly by altering the equivalent circuit constants and (2) indirectly by reducing the effective machine voltages through the demagnetizing action of fault currents. The stability limits as affected by the speed of breaker and relay operation vary through a wide range from (1) the limits corresponding to sustained faults to (2) a mere switching operation assuming extremely fast fault isolation. High-speed circuit breakers and relays are capable of covering most of this range and thus constitute a very important measure for increasing the stability limits, particularly for transmission systems.

The relation between the speed of fault isolation and the transient stability limits for a typical transmission system is indicated in figure 11 which also gives the impedance constants of the various system elements. The system is assumed to be subjected to a fault on one line near the high-voltage bus at the sending end and is cleared by the opening of the 2 breakers simultaneously. The curves assume hydroelectric-type generators, and receiving-end machines of relatively high inertia. The calculations were made for the 4 different types of faults shown on the curves, which are plotted in terms of the time required for the isolation of the fault and the ratio of the power that can be transmitted to the power limit corresponding to the switching out of one section of the transmission line. The dotted lines show the loads which can be carried with sustained short circuits of the various

types assuming quick-response excitation systems capable of preventing demagnetization of the machines.

The curves in figure 11 just discussed apply to a system subjected to a fault at the sending end. The relative stability conditions for the fault at sending and receiving ends of a somewhat different system were given in figure 3 which has been discussed previously in connection with the use of neutral impedances. It will be noted that a moderate value of neutral resistance at the sending end may make the fault at the receiving end on a grounded neutral system relatively more severe than at the sending end. However, the gains in stability due to the use of high-speed circuit breakers are of the same order for faults at the sending or receiving ends of the transmission system.

On metropolitan type systems the permissible time for isolating the fault will be relatively longer than for transmission systems since the latter are usually operated closer to the stability limits. Thus in the metropolitan systems it is possible to introduce reactance in the system in such a way as to limit the duty on circuit breakers. This problem can conveniently be studied by means of curves characteristic of the type of system equivalent to the "2-machine problem" using reactances as defined in the insert on figure 12. These curves indicate that by taking advantage of the faster speeds made possible by the recent developments of circuit breakers, increased amounts of reactance may be introduced in the system which may be used to either reduce the duty on circuit breakers or increase the continuity of power supply or reliability of this service to the customer.

The speed of circuit breakers and relays in relation to power system stability may conveniently be analyzed under 3 headings as follows:

1. Conventional or slow-speed breakers and relays for fault isolation.

2. High-speed breakers and relays capable of isolating fault in time to improve stability limit.

3. High-speed breakers and relays with reclosure in time to improve stability limit.

Examination of the curves of figures 11 and 12 will show that conventional slow-speed circuit breakers and relays of the type commonly in use prior to 1929 were so slow from the stability point of view that the limits corresponded to sustained faults. In this connection it may be observed also that the power limit for the 3-phase fault is almost negligible with the conventional slow-speed breakers formerly in use. The benefits which arise from the use of high-speed circuit breakers and relays in maintaining stability depend upon isolating the fault in an interval of time which is short in respect to the period of system oscillation. The preceding discussion has been based on the isolation of the fault in a single step. For sequential operation the individual breaker times will be less than that shown but need not be reduced to half value. This is, of course, due to the fact that the stability conditions are generally much improved upon the operation of the first circuit breaker.

With the development of higher speed circuit breakers it is now possible to obtain speeds of operation of 8 cycles for the full range of transmission voltages. In addition for special cases still faster speeds of operation, such as 3-cycle breakers, have been developed to meet the particular situation.

With composite systems involving long transmission lines from a source of power with interconnecting lines between various parts of the receiver, system studies will frequently show the desirability of using high-speed circuit breakers and relays in order to increase the stability limits. In a number of such cases it will be important to extend the application of the high-speed breakers to interconnecting lines of the receiver system. Otherwise, the stability limits will be determined not by faults on the main transmission line but by faults on the receiving system even though it is operating at lower voltage with transformers between it and the transmission line.

This development in the speed of circuit breakers has brought about important changes in the relaying of transmission lines. With fast circuit breakers it is no longer feasible to contemplate relay operating times of $^1/_4$ second to 3 seconds or the use of time intervals as the basis of discrimination. This has led to the use of distance or current balance types of relays which are capable of simultaneous action for the middle section of a transmission line with high-speed sequential tripping for the end sections.

In cases where the transmission system will be operated relatively close to the stability limits there is considerable advantage in providing simultaneous breaker operation. In general, such relay operation can be obtained only through the use of fundamental frequency relays operating in conjunction with a signal transmitted by pilot wires or carrier current between the ends of the line section. This has brought about an important development in the application of high-speed relaying with superposed carrier frequency. Various proposals have been considered as to the type of carrier signal to be transmitted. The relay indication to be transmitted by carrier frequency was considered first as some electrical indication, such as direction of the flow of power, but more recently as the position of various fundamental frequency relay elements which indicates the existence of a fault on the system within predetermined zones. The carrier-current relay system also provides opportunity for including relay measures for the prevention of undesired breaker operations in the event that the system does pull out of step.

*Reclosing Circuit Breakers*

The use of reclosing circuit breakers provides a means for carrying one step further the advantages possible with high-speed breakers and relays for fault clearing. For lower voltage systems and feeder circuits the use of automatic reclosing breakers makes it possible to maintain the stability of a system with induction motor load. Disconnection of the source is required for the suppression of the arc in the fault but the total time required for disconnection and for reclosure should be made sufficiently short as to prevent pullout of induction motor load. Where synchronous machines may maintain the arc, it is

necessary to isolate the affected line and to reconnect it in a period of time that is relatively short with respect to the period of system oscillation if stability is to be attained. Hence, if automatic reclosing breakers are considered for maintaining the stability on a transmission system it becomes a practical necessity to use carrier current relaying. The existence of multiple or repetitive lightning discharges may constitute an important factor in limiting the application of reclosing breakers for maintaining stability.

Single-pole breakers have been proposed at frequent intervals as a means for improving the stability of a transmission system. This device has been advocated on the basis that the remaining phases may be used to transmit power and thus minimize the system disturbance during the transition from the condition before the fault to the condition after the fault when the faulty line is disconnected. Most line interruptions which do not permanently ground a transmission conductor are due to flashovers which must be isolated to put out the arc-to-ground. Thus it is usually permissible to reclose the faulty line and restore the system to its original condition without at any time reducing the power limits to as low a value as would be the case if all three conductors were disconnected. To minimize objection to residual earth current from the standpoint of inductive co-ordination, it has been proposed to use breakers which are operated as single-pole units for arc suppression and reclosure but which are gang-operated for sustained faults. The advantages of single-pole reclosing breakers are minimized by the trend in the direction of providing protection against the more severe types of faults. To date the single-pole breaker scheme has not been installed on any transmission system.

## Other Methods of Increasing the Practical Operating Power Limits

### Flashover Prevention and Arc Suppression

Flashover prevention and arc suppression constitute a different type of measure for improving system operation. It is obvious, of course, that a system rarely subjected to faults may be operated relatively close to the stability limits. Consequently, under some conditions it is more advantageous to spend money for minimizing the likelihood of faults than in increasing the capacity of the system to withstand the system disturbances without loss of synchronism.

The principal cause of flashover on high-voltage lines is lightning. Much has been accomplished during the past 5 years to minimize flashovers resulting not only from induced strokes but particularly from direct strokes. Increased transmission line spacing and increased use of insulation in the form of insulator strings and wood have been generally adopted. On the higher voltage lines the use of ground wires is of great value when suitably located with respect to the conductors to be protected. Special efforts have been made to reduce the tower-footing resistance to a relatively low value in order to prevent a flashover of the insulator string as a result of the building up of high potential due to the flow of lightning current through the tower.

* Note—In certain cases of sequential tripping, time given applies to breaker only.

The use of the ground wire tends to reduce the zero-sequence impedence of the system and thus to increase the severity of the shock resulting from a single fault-to-ground or a double fault-to-ground. With the improvements in high-speed circuit breakers and relays these faults may be cleared promptly; consequently, the use of ground wires results in a gain from the stability point of view in reducing the number of flashovers which overbalances any disadvantage from the standpoint of the shock to the system in case fault occurs.

The fault suppression measures have as their object the interruption of the power-arc following a flashover without the necessity for isolating the affected circuit. The use of fused arcing rings or special tube type protectors in parallel with the insulators permits flashover to take place with the subsequent interruption of the power arc. Lightning arresters distributed along the line will accomplish this same general objective.

Arc-suppression devices of the Petersen type have received consideration for minimizing circuit outages in com-

nection with multiple-circuit system of the type in common use and with recently proposed single-circuit transmission line system. In America, however, little use is made of this type of arc-suppression device as dependence is placed on circuit-breakers and relays for automatically isolating a faulty section of line. This can be accomplished under favorable conditions even on high voltage circuits in about 12 cycles. This scheme has the merit of suppressing all types of faults that occur on systems regardless of whether they are of the single line-to-ground or more severe types. In addition it permits grounding the system so that the tendency for a single-phase fault to develop into a multiphase fault is minimized.

### High-Voltage Low-Frequency A-C and D-C Transmission

Low-frequency a-c systems have been proposed frequently for increasing the practical operating stability limits of long-distance transmission systems. More recently d-c transmission has been proposed as a means for

avoiding the stability limits since such a system inherently provides a nonsynchronous tie. In America, 60-cycle alternating current is very generally established for utilization. Consequently, the proposals to use low-frequency a-c and high-voltage d-c transmission schemes have included conversion means at the receiving end. In general, the use of the low-frequency a-c system involves no new problem in apparatus or application so that its use is not hindered on this account, though static apparatus may find application in the field of frequency conversion. In the case of d-c transmission, however, the conversion from a-c generation to the d-c high voltage required for the transmission line involves rectifiers for which there is no comparable operating experience; in the case of the invert-

ers at the receiving end still less work has been done. Consequently, d-c transmission has received very little practical consideration, although a 5,000-kw experimental d-c transmission system, which will transmit power 17 miles at 30,000 volts, is being built to obtain operating experience.

At the present time the limitations in 60-cycle systems, from the standpoint of system stability, are not of sufficient importance as to justify the adoption of either low-frequency a-c or high-voltage d-c transmission. The possible field for d-c transmission will depend largely on the usefulness of its operating characteristics aside from stabilty and on the future development of conversion apparatus. In this connection it should also be recognized that

there is a possibility of an improvement in a-c transmission at normal frequencies.

## Recent Practices Regarding Stability Features

In order to summarize the present status of the stability problem from the practical standpoint of its effect on power system design, table III has been prepared. This table gives the principal installations made during the past 10 years and lists the data on the various stability measures employed. While the list of installations is obviously incomplete, nevertheless, it is believed that the list is representative of the practice in regard to stability.

## Future Developments

In concluding this "First Report on Power System Stability," it is natural to turn from consideration of the

past practices and the present status and to contemplate the future. Probably the best forecast of the future can be made from an examination of the problems which are receiving active consideration at the present time. These problems include the development of faster breakers and relays, particularly of relays to meet the wide range of system conditions to be encountered. Flashover-prevention and arc-suppression measures are receiving a great deal of attention, particularly from the standpoint of the application of ground wires and lower tower-footing resistance on high-voltage lines, and flashover protector tubes for intermediate-voltage lines. Further study is being given to the reactances of synchronous machines, particularly as to the proper equivalent value to be used in stability studies. Reclosing breakers are receiving favorable consideration but much remains to be done to determine the extent of their proper field of application. The interconnection of individual power systems, each

with automatic frequency control for time-keeping purposes, has introduced problems which are receiving active consideration. Stability limits of particular systems are being examined from the standpoint of providing better instruction for the guidance of system operators during unusual or emergency circuit conditions.

## Bibliography

This is arranged in 2 parts. Part I is intended to give a substantially complete list of references to stability papers available in English, and part II gives a highly selected list of references to papers dealing with the solution of network problems which are inevitable in stability calculations. Foreign references have not been included because of their unavailability to the AIEE membership generally and also because of lack of space.

The arrangement of the bibliography contains some features requiring additional comment. The references are arranged in chronological order by years. However, within each year the papers are arranged alphabetically according to the authors' names. The arrangement has been selected for facilitating the search for a particular article, whether by author's name, title, or time of publication. In addition the character of papers is indicated from the standpoint of their present interest by means of the following symbols:

*H*—Historical interest
*A*—Analysis including methods of calculation
*M*—Discussion of measures for improving stability
*T*—Stability tests in the laboratory or in the field
*O*—Operating experience including means employed on specific projects
*P*—Physical explanation of stability phenomena
*R*—General review of stability problem

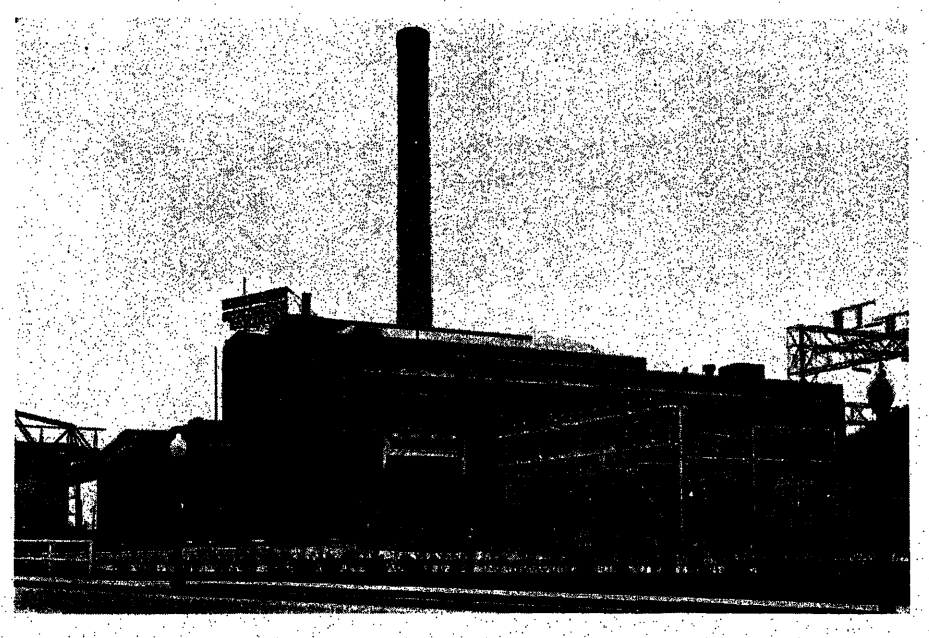
## Of Institute and Related Activities

### A Feature of the AIEE 1937 Summer Convention

Opportunity to inspect the new Port Washington power plant of The Milwaukee Electric Railway and Light Company will be among the high spots of the AIEE summer convention, to be held in Milwaukee, Wis., June 21–25, 1937. Convention headquarters will be in the Schroeder Hotel.

Since placed in regular service December 1, 1935, this modern steam-electric generating station has achieved new world records for economy in operation. Latest available figures, for the first 10 months of operation, show an average coal consumption of 11,094 Btu per kilowatt-hour of station output. International recognition was given this plant recently when it was visited by 73 delegates, representing 15 foreign nations, to the Third World Power Conference (held in Washington, D. C., September 7–12, 1936).

The plant is designed on the unit plan, with a single boiler for each turbo-generator; also one set of transformers, one 132-kv transmission line and one set of auxiliaries for each unit. The present installation of 80,000 kw capacity is the first of a probable ultimate capacity of 400,000 kw in 5 units. Throttle pressure is 1,230 pounds per square inch, and steam temperature at both throttle and reheat point 825 degrees Fahrenheit. Generator voltage is 22 kv.



The convention transportation committee is making plans for transporting AIEE delegates to the plant, which is located at Port Washington on the shore of Lake Michigan about 28 miles north of Milwaukee.

The personnel of the 1937 summer convention committee is as follows: Otto H. Falk, *honorary chairman;* K. L. Hansen, *chairman;* L. H. Hill, *vice-chairman;* C. H. Krueger, *secretary;* W. E. Crawford, *treasurer;* R. R. Benedict, A. G. Dewars, C. F. Harding, H. S. Osborne, G. G. Post, J. A. Potts, D. L. Smith, and W. H. Timbie. Subcommittee chairmen: J. F. H. Douglas, technical program; E. W. Seeger, finance; L. W. Copeland, entertainment; C. D. Brown, transportation; W. O. Helwig, registration and housing; W. E. Gundlach, publicity; G. F. Crowell, sports; S. H. Mortensen, inspection trips, and Mrs. A. C. Flory, ladies.

### Washington Award for 1937 Announced

Doctor Frederick Gardener Cottrell, Washington, D. C., who perfected the process by which the cost of helium gas was reduced from $1,700 to 10 cents per cubic foot, has been chosen to receive the Washington Award for 1937 "for his social vision in dedicating to the perpetuation of research the rewards of his achievements in science and engineering." A bronze plaque set in marble, the tangible symbol of the award, will be presented to Doctor Cottrell on February 23. Doctor Cottrell is president of Research Associates, Inc., and is widely known as a chemist and metallurgist, a former director of the United States Bureau of Mines, and director of the fixed nitrogen laboratory of the United States Department of Agriculture. Besides his achievements in the cheap production of helium, he is famous for his work in nitrogen fixation, for his processes of cleansing gases of dust and dirt by electrical precipitation, and for research in petroleum technology.

Doctor Cottrell is the fourteenth noted American engineer to receive this coveted award since it was founded in 1916 by John Watson Alvord of Chicago. The award is administered by the Western Society of Engineers in co-operation with the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers, The American Society of Mechanical Engineers, and the AIEE. The award is made annually—providing the members of the commission agree on a deserving candidate—as an honor conferred on a brother engineer by his fellows for accomplishments which pre-eminently promote the happiness, comfort, and well-being of humanity. There have been several years when no award was made.

**Port Washington plant of Milwaukee (Wis.) Electric Railway and Light Company**

### Winter Convention to Be Reported in March Issue

As this issue goes to press, the Institute's 1937 winter convention is under way at New York. Marking the resumption of a 5-day winter convention schedule, the meeting has all appearances of being a highly successful affair. First day's registration was 470, compared with 602 in 1936, 633 in 1935, and 433 in 1934. On the second day 357 registered, compared with 444 in 1936, 301 in 1935, and 433 in 1934.

A complete report of the convention and its various features is scheduled for inclusion in the March issue.

### Columbia University Offers E.E. Scholarship

The governing bodies of Columbia University have placed at the disposal of the AIEE each year a scholarship in electrical engineering in the school of engineering of Columbia University for each class. The scholarship pays the annual tuition fees of $380. Reappointment of the student to the scholarship for the completion of his course is conditioned upon the maintenance of a good standing in his work.

To be eligible for the scholarship, the candidate recommended will have to meet the regular admission requirements in,

regard to which full information will be sent without charge upon application to the secretary of the University or to the national secretary of the Institute.

In a letter addressed to the national secretary of the Institute, an applicant for this scholarship should set forth his qualifications (age, place of birth, education, reference to any other activities, such as athletics or working way through college, references, and photograph). A committee composed of W. I. Slichter, *chairman*, Francis Blossom, and H. C. Carpenter will consider the applications and will notify the authorities of Columbia University of their selection of a candidate. The last day for filing of applications for the year 1937–38 will be June 1, 1937.

The course at the Columbia school of engineering is a graduate course which may be either elective leading to the degree of master of science or prescribed leading to the degree of electrical engineer. For the former, requirement for admission is the completion of 4-year course in electrical engineering as evidenced by a bachelor's degree from an approved institution. For the professional degree, the requirements are more specific as to course content and include a considerable proficiency in mathematics, physics, and chemistry, and some knowledge of the humanities, as well as the usual undergraduate technical courses. The candidate is admitted on the basis of his previous collegiate record without undergoing special examinations. Other qualifications being equal, members of the student Branches of the AIEE will be given preference.

The purpose of this advanced course is to produce a high type of engineer, trained in the humanities as well as in the fundamentals of his profession. It is hoped that Enrolled Students and others qualified will show a keen interest in this scholarship.

## Who's Who in Engineering

That all qualified engineers will be included in the fourth (1937) edition of "Who's Who in Engineering," is the expressed hope of those participating in the preparation of that volume. First issued in 1922–23, reissued in 1925 and 1931, "Who's Who in Engineering" has made a place for itself as a reference and record volume. Its principal failing has been that many qualified engineers have not been included, a deficiency that apparently came about through the failure of individuals to return questionnaires with the data required for the preparation of entries. Through the active co-operation of American Engineering Council, it is now hoped that this earlier deficiency can be overcome, although the final answer still rests with individuals.

Questionnaires were mailed some weeks ago "to every engineer for whom a permanent address [was] available, so that none may be missed." Chairman Potter of AEC's committee urges Institute members to co-operate by promptly filling and returning these questionnaires. It is pointed out that "space in the volume cannot be purchased," and that there is no obligation.

## Electronic Tube Nomenclature Being Studied

| Generic Term | Output Energy | Character of Space | Control Means | Type Cathode | Names | Definition |
|---|---|---|---|---|---|---|
| *Electronic Tubes (or Tanks) | Electrical | High-Vacuum | None | Thermionic | Kenotron | A high-vacuum thermionic tube in which no means is provided for controlling the unidirectional current flow |
| | | | | Photoelectric | Phototube | A vacuum tube in which electron emission is produced directly by radiation falling upon an electrode. A high-vacuum phototube is one that is evacuated to such a degree that its electrical characteristics are essentially unaffected by gaseous ionization |
| | | | Electrostatic | Thermionic | Pliotron | A high-vacuum thermionic tube in which one or more electrodes are employed to control the unidirectional current flow |
| | | | Electromagnetic | Thermionic | Magnetron | A high-vacuum thermionic tube in which a magnetic field is employed to control the unidirectional current flow |
| | | Gas-Filled | None | Thermionic | Phanotron | A hot-cathode gas-discharge tube in which no means is provided for controlling the unidirectional current flow |
| | | | | Cold | Glow Tube | A cold-cathode gas-discharge tube in which no means is provided for controlling the unidirectional current flow |
| | | | | Pool | Pool Tube (or Tank) | A gas-discharge tube (or tank) with a pool-type cathode (liquid or solid) in which no means is provided for controlling the unidirectional current flow |
| | | | | Photoelectric | Phototube | See phototube definition under "high-vacuum tubes." A gas phototube is one into which a quantity of gas has been introduced, usually for the purpose of increasing its sensitivity |
| | | | Electrostatic Electrode | Thermionic | Thyratron | A hot-cathode gas-discharge tube in which one or more electrodes are employed to control electrostatically the starting of the unidirectional current flow |
| | | | | Cold | Grid-Glow Tube | A cold-cathode gas-discharge tube in which one or more electrodes are employed to control electrostatically the starting of the unidirectional current flow |
| | | | | Pool | Grid-Pool Tube (or Tank) | A gas-discharge tube (or tank) with a pool-type cathode (liquid or solid) in which one or more electrodes are provided for controlling electrostatically the starting of the unidirectional current flow |
| | | | Ignition Electrode | Pool | Ignitron | A gas-discharge tube (or tank) with a pool-type cathode (liquid or solid) in which an ignition electrode is employed to control the starting of the unidirectional current flow in each operative cycle |
| | | | Electromagnetic | | | (Not used at present) |
| | Light | | | | | |
| | Ultraviolet | | | | | |
| | X-Ray | | | | | |
| | Cathode-Ray | | | | | |

* "Electronic Tube" is a generic term, applied to various designs of tubes (or tanks) consisting of 2 or more elements in a container, usually of glass, and having a high vacuum or filled with gas at reduced pressure.

AN important preliminary step toward alleviation of the chaotic situation that has prevailed in connection with the multifarious names of electronic tubes has been achieved, according to recent advices from the American Standards Association, of which the Institute is an active member-body. As a tentative basis for the simplification of tube nomenclature, both the General Electric and the Westinghouse Electric & Manufacturing companies have agreed to abandon any trademark rights either company had in the several names indicated in the accompanying tabulation, "in the hope that this agreement will pave the way for the adoption of these names as American standards." It is recognized that this is but an initial step, and that its principal significance is in connection with the names of tubes now commonly used for industrial purposes. As a forward step, however, this list of names is hailed with satisfaction in many quarters, and, until something better becomes available, has been adopted for use in ELECTRICAL ENGINEERING. Comments are invited.

## Committee on Broadening of Institute Activities

To meet the insistent and repeated demand for a broadening of the Institute's activities to cover discussions of social and economic subjects having engineering aspects, the AIEE executive committee, at its meeting of December 10, 1936, authorized the appointment of a special committee on broadening of Institute activities. The committee appointed consists of the following:

H. S. OSBORNE, *chairman* (chairman, technical program committee)

T. F. BARTON (chairman, committee on legislation affecting the engineering profession)

H. V. CARPENTER (chairman, committee on code of principles of professional conduct)

L. W. W. MORROW (chairman, committee on coordination of Institute activities)

R. W. SORENSEN (chairman, committee on economic status of the engineer)

I. M. STEIN (chairman, publication committee)

W. H. TIMBIE (chairman, Sections committee)

J. B. WHITEHEAD (chairman, committee on Institute policy)

Circumstances leading up to this action are outlined briefly in the following extract from the minutes of the executive committee:

"Further consideration was given to the subject of broadening Institute activities to cover discussions of social and economic subjects that have engineering aspects. At its October meeting, the board of directors passed a motion concurring in the suggestion that such topics are of general interest to electrical engineers, calling attention to 'the fact that the Institute has always offered facilities and organization for discussion of such questions,' and suggesting that papers on these subjects be submitted to the proper committees of the Institue for consideration for national presentation and publication.

"President MacCutcheon reported the impressions which he received when visiting Sections in the West and Middle West, and analyzed the attitude of the Institute membership as follows: Approximately 80 per cent of Institute members are in favor of a judicious broadening of Institute activities, but 60 per cent are strongly opposed to undertaking anything that would not be in the interest of the Institute, and about 20 per cent of them are inclined to go so far as to be in danger of damaging the profession and the Institute. He met with the executive committee of the Chicago Section and explained to them the board's attitude toward the suggestions of the group of Chicago members concerning the broadening of Institute activities. So far as Institute publications are concerned, it appeared that unquestionably 90 per cent of the members with whom he came in contact thoroughly agreed that they do not want to see any of the necessary technical material omitted, but they also desire something more; and that, Mr. MacCutcheon pointed out, will be taken care of by the appropriation in the budget for 100 additional pages in ELECTRICAL ENGINEERING. He then referred to his efforts to secure papers on subjects of general interest from certain prominent men, and suggested the desirability of each member of the board making a similar effort, so that in 2 or 3 months such papers will be coming in.

"Then followed a discussion on the best procedure for handling the papers on social and economic subjects which may be submitted, or for procuring such papers. It was pointed out that in the Institute organization there are the technical committees to make sure that papers on technical subjects are forthcoming, but that there is no one who has particular jurisdiction over the papers on economics, administration, etc., which the membership seems to want. The desirability of setting up a particular committee for this purpose was discussed. The

## Westinghouse Commemoration at ASME Convention

THE ninetieth anniversary of the birthday of George Westinghouse was commemorated December 1, 1936, during the 57th annual meeting of The American Society of Mechanical Engineers, by a special 2-session program which consisted of an afternoon session at which former friends and associates of Mr. Westinghouse brought personal testimony of his engineering achievements, and an evening session at which formal addresses were delivered. The group on the platform during the afternoon session is shown above; they are, standing, left to right: J. F. Miller, vice-chairman of the Westinghouse Air Brake Company, Pittsburgh, Pa.; N. W. Storer (A'95, F'13, member for life) retired consulting railway engineer of Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.; Thomas Campbell, veteran employee of the Westinghouse Air Brake Company; Francis Hodgkinson (A'02) consulting mechanical engineer and former turbine expert for the Westinghouse company, New York, N. Y.; A. W. Berresford (A'94, F'14, member for life, past-president) New York, N. Y.; C. R. Beardsley (A'08, F'30) superintendent of distribution of the Brooklyn (N. Y.) Edison Company; Roy V. Wright, editor of *Railway Age*, New York, N. Y.; and Charles F. Scott (A'92, F'25, HM'29, member for life, past-president) professor of electrical engineering emeritus of Yale University, New Haven, Conn.; seated, left to right: L. B. Stillwell (A'92, F'12, member for life, past-president) consulting engineer, Princeton, N. J.; W. W. Nichols, assistant to the chairman, Allis-Chalmers Manufacturing Company, New York, N. Y.; Frank W. Smith (A'05, M'12) president of the Consolidated Edison Company, New York, N. Y.; E. R. Hill (A'99, F'12, member for life) consulting engineer, Gibbs and Hill, New York, N. Y.; J. V. B. Duer (A'15, F'29) chief electrical engineer of the Pennsylvania Railroad Company, Philadelphia; and Samuel Vauclain, chairman of the board of the Baldwin Locomotive Works, Philadelphia. W. L. Batt and Ralph Budd also took part in the ceremonies.

## Membership—

Mr. Institute Member:

Without your assistance your membership committee is definitely handicapped. Examine the roster of electrically interested individuals in your acquaintance and forward the names of men you would choose as Institute members, who are not now members, to the chairman of your Section membership committee. Personally obligate yourself to secure one new member for the Institute—YOUR INSTITUTE—your professional organization.

James M. Dodds

Vice-Chairman, District No. 4
National Membership Committee

suggestion was made that the matter should be handled in a positive, rather than a negative, manner, by recognizing the demand on the part of the membership for the type of papers under discussion and taking the initiative in procuring such papers from the proper sources, so that dependence need not be placed entirely upon papers that originate spontaneously. The thought was expressed that diplomatic situations may arise unless there is some centralized specifying authority to investigate the possibilities before seeking a paper, and that a man who is approached to write a paper should be given the specifications for such paper.

"VOTED that a special committee on broadening of Institute activities be appointed, consisting of the chairman of the technical program committee as chairman, and the chairmen of the committees on code of principles of professional conduct, co-ordination of Institute activities, economic status of the engineer, Institute policy, legislation affecting the engineering profession, publication, and Sections."

**Johns Hopkins Engineers to Mark 25th Anniversary.** The school of engineering of The Johns Hopkins University, Baltimore, Md., will celebrate during the latter part of February 1937, the 25th anniversary of its founding. Plans include an "engineering show" that will involve displays of engineering equipment and principles, and from various sources exhibits are being gathered. At the "commemoration day" exercises to be held February 22, Dr. Karl Taylor Compton (F'31) president of the Massachusetts Institute of Technology is scheduled to deliver the principal address. During the exercises, honorary degrees will be conferred upon a small group of prominent engineers.

**Arc-Welding Foundation Established.** In order to stimulate scientific development, the Lincoln Electric Company has completed plans for establishing a fund and foundation to encourage study and research for the benefit of the industry. The fund has been named "The James F. Lincoln Arc Welding Foundation" in honor of the president of the company. Principal direction of the work of the foundation will be given by Doctor E. E. Dreese (M'25) chairman of the electrical engineering department of Ohio State University. Commenting on the action, Mr. Lincoln (A'08, M'20) stated

". . . . The sole purpose of this new foundation is to challenge the attention of manufacturers whose products benefit society; and to stimulate the ingenuity of every engineer and skilled worker interested in extending the frontiers of knowledge and achievement."

## AIEE Members Among "12 Greatest Inventors"

Three deceased members of the AIEE were named among those chosen recently as America's "12 greatest inventors for the past century." The list of names was presented dramatically during a dinner held in Washington, D. C., to celebrate the 100th anniversary of the institution of the United States Patent Office. Those honored and their principal achievements were:

ALEXANDER GRAHAM BELL (A'84, M'84, deceased August 2, 1922) the telephone

THOMAS ALVA EDISON (A'84, M'84, HM'29, deceased October 18, 1931) the electric light and the phonograph

ROBERT FULTON, the first commercial steamboat

CHARLES GOODYEAR, the vulcanization process for rubber

CHARLES MARTIN HALL, aluminum manufacture

ELIAS HOWE, the first practical sewing machine

CYRUS HALL MCCORMICK, the first practical reaper

OTTMAR MERGENTHALER, the linotype

SAMUEL F. B. MORSE, the electric telegraph

GEORGE WESTINGHOUSE (A'02, deceased March 12, 1914) the air brake

ELI WHITNEY, the cotton gin

WILBUR WRIGHT, the airplane

# American Engineering Council

## Seventeenth Annual Meeting Held in Washington, D. C.

THE AIEE was represented at the seventeenth annual assembly of American Engineering Council in Washington, D. C., January 14 to 16, 1937, by its 5 delegates, President A. M. MacCutcheon, William McClellan, C. O. Bickelhaupt, C. E. Stephens, and National Secretary H. H. Henline. Many other Institute members were present at the several sessions either as members of committees, representatives of local clubs, or speakers, among which were included F. J. Chesterman, general chairman of the public affairs committee of AEC: Thomas R. Tate, chief of the power resources division of the Federal Power Commission and secretary of the AIEE Washington Section; and Harry W. Osgood, chairman of the Washington Section and member of the engineers dinner committee. Representatives of the 48 national, state, and local societies which comprise the Council were present. A report of the AEC meeting and the seventh conference of engineering society secretaries, as furnished by Frederick M. Feiker, executive secretary follows:

A session on programs of united action for member societies opened the conference of secretaries of engineering societies on the morning of January 14, O. L. Angevine, secretary of the Rochester (N. Y.) Engineers' Club presiding as chairman of the conference. Among the many discussions were those by A. A. Potter, president AEC, who spoke on intersociety co-operation, Watson Davis, of Science Service, whose subject was publicity, and F. J. Chesterman, who talked about public affairs. The conference continued throughout the afternoon with discussions on the co-ordination of programs and meeting dates, the Third World Power Conference, and various programs local societies had found to be successful.

That afternoon was also the occasion for meeting in informal round-table discussion of the AEC divisional committees. With F. M. Feiker, executive secretary, AEC, presiding, A. A. Potter, president, AEC, opened the discussion on operating commit-

tees. The session was devoted to a preliminary discussion of reports of AEC committees that were presented on January 15. Secretary and Mrs. Feiker entertained the delegates at a reception and tea at their home at the close of the session.

At a symposium on public affairs held on Thursday evening, F. J. Chesterman, chairman, several important questions engaging the attention of the administration and the nation were discussed, such as social security, old age and unemployment compensation, industrial co-operation with and without government supervision, conservation of natural resources, national, state, and local public works activities and rural electrification. The speaker on social security was Arthur J. Altmeyers, of the Social Security Board. Colonel E. W. Clark, executive assistant, Public Works Administration, in his address, made a plea for greater social-mindedness in engineers. In his discussion of natural resources, Thomas R. Tate, chief, power resources division, Federal Power Commission, displayed numerous large-scale maps of power systems in the United States, including one showing the geographical regions into which it is proposed to divide the nation for purposes of power production and distribution.

### Reports of Committees

At the business session on Friday morning, A. A. Potter presiding, a roll call of representatives was followed by the president's address, and reports of the executive secretary, treasurer, and numerous operating committees.

President Potter spoke briefly on the efforts Council had made during the year to encourage the activities of the committees and to co-ordinate the work of engineering societies. He spoke of the need for more factual data on the impart of technology on social security and urged the active support of Council in efforts to assist in their determination and dissemination, in the hope that the public more generally may come to regard engineering and the engineer in their true economic and social significance.

Mr. Feiker read a report which covered the varied and important work of Council and its numerous committees. Unfortunately, limitations of space forbid even a summary of Mr. Feiker's report, but plans are under consideration to bring Council's activities before the readers of Electrical Engineering in later issues.

The report of the treasurer showed successful operation of Council's financial affairs within the income received and a balance of approximately $2,000 to carry over into 1937. A budget of estimated expenditures for 1937, amounting to $39,431 was adopted. Reports were presented on publicity, membership and representation, regional activities, finance, constitution and by-laws, and nominations.

Abel Wolman, chairman of the water resources committee, addressed the assembly luncheon on the engineer's opportunities and responsibilities in the conservation of natural resources.

Mr. Wolman's excellently delivered address reviewed the steps by which, from the pressure of PWA activities, and the work of the Mississippi Valley committee and the water planning board the water resources committee was evolved. He described briefly some of the more important principles of action of the water resources committee. One was the development of coordinated national water plans. Another was that national water development concerned people primarily, rather than merely water. It was necessary, he said, to effect a centralization of points of view on a river basin as a whole in order to obtain a necessary perspective. He then described briefly some specific undertakings of the committee and the work of several subcommittees that experience had shown that it was necessary to organize.

Following the luncheon, reports of numerous public-affairs committees of AEC were presented. F. J. Chesterman presided.

Although it is impossible to summarize the numerous reports presented, it may be stated that extensive discussions followed the presentation of the reports on patents, R. S. McBride, chairman; public works, Alonzo J. Hammond, chairman; rural electrification, L. F. Livingston, chairman; conservation and utilization, Leonard J. Fletcher, chairman, and surveys and maps, John S. Dodds, chairman. These reports were accepted and referred to the executive committee for action.

Morris L. Cooke, administrator, Rural Electrification Administration, spoke on the achievements of the REA which he characterized as "rural electrification in spite of the experts." His 3 levels of interest in the work, were, he said, (1) that of "gadgets," the electrical devices themselves, (2) that of the "cultural renaissance for agriculture," and (3) national survival as threatened by unwise use of soil and water.

### "All Engineers' Dinner"

As usual, the high point of the AEC annual assembly was the "all engineers' dinner," held on the night of January 15 with about 450 in attendance and President A. A. Potter presiding. A reception preceded the dinner. A feature of the dinner program was the presentation of honorary membership of the ASME to Admiral Cone, retired, of the United States Navy.

Acting as toastmaster was Colonel D. H. Sawyer, director, Federal Employment Stabilization Board, who introduced Messrs. Angevine, Bickelhaupt, MacCutcheon, Mead, Coleman, Feiker, and Blasinghame and spoke on the construction during the depression.

Admiral Cone was presented by M. X. Wilberding, chairman of the ASME Washington section. In introducing Admiral Cone, Mr. Wilberding spoke briefly of his naval career.

In responding to the speech of presentation by J. H. Herron, president of the ASME, Admiral Cone expressed his appreciation of the honor done him, and said that he would maintain the high standards set by those distinguished engineers who had previously been elected to honorary membership in the ASME.

The principal addresses at the dinner were by Rear-Admiral Harold J. Bowen, engineer-in-chief of the United States Navy, who spoke on national defense, by Hon. J. C. O'Mahoney, senator from the State of Wyoming, on the interstate regulation of business by federal license, and by C. F. Hirshfeld, whose subject was the engineer's responsibilities in social and economic questions. Because of Mr. Hirshfeld's illness his address was read by R. L. Sackett.

Admiral Bowen said that a modern navy is highly mechanized and depends on the engineer for maintenance, and called attention to the diversity and extent of the vessels, aircraft, shore establishments, and communication systems of which it is comprised. He gave many examples of the stimulation to naval engineering coming from industry, as well as that received by industry from the Navy. In closing he asserted that naval defense is a struggle between applied science as utilized by the combatants and that a navy cannot rise above the level of the engineering development of the nation to which it belongs.

In his penetrating and carefully reasoned address Mr. Hirshfeld urged the engineer to enlarge the sphere of his influence by accepting a larger measure of responsibility in solving social and economic problems resulting from the impacts of applied science. He made a plea for a factual study of such grave questions as technological unemployment, relative returns to capital and labor of the fruits of industry, and competition. As examples of public questions in which engineers might interest themselves in their own communities as a public service he mentioned traffic regulation, air pollution, noise abatement, and public transportation. He closed by asking whether or not the engineer would have the fortitude to serve humanity in the future in the same grand manner in which he had served it on technological matters in the past.

Senator O'Mahoney gave numerous examples of corporation created under the laws of a single state which do business in several or all states and in world trade, and argued that there exists a need for the regulation of interstate business by means of federal licenses. He explained some of the principal features of a bill before the Congress introduced by him as a device for the regulation he proposed.

### Session on Engineering Economics

Continuing its meeting on Saturday morning with a session on engineering economics, the assembly listened to further reports. Mr. Chesterman made a plea for engineers to take a broader view of their profession in line with the thoughts expressed in Mr. Hirshfeld's address at the dinner, and had a discussion on effective publicity on engineers and their work.

C. E. Stephens reported for several of the united action committees; and a resolution was passed in favor of an extension of the merit system.

In presenting a report of the engineering economics committees Ralph E. Flanders reviewed the status of the third progress report of the committee on consumption, economics, and distribution. For the committee on special surveys and studies he made the proposal, which was referred to the executive committee by vote of the assembly, that Council bring about co-operation between its engineering economics committees and social-science groups.

J. Frederic Dewhurst, of the committee on social security of the Social Science Research Council, spoke briefly on social science and engineering. The engineering profession, he said, was in a position to make a con-

tribution to the preventive side of social security.

Officers elected at the assembly meeting were, for vice-presidents C. O. Bickelhaupt, and John S. Dodds, representing the state and local member organizations. C. E. Stephens was elected treasurer. In all cases these were re-elections. The term of president is for 2 years, and as Dean Potter has served but one, he will continue in that office for 1937. Representatives and alternates to the assembly were also elected from the 6 geographical districts into which AEC membership organizations are divided. F. M. Feiker was re-elected executive secretary. Chairmen of committees selected were William McClellan, finance; C. O. Bickelhaupt, membership and representation; and F. J. Chesterman, public affairs.

# Letters to the Editor

CONTRIBUTIONS to these columns are invited from Institute members and subscribers. They should be concise and may deal with technical papers, articles published in previous issues, or other subjects of some general interest and professional importance. ELECTRICAL ENGINEERING will endeavor to publish as many letters as possible, but of necessity reserves the right to publish them in whole or in part, or reject them entirely.

ALL letters submitted for consideration should be the original typewritten copy, double spaced. Any illustrations submitted should be in duplicate, one copy to be an inked drawing but without lettering, and other to be lettered. Captions should be furnished for all illustrations.

STATEMENTS in these letters are expressly understood to be made by the writers; publication here in no wise constitutes endorsement or recognition by the American Institute of Electrical Engineers.

## An Analysis of Electrical Engineering Graduates

*To the Editor:*

In the article, "An Analysis of Electrical Engineering Graduates," which appeared on pages 952-3 of the September issue of ELECTRICAL ENGINEERING, Brown University, at Providence, R. I., unfortunately was omitted from the list of American colleges offering a 4-year course in electrical engineering, leading to a degree of bachelor of science in electrical engineering or its equivalent. Since the publication of that article, information from Duke University, Durham, N. C., also has been made available.

Students at Brown who specialize in electrical engineering receive the degree of bachelor of science in engineering on completion of the 4-year course. Following are the numbers of graduates who specialized in electrical engineering at Brown during the period of the survey: 1927-28—14; 1928-29—13; 1929-30—11; 1930-31—6; 1931-32—5; 1932-33—12; 1933-34—11; 1934-35—9.

Duke University, which offers a 4-year course leading to the degree of bachelor of science in electrical engineering, graduated the following numbers of electrical engineers: 1927-28—2; 1928-29—6; 1929-30—3; 1930-31—5; 1931-32—4; 1932-33—10; 1933-34—13; 1934-35—11.

Very truly yours,

CLIFFORD A. FAUST (A'35)
President, National Executive Council, Eta Kappa Nu Association; In Charge of Power Utility Division of Advertising, Ohio Brass Company, Mansfield

## Preparation of Institute Papers

*To the Editor:*

We note your interest in readers' comments on the new paper and format of ELECTRICAL ENGINEERING. The new page is indeed pleasing and easier to read. We regret, however, that you are now breaking up the continuity of articles in the usual magazine fashion. The continuation of articles on back pages, fostered by editors chiefly in order to take the reader into the advertising columns of ordinary magazines, is a nuisance which is probably unnecessary in a publication of this type.

At various times instructions are issued regarding the methods of preparing papers for the Institute. We feel that a few comments might be pertinent at this time.

It might be presumed that Institute papers, while of greater interest to the specialist in whose field they are written, are also to be read by many with a normal curiosity and the desire to keep informed in related subjects, even though the mathematics may be unfamiliar. Papers might better be written with the idea more clearly in mind that the reader knows less about the subject than the writer, and that the time and effort of the former are to be conserved as much as possible. Several suggestions can be made as an aid to easier reading.

Even though the aim of the paper might be well presented in the introduction, the reader can follow the processes much more readily if the aim of each step in the development of the paper is presented in a brief statement. This, combined with shorter paragraphs and more frequent subtitles, is a great aid to rapid scanning and easier grasp.

The reader who expects to make use of the material presented, would be aided if more careful attention were given to the following considerations:

1. More adequate definition of symbols and terms used. If they are obscure, a brief background or more complete references would be useful. (Many symbols are not adequately defined by the title, as for instance, "synchronous reactance.") Understanding of differential equations is frequently aided by identifying the type to which they belong with a brief statement of the manner of solution.

2. "Word derivations" of equations are helpful. Lack of space may frequently make complete mathematical development inadvisable. Yet if the equation is important to the material at hand, the primary assumptions on which it is based and an outline of the steps followed could be given in a brief paragraph. Such explanations are especially necessary if simplifying assumptions have been made in the development.

3. Time and wasted effort could be saved the reader if more care were taken to indicate (when known) the limitations of various data. This is especially true when the exact process of obtaining data is not given and the user has small opportunity of determining the inherent limitations.

4. Many Institute papers would be greatly improved if the author kept more firmly in mind that he must avoid the slightest suspicion of aiming at a display of his own erudition rather than to present the reader with interesting and useful information.

Several years ago Professor Karapetoff made the prediction that the time would come when electrical engineers would concern themselves more with the fundamental nature of classical vector theory. Papers presented before the Institute for the past year indicate that this prediction was justified.

In view of the present growth of such application and its probable continuation, it might be well through adequate definition, to avoid the confusion which may readily arise. Classification of a term as a *vector* may no longer be an identification at all, when one considers that the writer may have in mind the complex number vector, those of classical vector analysis, those based on the work of Hamilton, of Gibbs-Wilson, or the more modern concepts and variations of them associated with certain forms of tensor analysis, the complex vector of A. Pen-Tung Sah, etc.

It would be well to remember that experiments (and this might hold for mathematical developments as well) are accepted by science only if they are susceptible to reproduction. Hence, while one may have no reason to doubt that a writer has obtained the results or made the analyses he claims, nevertheless, through inadequate definition of symbols, unannounced assumptions in his derivations, and a presentation not aimed to be of maximum value to the reader, the latter may frequently be unable to reproduce the work presented. Such reproduction is necessary to progressive growth and development of a science.

Very truly yours,

A. F. PUCHSTEIN (A'20, M'27)
Chief Engineer

T. C. LLOYD (A'31)
Development Engineer
Robbins & Myers, Inc., Springfield, Ohio

## Electrical Engineering's New "Easy-Reading Page"

*To the Editor:*

... You are to be congratulated on the makeup of the January 1937 issue of ELECTRICAL ENGINEERING. I admit my first reaction to the cream-colored paper was negative. However, as I sat in my special chair last evening reading your "easy-reading page" under our IES lamp, I found my technical reading to be a pleasure indeed. I hope you do not go back to the white paper. I find this paper very much more restful, for my eyes are quite sensitive to glare. Listing the author and title at the bottom of each page is an improvement. The 2 pages which include the be-

ginning of an article always have an uncanny way of sticking together. The titles and page numbers are so much more convenient at the bottom than they would be at the top. When this information is given at the top, one either must open the magazine wide or lean halfway across the desk. I'm sorry that I can't offer any constructive criticism. You are too far ahead of me . . .

Very truly yours,

V. P. HESSLER (A'29)
Instructor in Electrical Engineering, Iowa State College, Ames

*To the Editor:*

. . . The new style paper appeals to me, since it seems to hold what was promised, elimination of glare. I believe the carrying over of the name of author and abbreviated title on all pages of the papers will help considerably in locating desired references.

Very truly yours,

J. H. HAGENGUTH (A'28)
Electrical Engineer, High Voltage Engineering Laboratory, General Electric Company, Pittsfield, Mass.

*To the Editor:*

As one whose eyes are sensitive to glare, due undoubtedly to poor lighting and "hard-reading pages" in youth, I want to commend you most heartily on the adoption of the "easy-reading page."

Very truly yours,

FREDERICK HOLMES (A'22, M'27)
President, Duncan Electric Manufacturing Company, Lafayette, Ind.

*To the Editor:*

. . . I think that a very great improvement has been made in the general style and make-up . . .

Very truly yours,

A. S. LANGSDORF (A'03, F'12)
Dean of the Schools of Engineering and Architecture, Washington University, St. Louis, Mo.

*To the Editor:*

I find that the new "easy-reading page" is exactly that. I hope that you will continue to use it.

WILLIS W. SNYDER (A'35)
Meter Department, Niagara Alkali Company, Niagara Falls, N. Y.

*To the Editor:*

I wish to comment very favorably on the change you have just made in the paper on which ELECTRICAL ENGINEERING is printed. The light buff color is far easier on the eyes and under artificial light the glare is reduced almost to the vanishing point.

Also I like very much your initial page entitled "High Lights." It is an excellent idea to have a brief summary of this sort given first. One can see at a glance what articles are of most interest and will then be induced to look them up and read them more thoroughly.

I certainly hope that both of these features are continued.

Yours very truly,

R. W. WARNER (M'28)
Professor and Head of the Department of Electrical Engineering, University of Kansas, Lawrence

*To the Editor:*

I would like to register enthusiastic approval of the new type and tinted paper used in ELECTRICAL ENGINEERING. I think the paper color very well chosen since the temptation usually is to use too yellow a stock.

Very truly yours,

L. J. BUTTOLPH (M'36)
Electrical Engineer, General Electric Vapor Lamp Company, Hoboken, N. J.

*To the Editor:*

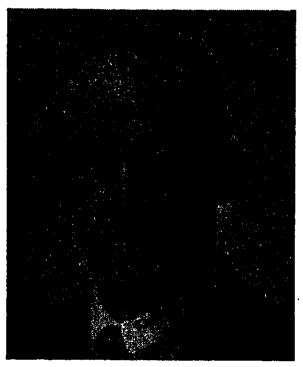
May I add my word of approval of your continued efforts to make ELECTRICAL ENGINEERING the best possible kind of publication?

The "easy-reading page" which you present with the January issue is, in my opinion, a significant contribution of the electrical engineering profession to human welfare. There is no doubt but what this sort of thing has long been needed, and I trust that continued efforts may be fruitful along this line.

Sincerely yours,

M. S. COOVER (A'16, M'32)
Head of Electrical Engineering Department, Iowa State College, Ames

*To the Editor:*

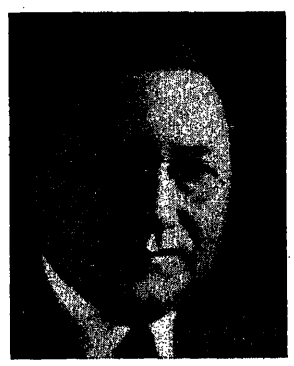


I was very much interested in your easily read page which appeared in the January 1937 issue of ELECTRICAL ENGINEERING. . . all comments which I have heard have been favorable. . . After I had gotten over my first unfavorable impression of seeing the yellowed edges of the sheets before the book was opened, I liked it very much. . . .

Very truly yours,

WILLARD CHAMPE (A'25, M'35)
Electrical Engineering Department, The Commonwealth & Southern Corporation, Jackson, Mich.

# Personal Items



ASGER VILSTRUP (A'20, M'27) chief electrical engineer, British Columbia Electric Railway Company, Ltd., has been elected president of the Engineering Profession in British Columbia for the year 1937. Mr. Vilstrup was born at Borris, Denmark, in 1884, and received his technical education at the College of Electrical Engineering, in Copenhagen, Denmark. Upon completion of his studies, he was employed by several

ASGER VILSTRUP

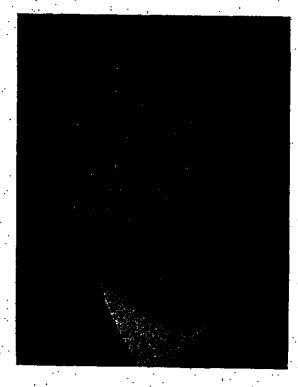
electrical companies in England, including British Insulated and Helsby Cables, Ltd., during the period 1903–09. In 1911 Mr. Vilstrup went to Canada to become field draftsman and subforeman on hydroelectric construction at Lake Buntzen for the British Columbia Electric Railway Company, Ltd. Three years later he was made assistant engineer in the electrical department of that company at Vancouver. In that position he was engaged in the design of substations and transmission and distribution lines, and in the maintenance of the power plant and distribution systems. In 1929 Mr. Vilstrup was appointed assistant plant manager, and during the year 1935–36 was acting plant manager. He was made chief electrical engineer in 1936. He has been active in the affairs of the Institute's Vancouver Section for several years (chairman 1925–26) and was active in the arrangements and administration of the AIEE Pacific Coast convention held at Vancouver in 1932.

P. S. MILLAR (A'03, M'13) president, Electrical Testing Laboratories, Inc., New York, N. Y., was elected president of the United States National Committee of the International Commission on Illumination at the recent annual meeting of the Committee. Mr. Millar was born at Andover,

P. S. MILLAR

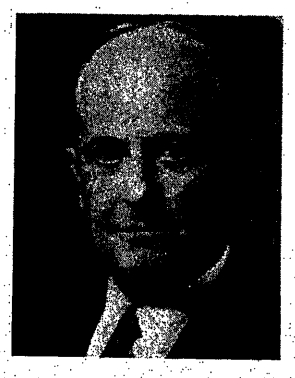
N. J., in 1880, and obtained his formal technical eduction at Paterson Classical and Scientific School and through the International Correspondence Schools. In 1897 he entered the employ of the Lamp Testing Bureau (now Electrical Testing Laboratories, Inc.) and in 1899 became assistant

manager of that company. He became general manager in 1914, and has been president since 1930. Mr. Millar has done much original work in illumination research, being co-inventor of the Sharp-Millar photometer, and has contributed liberally to the technical press. He has been a member of the Institute's committees on electrophysics, 1917–18; meetings and papers (now technical program), 1925–28; and a member since 1924 and chairman from 1925 to 1928 of the committee on production and application of light. Mr. Millar is a fellow of the American Physical Society, member of the council of the Association of Consulting Chemists and Chemical Engineers, secretary-treasurer of the Association of Edison Illuminating Companies, member and past-president of the Illuminating Engineering Society, and director of the Thomas Alva Edison Foundation.



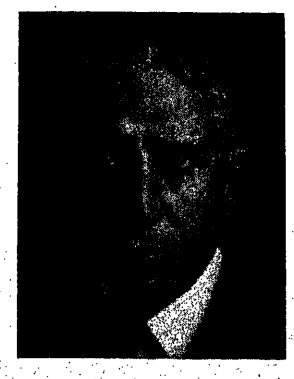
WILLIAM KELLY (F'25) formerly president of the Buffalo, Niagara, and Eastern Power Corporation, recently was elected president of the Niagara, Lockport, and Ontario Power Company. Colonel Kelly was born in New York, N. Y., in 1877, attended the Sheffield Scientific School of Yale University, and was graduated from the United States Military Academy in 1899. During 1902–03 he pursued graduate work in the U.S. Army Engineer School of Application. Upon graduation in 1899, Colonel Kelly was placed in charge of design of electrical installations for sea coast defenses. He continued to serve in that capacity, and concurrently (1906–10) as assistant engineer commissioner of the District of Columbia, until 1913. During the World War he served as chief engineer of the 42nd Division and Fourth Army Corps, and reported for the peace conference on several rivers that were internationalized. When the Federal Power Commission was organized in 1920, Colonel Kelly was appointed its chief engineer and, while serving in that capacity, presented a report on the Colorado River as a source of hydroelectric power and irrigation supply. He was also an active member of the superpower committee for the northeastern area of the United States and a member of the American section of the International Board of Engineers, investigating the St. Lawrence waterway project. In 1925 he was appointed director of engineering of the National Electric Light Association, and in the following year became affiliated with the Buffalo, Niagara, and Eastern Power Corporation. Colonel Kelly became president of that company in 1933. He is a member of the Society of American Military Engineers and the American Society of Civil Engineers; he received the James Laurie prize of the latter society in 1925.

H. M. SHARP (M'34) superintendent of the Huntley stations, Buffalo General Electric Company, Buffalo, N. Y., has been elected a vice-president of the Buffalo, Niagara, and Eastern Power Corporation. Mr. Sharp was born at Buffalo, N. Y., in 1892, and received the degree of mechanical engineer at Cornell University in 1915. Following his graduation, he served briefly as an instructor in mechanical engineering at Cornell University, as an assistant engineer with the Bethlehem Steel Company, Lackawanna, N. Y., and with the U.S. Army, before becoming efficiency engineer at Huntley station in 1919. In 1926 he accepted a similar position with the Indiana Electric Corporation, Terre Haute, Ind., but returned to the Buffalo General Electric Company in 1928 as assistant chief engineer of Huntley station. On completion of the second Huntley station, Mr. Sharp was made assistant superintendent of both stations in 1930; in 1931 he became superintendent, which position he has held for the last 6 years.

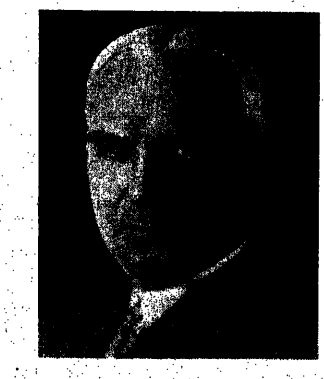


N. R. GIBSON (M'32) vice-president of the Buffalo, Niagara, and Eastern Power Corporation, Buffalo, N. Y., has been appointed vice-president of the Buffalo General Electric Company and the Niagara, Lockport, and Ontario Power Company, and director of the Niagara Electric Service Corporation. Mr. Gibson was born at Guelph, Ont., Canada, in 1880, and was graduated from the University of Toronto in 1901, with a diploma in mechanical and electrical engineering; in 1904 he received the degree of bachelor of arts and sciences, and in 1931 the honorary degree of doctor of engineering at the same institution. Following his graduation in 1904 he served briefly with several contracting companies before becoming associated (1908) with Smith, Kerry, and Chase, consulting engineers in Toronto, Ont., Canada, where he was in charge of the civil and hydraulic department. During 1913–15 Mr. Gibson served as consulting engineer to the Ontario Power Company, Niagara Falls, Ont., and the Electric Power Company, Ltd., Toronto; later, he served as chief engineer for the Ontario Power Company, 1915–16, and assistant chief engineer of the Electric Power Company, 1916–17. From 1918 to 1925 he was hydraulic engineer of the Hydraulic Power Company (now Niagara Falls Power Company), Niagara Falls, N. Y., later serving as executive engineer, chief engineer, and vice-president and chief engineer; concurrently he was vice-president and chief engineer of the Buffalo, Niagara, and Eastern Power Corporation and vice-president of the Niagara Hudson Power Corporation, New York, N. Y. Mr. Gibson is a member of the American Society of Civil Engineers and The American Society of Mechanical Engineers.

L. T. BLAISDELL (A'20, M'22, vice-president) southwestern district manager, General Electric Company, Dallas, Texas, has been elected a commercial vice-president of the company. Mr. Blaisdell was born at Carlisle, Mass., in 1886, and following his graduation from the Massachusetts Nautical Training School, in 1904, he entered the employ of the General Electric Company as a student engineer at Lynn, Mass., where he remained until 1907. During the period 1907–11 he served as construction engineer, in which capacity he supervised the installation of power-plant equipment on many naval vessels built along the Atlantic coast and served as engineer on many trial trips. From 1911 to 1917 he served as commercial engineer in the Baltimore, Md., offices of the General Electric Company, and in 1917 was transferred to the Washington, D. C., offices to follow various activities of the federal government. He served in that position until 1923 when he was transferred to Dallas as southwestern district manager. Mr. Blaisdell was chairman of the AIEE Washington Section, 1922–23, and of the Dallas Section, 1930–31.



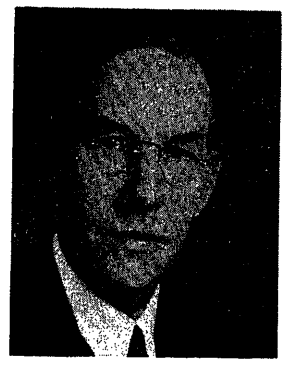
R. B. HOWLAND (A'11, M'22) formerly assistant to the president of United Engineers & Constructors, Inc., Philadelphia, Pa., recently was elected a vice-president and director of that company. Mr. Howland was born at Marion, Mass., in 1885, and received the degrees of bachelor of arts (1906) and bachelor of science in electrical engineering (1910) at Drury College and Purdue University, respectively. Following his graduation in 1910, he became associated



L. T. BLAISDELL

WILLIAM KELLY

R. B. HOWLAND



N. R. GIBSON

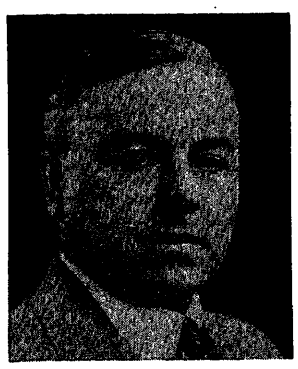
F. M. FARMER

H. J. MAC LEOD

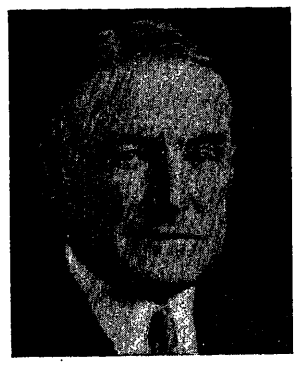
E. D. UHLENDORF

with the Stone and Webster Company, first as an electrician and switchboard operator for the Pacific Coast Power Company, Sumner, Wash., and later as assistant general superintendent of the Mississippi River Power Company, Keokuk, Iowa. In 1917 Mr. Howland accepted a position as superintendent of power, and subsequently as superintendent of power and utilities, with the American International Shipbuilding Corporation, Hog Island, Pa. He returned briefly to the services of the Mississippi River Power Company in 1919, and then became affiliated with Dwight P. Robinson & Co., Inc., New York, N. Y., as assistant electrical engineer. When Dwight P. Robinson & Co. was merged with 3 other engineering organizations to form United Engineers & Constructors, Inc., in 1929, Mr. Howland was made assistant to the president of the new organization, and has held that position since. He is a member of Tau Beta Pi.



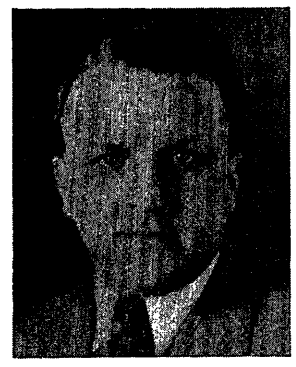
M. O. TROY (A'08, M'12) manager of the central station department, General Electric Company, Schenectady, N. Y., has been elected a commercial vice-president of the company. Mr. Troy was born at Burlington, N. C., in 1872, and received the degree of bachelor of science in electrical engineering at the University of Virginia in 1896, following which he entered the employ of the General Electric Company as a test engineer. He was transferred to the West Lynn works of that company as foreman of transformer test in the following year, and in 1898 became associated with Prof. Elihu Thomson (A'84, M'91, F'13, HM'28, Edison Medalist '09, past-president) in development work on constant-current transformers. In 1901 Mr. Troy was made assistant engineer of the a-c engineering department of the West Lynn works and was later transferred to the transformer sales department. In 1907 he became manager of sales of transformers, lightning arresters, and voltage regulators, and in 1923 was appointed executive assistant manager of the central station department. Mr. Troy became manager of the department in 1928.

P. H. THOMAS (A'00, F'12, past vice-president, member for life) formerly chief of the power requirements division, National Power Survey, Federal Power Commission, Washington, D. C., has been appointed regional director of the Commission, with offices at Atlanta, Ga. Mr. Thomas was born at Boston, Mass., in 1872, and received the degree of bachelor of science in electrical engineering at the Massachusetts Institute of Technology in 1893. Following his graduation, he entered the engineering department of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., where his work consisted of lightning-arrester and high-voltage engineering, and remained with that company until 1903, when he became chief engineer of the Cooper-Hewitt Electric Company. In 1907 Mr. Thomas established his own consulting engineering offices at New York, N. Y., and continued his private practice until he was appointed consulting electrical engineer to the firm of Guggenheim Brothers, in 1916. In 1928 he re-established his own consulting engineering offices, continuing until he was appointed chief of the power requirements division of the National Power Survey in 1934. Mr. Thomas was manager of the Institute, 1907–10; vice-president, 1910–12; and has been a member of the committees on electrophysics, meetings and papers (now technical program), standards, power transmission and distribution, award of Institute prizes, Lamme Medal, and Edison Medal. He is a member of The American Society of Mechanical Engineers.

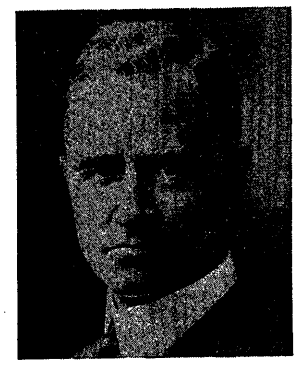


E. D. UHLENDORF (A'13) formerly a member of the operating committee, Byllesby Engineering and Management Corporation, Chicago, Ill., has been appointed executive engineer of Public Utility Engineering and Service Corporation, successor to the Byllesby company. Mr. Uhlendorf was born at Chicago in 1887, and attended the Armour Institute of Technology, specializing in civil engineering. He has been associated with Public Utility Engineering and Service Corporation and its predecessor continuously since 1911, with the exception of a 3-year period during which he was engaged in special public utility evaluation work. He has had charge of many important appraisal projects for rate making and security issues, and has appeared as expert witness before several commissions and courts. Mr. Uhlendorf became a member of the operating committee of the Byllesby Engineering and Management Corporation in 1925. He is a member of the American Society of Civil Engineers and the Society of American Military Engineers.

F. M. FARMER (A'02, F'13, director) vice-president and chief engineer of the Electrical Testing Laboratories, Inc., New York, N. Y., has been elected chairman of the standards council of the American Standards Association for the year 1937. Mr. Farmer was born at Ilion, N. Y., in 1877, and was graduated from Cornell University in 1899. In 1903, after spending a year in the test department of the General Electric Company and 2½ years in the inspection division of the U.S. Navy at the Brooklyn (N. Y.) Navy Yard, he joined the staff of the Electrical Testing Laboratories, Inc., then known as the Lamp Testing Bureau. Mr. Farmer has been active in various phases of ASA work, as chairman of 2 sectional committees and member of 2 others, and as a member of the electrical standards committee and the United States National Committee of the International Electrotechnical Commission. In addition, he is active in Institute affairs, having been member or chairman of many of the technical committees, and is at present a member of the board of directors. Since 1935 he has been Institute representative on the Engineering Foundation board and on the engineering societies monograph committee. Mr. Farmer is a past-president of the American Welding Society and of the American Society for Testing Materials, a fellow of the American Association for the Advancement of Science, and a member of the Institution of Electrical Engineers and The American Society of Mechanical Engineers.



H. J. MAC LEOD (A'23) formerly professor of electrical engineering, University of Alberta, Edmonton, Canada, has been appointed head of the department of mechanical and electrical engineering at the University of British Columbia, Vancouver. Professor Mac Leod was born at New London, Prince Edward Island, in 1887, and received the degrees of bachelor of science (1914) and master of science (1916) from McGill University and the University of Alberta, respectively. In 1921 he received the degrees of master of arts and doctor of philosophy at Harvard University. Following his graduation from McGill University, he served for 2 years as lecturer in electrical engineering at that institution, and after 3 years' (1916–19) army service, entered Harvard University to pursue graduate work in electrical physics. In 1921 he was appointed associate professor of electrical engineering at the University of



A. L. JONES

E. H. GINN

J. M. COSTELLO

T. S. KNIGHT

Alberta and in 1924 professor of electrical engineering. He is a member of the Engineering Institute of Canada.

T. S. KNIGHT (A'05) New England district manager, General Electric Company, Boston, Mass., has been elected a commercial vice-president of the company. Mr. Knight was born in Massachusetts in 1882, and was graduated from Tufts College in 1903, with the degree of bachelor of science in electrical engineering. Following his graduation, he entered the testing department of the Stanley Electric Company, and in the following year was transferred to the switchboard engineering department. When the Stanley Electric Company became a part of the General Electric Company, Mr. Knight was retained in the switchboard engineering department at the Schenectady, N. Y., works of the new company. In 1908 he was transferred to the Boston, Mass., offices of the General Electric Company, and placed in charge of switchboard engineering there. He has been New England district manager since 1926.

A. L. JONES (A'07, M'26) Rocky Mountain district manager, General Electric Company, Denver, Colo., has been elected a commercial vice-president of the company. Mr. Jones was born at Balston, N. Y., in 1879, and received the degree of mechanical engineer in electrical engineering at Cornell University in 1904. Upon graduation, he entered the testing department of the General Electric Company, at Schenectady, N. Y., continuing as a test engineer until he was transferred to the power and mining engineering department in 1906. In 1909, Mr. Jones was transferred to the Denver offices of the General Electric Company as district engineer, in which capacity his work consisted of engineering supervision of construction and construction contracts. He was appointed district manager in 1928.

J. M. COSTELLO (A'27) vice-president and general manager, The Syracuse Lighting Company, Inc., Syracuse, N. Y., has been elected a vice-president of the Niagara, Lockport, and Ontario Power Company. Mr. Costello was born at Clyde, N. Y., in 1891, and has been affiliated with the Niagara, Lockport, and Ontario Power Company, and its associated companies, since 1911. During his service of more than 25 years, he has acted as division superintendent and as district manager of that company; also as district manager and as general manager of the Livingston-Niagara Power Company. Mr. Costello was made executive manager of the Niagara, Lockport, and Ontario Power Company in 1928, and vice-president and general manager of The Syracuse Lighting Company in 1930.

E. H. GINN (A'03) southeastern district manager, General Electric Company, Atlanta, Ga., has been elected a commercial vice-president of the company. Mr. Ginn was born at Worcester, Mass., in 1878, and was graduated from the Worcester Polytechnic Institute in 1900. Following a year's graduate study at the same institution, he entered the testing department of the General Electric Company, Schenectady, N. Y., and after a brief service as test engineer was transferred to the railway engineering department in the Atlanta offices of that company. He was appointed district sales manager in 1918 and district manager in 1922.

THOMAS FITZGERALD (A'02) vice-president and general manager, Pittsburgh (Pa.) Railways Company, has been elected a member of the board of directors of the Philadelphia Company. Mr. Fitzgerald is a native (1878) of Baltimore, Md., and a graduate of The Johns Hopkins University in the class of 1898. Following his graduation, he entered the employ of the Baltimore and Ohio Railroad Company as an inspector, and after serving with several companies, eventually became general manager of the Cincinnati (Ohio) Traction Company in 1913. In 1917 he resigned that position to join the U.S. Army, and following the World War Mr. Fitzgerald established his own consulting engineering offices at Pittsburgh, Pa. In 1924 he became vice-president of the Pittsburgh Railways Company, and later vice-president and general manager.

L. S. BOGGS (A'93, M'98, member for life) service engineer, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., has retired from active service. Mr. Boggs was born at Lafayette, Ind., in 1867, and was graduated from Purdue University in 1888 with the degree of bachelor of mechanical engineering; in 1892 he obtained the advanced degree of mechanical engineer from the same institution. Following his graduation in 1888, he entered the employ of the Sprague Electric Railway Company, remaining there until 1891. After a year of graduate study, Mr. Boggs was appointed engineer of power for the Columbian Exposition at Chicago, Ill., in 1893 and in 1894 he held a similar position at the Cotton States and International Exposition at Atlanta, Ga. In 1896 he became superintending engineer for the Pioneer Electric Power Company, Ogden, Utah, where he remained for 4 years before becoming associated with Sargent and Lundy, Inc., Chicago, Ill. Mr. Boggs has been associated with the Westinghouse company since 1904, having started as a construction engineer. He took an active part in many major railway electrification projects, both in the United States and in South America.

E. W. JUDY (A'26) vice-president of the Duquesne Light Company, Pittsburgh, Pa., recently was elected a member of the board of directors of the Philadelphia Company. Following a 3-year preliminary training, Mr. Judy became associated with the Stone and Webster Company at Seattle, Wash., in 1909, where he remained until 1914, when he became superintendent of construction for the Southern Sierras Power Company, Riverside, Calif.; later he became local superintendent and district manager for that company. In 1923 he joined the Duquesne Light Company as superintendent of overhead lines, subsequently becoming superintendent of the distribution department, operating manager, and vice-president.

E. F. NUEZEL (A'27) formerly underground transmission and distribution engineer, Union Gas and Electric Company, Cincinnati, Ohio, has become superintendent of the underground department of the Cincinnati Gas and Electric Company. Mr. Nuezel is a native of Cincinnati, and an electrical engineering graduate of the University of Cincinnati. Upon graduation, he entered the electrical distribution department of the Union Gas and Electric Company in 1922 as assistant engineer on maintenance and construction. In 1927 he joined the engineering staff of the Colum-

bia Engineering and Management Corporation as assistant engineer on engineering planning, but later returned to the Union Gas and Electric Company as underground transmission and distribution engineer.

L. O. DORFMAN (A'19, M'28) manager of the engineering division, Westinghouse Electric & Manufacturing Company, Cincinnati, Ohio, has been made engineering manager of the New England district of that company, with offices at Boston, Mass. Mr. Dorfman was born at Pittsburg, Texas, in 1892, and received the degree of electrical engineer at the University of Texas in 1916. He entered the employ of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., immediately following his graduation, and his service with that company has been uninterrupted, except for a period of service with the U.S. Army during the World War. He was transferred to the Cincinnati offices of the Westinghouse company in 1927.

A. H. MORTON (A'24) National Broadcasting Company, New York, N. Y., has been appointed manager of the department of managed and operated stations of the National Broadcasting Company. Mr. Morton is a native (1895) of Chicago, Ill., and an engineering graduate of the University of Illinois. During 1917–19 he served in the U.S. Army, and following his resignation was associated with the General Electric Company for 2 years before joining the Radio Corporation of America as manager of the Washington, D. C., offices of that company. In 1923 Mr. Morton was transferred to the New York, N. Y., offices as head of the commercial department of RCA Communications, and in 1929 was made European manager for the Radio Corporation of America.

D. S. MACCORKLE (A'30) has resigned as cable engineer in the engineering department of the New York and Queens Electric Light and Power Company, Flushing, N. Y., and is now associated with the Habirshaw Cable and Wire Corporation, Yonkers, N. Y., as a sales engineer. Mr. MacCorkle is a native (1905) of Flushing, N. Y., and an electrical engineering graduate of Washington and Lee University. Upon graduation, he entered the student training course of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa., in 1926. After spending a year as a sales engineer for the Westinghouse company, he accepted a position as assistant engineer for the New York and Queens Electric Light and Power Company in 1928.

J. E. M. MITCHELL (A'27) formerly southern district sales manager, Jeffrey DeWitt Insulator Company, Kenova, W. Va., has been advanced to the position of general sales manager of the company. Mr. Mitchell is a native (1890) of Edisto Island, S. C., and an electrical and mechanical engineering graduate of Clemson College. Following his graduation, he entered the employ of the General Electric Company, Schenectady, N. Y., as a test engineer, and for a time served under Dr. C. P. Steinmetz. Mr. Mitchell served briefly with several companies, and with the U.S. Army Corps of Engineers, before becoming southern district sales manager for the Jeffrey DeWitt Insulator Company in 1924.

H. W. EALES (A'17, F'25, past vice-president) who has been chief electrical engineer of the Byllesby Engineering and Management Corporation, Chicago, Ill., has been appointed chief electrical engineer of the Public Utility Engineering and Service Corporation, Chicago, successor to the Byllesby organization. Mr. Eales has been active in Institute affairs, having been a member of many of the technical committees and a vice-president (1921–26) representing the South West District. He has also been active in committee work of the Edison Electric Institute and the Association of Edison Illuminating Companies, and is a member of Phi Beta Kappa and Sigma Xi.

G. H. JUMP (A'18, M'30) engineer in the Buffalo, N. Y., offices of the General Electric Company, has been appointed New England district engineer for the company, with headquarters at Boston, Mass. Mr. Jump was born at Binghamton, N. Y., in 1888, and received the degree of electrical engineer at Syracuse University in 1910. Immediately following his graduation, he entered the employ of the General Electric Company, Schenectady, N. Y., as a student engineer and has since been associated with that company in various capacities. He was transferred to the Buffalo offices in 1916 and was appointed engineer in charge in 1918.

R. A. JONES (A'20) engineer in the Syracuse, N. Y., offices of the General Electric Company, has been transferred to the Buffalo, N. Y., offices in a similar capacity. Mr. Jones is a native (1892) of Wabasha, Minn., and an electrical engineering graduate (1916) of the University of Minnesota. Upon his graduation, he entered the testing department of the General Electric Company, Schenectady, N. Y. In 1917 he was transferred to the power and mining engineering department of that company, and was appointed to the Syracuse offices in 1923.

D. J. DEBOER (A'34) formerly assistant electrical engineer, Sargent and Lundy, Inc., Chicago, Ill., recently was appointed chief electrical engineer of the Loup River Public Power District, Columbus, Nebr. Mr. DeBoer is a native (1897) of Corsica, S. D., and an electrical engineering graduate (1922) of South Dakota State College. He has been associated with the Sargent and Lundy firm, directly and indirectly, since 1927.

W. B. RITTENHOUSE (A'03) for many years associated with H. M. Byllesby and Company and the Byllesby Engineering and Management Corporation, Chicago, Ill., has been appointed assistant manager of the engineering division of the Public Utility Engineering and Service Corporation, successor to the Byllesby Engineering and Management Corporation.

F. H. LANE (M'23) for 19 years manager of engineering and construction for the Byllesby Engineering and Management Corporation, Chicago, Ill., has been appointed manager of the engineering division of the Public Utility Engineering and Service Corporation, successor to the Byllesby organization, with which Mr. Lane has been associated continuously since 1904.

H. L. HAZEN (A'26) assistant professor of electrical engineering at Massachusetts Institute of Technology, Cambridge, recently was made associate professor. Professor Hazen, a graduate of that institution, was employed by the General Electric Company at Schenectady, N. Y., for a year prior to joining the faculty in 1925.

A. B. BERRESFORD (A'31) an electrical engineering graduate (1929) of Cornell University, recently passed the examinations of the National Board of Medical Examiners and expects to enter the general practice of medicine at Ithaca, N. Y., in the near future.

PETER FRIES, JR. (A'34) an electrical engineering graduate (1933) of the College of the City of New York, recently was admitted to the bar of the State of New York, and has opened offices for the general practice of law at New York, N. Y.

G. A. PRICE (A'33) formerly employed in the engineering department of the Susquehanna Silk Mills, Sunbury, Pa., now is employed as general draftsman for the Hygrade Sylvania Corporation, St. Marys, Pa.

H. A. WARREN (A'36) formerly a draftsman for the Florida Mapping Project, Gainesville, now is an electrical maintenance engineer for the United Clay Mines Corporation, Trenton, N. J.

G. E. MULLIN, JR. (A'36) sales engineer, General Electric Company, Indianapolis, Ind., has been transferred to the rural electrification section of that company at Schenectady, N. Y.

T. S. BAKER (A'28) formerly chief engineer, Press Wireless, Inc., Hicksville, N. Y., recently was appointed superintendent of radio construction for the U.S. Signal Corps, with headquarters at Washington, D. C.

L. H. DEE (A'36) has resigned his position with Fairbanks, Morse, and Company, New York, N. Y., to become associated with Standard Air Conditioning, Inc., New Rochelle, N. Y.

H. A. BOYCE (A'34) formerly division transmission engineer, American Telephone and Telegraph Company, Cleveland, Ohio, has been transferred to the Cincinnati, Ohio, offices of that company.

G. M. COFFMAN (A'35) formerly a radio engineer for the George W. Taylor Company, Williamson, W. Va., now is employed by the American Rolling Mill Company, Ashland, Ky.

C. M. MACKEY (A'34, M'36) manager of the Oklahoma City (Okla.) branch of the Westinghouse Electric Supply Company, has been transferred to the Houston, Texas, offices of that company.

B. P. RUCKER (A'03, F'13) engineer, Federal Power Commission, Washington, D. C., recently was transferred to the Atlanta, Ga., regional offices of the Federal Power Commission.

R. D. GOODRICH (A'33) formerly an electric dredge engineman, U.S. Engineers, Fort Peck, Mont., now is a junior hydraulic engineer with the U.S. Geological Survey, St. Louis, Mo.

M. L. KHANNA (A'31) formerly a student engineer for The Vilter Manufacturing Company, Milwaukee, Wis., has been transferred to Lahore, India, as a representative of that company.

R. W. RHODES (A'23) who has been an electrical engineer for Charles H. Tenney and Company, Boston, Mass., now is with the New England Power Service Company, Worcester, Mass.

T. L. BERRI (A'35) formerly a junior engineer, Southwestern Light and Power Company, Lawton, Okla., now is employed in the relay department of the Public Service Company of Colorado, Denver.

U. N. HALLIDAY (A'28) formerly district manager, Pacific Electric Manufacturing Corporation, San Francisco, Calif., now is employed by the John Roebling's Sons Company, Los Angeles, Calif.

# Obituary

EDWARD BARNARD MEYER, of Newark, N. J., junior past-president of the Institute, died January 30, 1937, just as these pages were going to press. For additional information, see the March issue of ELECTRICAL ENGINEERING.

FRANK ARTHUR LAWS (A'09, M'12, F'28) emeritus professor of electrical measurements, Massachusetts Institute of Technology, Cambridge, died in November 1936. Professor Laws was born May 28, 1867, at North Bridgewater, Mass., and was graduated from Massachusetts Institute of Technology in 1889, with the degree of bachelor of science, following which he was retained on the faculty as an assistant in physics. In 1891 he was made an instructor in physics, and in 1894 an instructor in electrical measurements. From 1897 until 1902 he served as assistant professor of physics before being appointed assistant professor of electrical testing. In 1906 he was appointed associate professor of electrical testing, and continued in that capacity until 1913, when he received a professorship of electrical engineering. He was retained at that time by the Massachusetts Gas and Electric Commission to make tests of electric meters, and later performed special work in electrical measurements for the Edison Electric Illuminating Company of Boston, the General Electric Company, and various electric light and power companies throughout New England. He was appointed professor of electrical measurements in 1921. Professor Laws was the author of many technical papers dealing with the subject of electrical measurements, and on that subject prepared a textbook, which became widely used and acknowledged to be one of the leading textbooks of its kind in the English language. He served the Institute during 1917–19 and 1920–22 as a member of the committee on standards, and during 1929–33 as a member of the committee on instruments and measurements. He was a member of the National Electric Light Association and a fellow of the American Academy of Arts and Sciences.

WILLIAM BENJAMIN JACKSON (A'97, M'98, F'13, Life Member, past vice-president) retired rate consultant to The New York Edison Company, New York, N. Y., died January 20, 1937. Colonel Jackson was born June 23, 1870, at Kennett Square, Pa., and was graduated from Pennsylvania State College in 1890 with the degree of bachelor of science; he received the degree of mechanical engineer from the same institution in 1895. After serving with several companies from 1890 to 1894, he was employed by The United Electric Light and Power Company, New York, N. Y., as an inspector, but shortly thereafter entered the testing department of the Stanley Electric Manufacturing Company at Pittsfield, Mass., and finally became assistant to the chief engineer of that company. In 1895 Colonel Jackson became manager of the Lowell (Mich.) Water and Light Company, and in 1897 he accepted a similar position with the Peninsular Light and Power Company, Grand Rapids, Mich. During 1898–99 he was chief engineer and superintendent of the New York and Staten Island Electric Company and consulting engineer of the Staten Island Electric Railway Company; from 1899 to 1901 he served as chief engineer and superintendent of the Colorado Electric Power Company, Cripple Creek. Beginning in 1901, and for 2 years thereafter, he was special engineer abroad for the Stanley Electric Manufacturing Company, and from 1903 until 1918 Colonel Jackson was a member of the consulting engineering firm of D. C. and William B. Jackson, of New York. He served The New York Edison Company from 1919 until his retirement in 1933. He presented many papers before the Institute and was a member of several of the technical committees; in addition, he served as the Institute's manager from 1912 to 1915 and as a vice-president during 1918–19. He was a member of the American Society of Civil Engineers, Society of American Military Engineers, and The American Society of Mechanical Engineers.

ALBERT T. PERKINS (M'25, Life Member) consulting tranportation engineer, St. Louis (Mo.) Union Trust Company, died November 22, 1936. Colonel Perkins was born October 2, 1865, at Brunswick, Me., and received the degree of bachelor of arts at Harvard University in 1887; he also received the honorary degree of master of arts from Harvard University in 1919. Following his graduation, he entered the employ of the Chicago, Burlington, and Quincy Railroad Company, and during the period 1887–96 held various positions in that company. From 1897 to 1902 he was superintendent of terminals in the St. Louis division of that company, and from 1902 until 1906 held a similar position in the St. Joseph division. In 1906 Colonel Perkins became consulting engineer and railroad adviser to the St. Louis Union Trust Company, and served in that capacity continuously for 30 years; however, he served at the same time as president of the Brownsville and Matamoros Bridge Company; Marshall and East Texas Railway Company; Chicago, Milwaukee, and Gary Railway Company; New Iberia and Northern Railway Company; Appalachicola Northern Railroad Company; and the West Texas Abstract and Guarantee Company. In addition, he was consulting engineer for the Southern Traction Company of Texas and manager for the receiver of the United Railways Company of St. Louis. Colonel Perkins had a brilliant military record during the World War and was awarded the Distinguished Service Medal and the British Order of St. Michael and St. George.

THOMAS EDWARD PENARD (A'08) assistant superintendent, station engineering department, Edison Electric Illuminating Company of Boston, Mass., died October 27, 1936. Mr. Penard was born May 7, 1878, at Paramaribo, Dutch Guiana, and was graduated in electrical engineering at the Massachusetts Institute of Technology in 1900, following which he was engaged briefly as a draftsman for 2 structural companies before becoming associated with the Edison Electric Illuminating Company of Boston in 1901. His first position with that company was as a draftsman, but he later became an electrical engineer, and in that capacity was active in the design of the company's electrical systems. He became assistant superintendent of the station engineering department in 1931. Mr. Penard was active in education work, having served as instructor and superintendent of several evening schools in Boston, and for a time was dean of the evening school of Northeastern University. He served the Institute as a member of the committees on industrial and domestic power (now general power applications), 1920–21, and instruments and measurements, 1927–29.

ARTHUR JOHN RALPH (A'22, M'31) technician in the electrical engineering department of Yale University, New Haven, Conn., died February 11, 1936, according to word just received at Institute headquarters. Mr. Ralph was born February 23, 1861, at Berkshire, England, and received his electrical training by serving an apprenticeship in the philosophical instrument trade in England. He came to the United States in 1889 and entered the instrument department of the Schuyler Electric Company, Middletown, Conn., in 1890. When the General Electric Company absorbed the

Schuyler Electric Company in 1892, Mr. Ralph was placed in charge of the experimental laboratory of the Middletown works, where he remained until he accepted a position as superintendent of the New Haven, Conn., plant of The Walker Electric Company. In 1898 the Walker Electric Company was absorbed by the Westinghouse Electric & Manufacturing Company, and Mr. Ralph was retained as assistant in the detail department of the New Haven plant. He remained in that position until 1900, when he became factory superintendent of the Kidder Motor Vehicle Company, New Haven. In 1904 he became head of the assembling department of the Connecticut Computing Machine Company, New Haven, and in 1911 a designer of automatic ammunition machinery for the Winchester Rifle Company. He joined the staff of Yale University as technician in the electrical department in 1916.

CHARLES JOYCE RUSSELL (A'04, member for life) vice-president in charge of rates and standard practice of the Philadelphia (Pa.) Electric Company, died December 8, 1936. Mr. Russell was born March 10, 1864, at Norway, Me., and attended the Lawrence Scientific School and Massachusetts Institute of Technology. In 1886 he became associated with the Holtzer Cabot Electric Company, where he did general electrical installation and storage battery work. After serving for one year as superintendent of the H. B. Cutter Company, Philadelphia, and a similar period as superintendent of the electrical department of the Tacony Iron and Metal Company, Philadelphia, he became superintendent of the Manufacturers Electric Company in 1891. In 1899 Mr. Russell became superintendent of the combined Manufacturers and Suburban Electric Companies, retaining that position until the companies were absorbed by the Philadelphia Electric Company in 1904, when he became district manager. He retained that position until he was appointed vice-president in charge of the commercial department in 1925; later he became vice-president in charge of rates and standard practice.

FRANCIS EUGENE DONOHOE (A'06, member for life) special representative, General Cable Corporation, New York, N. Y., died December 2, 1936. Mr. Donohoe was born October 28, 1863, at Lowell, Mass., and received his education in the public schools of Boston, Mass. He started his technical career in the experimental laboratories of the American Bell Telephone Company, Boston, Mass., and after 3 years of service with that company, joined the Edison General Electric Company as a salesman in 1889. In 1891 he became associated with the Safety Insulated Wire and Cable Company, New York, N. Y., where he remained for 3 years before accepting the position of western manager of the American Electrical Works, Chicago, Ill., in 1894. In 1906 Mr. Donohoe was appointed eastern sales manager of the same company, and was transferred to New York, N. Y., where in 1913 he became sales manager of the National Conduit and Cable Company. In 1925 he returned to the employ of the Safety Insulated Cable and Wire Company as special agent, and when that company was merged with another to form the General Cable Corporation, Mr. Donohoe was retained in the same capacity in the new company.

DAVID HENRY KELLY (A'17) district manager, Allis-Chalmers Manufacturing Company, Philadelphia, Pa., died December 7, 1936. Mr. Kelly was born at Steubenville, Ohio, July 2, 1883, and attended the University of Illinois, where he was graduated with the degree of electrical engineer in 1904. After a brief period of employment with the El Paso Smelting and Refining Company, he entered the employ of the Bullock Electric Manufacturing, Company, Norwood, Ohio, at about the time that company became a part of the Allis-Chalmers Company. Mr. Kelly served as sales engineer in that company's Cincinnati (Ohio), Philadelphia (Pa.), and Washington (D. C.) offices, and at the conclusion of his service in the World War was transferred to the New York, N. Y., offices. He had been manager of the Philadelphia offices since 1920. He was active in local Institute affairs, and was chairman of the Philadelphia Section during 1930–31.

LESTER ROBLEY SAILER (A'31, M'36) instructor in electrical engineering, Columbia University, New York, N. Y., died December 13, 1936. Mr. Sailer was born July 14, 1906, at New York, N. Y., and received the degrees of bachelor of arts (1929), bachelor of science in electrical engineering (1930), and electrical engineer (1935) at Columbia University. Following his graduation in electrical engineering, he was appointed an instructor in electrical engineering, at Columbia University, and was retained in that position continuously; he also served as an assistant in physics for the 3 scholastic years during 1927–30. In addition to his regular teaching duties, Mr. Sailer undertook consulting engineering assignments from several commercial organizations in New York, N. Y., and from Columbia University. He was a member of the Society for the Promotion of Engineering Education.

CHARLES V. WOODWARD (A'24) manager of the Baltimore, Md., offices of the Westinghouse Electric & Manufacturing Company, died November 19, 1936. Mr. Woodward was born July 23, 1878, and received his formal technical education at Pennsylvania State College. Upon completion of his studies he entered the employ of the Westinghouse Electric & Manufacturing Company at the East Pittsburgh, Pa., works in 1906, but was transferred in 1909 to the Philadelphia, Pa., offices, where he specialized in transportation and power engineering. He was identified with the development of several light traction companies in the state of Pennsylvania. In 1923 Mr. Woodward was transferred to the Baltimore offices of the Westinghouse company in the capacity of manager, which position he retained continuously for 13 years.

ALBERT GEORGE THOMAS GOODWIN (A'20) chief electrical engineer, The Broken Hill Proprietary Co., Limited, Newcastle, N. S. W., Australia, died November 12, 1936. Mr. Goodwin was born July 6, 1893, at Melbourne, Vic., Australia, and received his technical education at Working Men's College (Australia). In 1910 he was apprenticed to the Melbourne Electric Supply Company, and after having served in the field positions of shift engineer and technical assistant, was made a station superintendent. In 1917 Mr. Goodwin was employed by The Broken Hill Associated Smelters, as assistant to the power plant erecting engineer, and in the following year was made power plant engineer in charge of plant. Later he was transferred to the iron and steel works of The Broken Hill Proprietary Co., Limited, and eventually became chief electrical engineer.

LOUIS FERDINAND REINHARD (A'10, M'13, F'20) sales engineer, Geuder, Paeschke & Frey Co., Milwaukee, Wis., died in June 1936, according to word just received at Institute headquarters. Mr. Reinhard was born at Milwaukee, October 1, 1884, and was graduated in electrical engineering from the University of Wisconsin in 1907. Immediately following his graduation, he entered the engineering department of the Mechanical Appliance Company, Milwaukee, and was appointed chief engineer of that company in 1909. He remained in that position until 1920, when he accepted a position as engineer with Geuder, Paeschke & Frey Co. Later Mr. Reinhard was made a sales engineer, and eventually became sales manager in the contract stamping division of that company.

FRANCIS RAYMOND WELLES (A'87, member for life) retired, Altadena, Calif., died December 14, 1936, at Vernet-les-Bains, France. Mr. Welles was born at Athens, Pa., in 1854, and was graduated from the University of Rochester in 1875 with the degree of bachelor of arts. During the 5 years following his graduation, he was associated in business with E. M. Barton (A'87) founder of the Western Electric Company, and in 1880 left the United States to establish factory branches of that company in foreign lands. In 1882 he formed the first branch at Antwerp, Belgium, where the first multiple telephone switchboard used in Europe was manufactured. Mr. Wells served as manager of that branch until he retired in 1913.

JOHN JENKINSON (A'22) superintendent of the meter department of the British Columbia Electric Railway Company, Ltd., Vancouver, died October 14, 1936, according to information received at Institute headquarters. Mr. Jenkinson was born April 20, 1870, at Askan, Lancashire, England, and received his formal education in that country. In 1898 he went to Canada and accepted a position with the British Columbia Electric Railway Company, Ltd., where he remained continuously for 38 years. He was in complete charge of the meter department of that company from the time of its establishment.

# Membership

## Recommended for Transfer

The board of examiners, at its meeting on January 20, 1937, recommended the following members for transfer to the grade of membership indicated. Any objection to these transfers should be filed at once with the national secretary.

**To Grade of Member**

Aiken, E. H., supervisor of division of operations, District 5, Works Progress Administration, San Bernardino, Calif.

Davis, F. E., engineer, Commonwealth and Southern Corporation, Jackson, Mich.

Greenfield, E. W., cable research engineer, Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.

Hall, Sherman M., assistant manager, statistical bureau, Consolidated Edison Company, New York, N. Y.

Hase, R. C., transmission engineer, Southwestern Bell Telephone Company, St. Louis, Mo.

Isenberg, H. D., vice-president, Federal Insulation Company, Chicago, Ill.

Karsten, E. J., electrical engineer, United Light and Power Engineering and Construction Company, Kansas City, Mo.

Langdell, J. C., engineer, Commonwealth and Southern Corporation, Jackson, Mich.

Leslie, J. O., operating electrical engineer, E. M. Gilbert Engineering Corporation, Reading, Pa.

Likel, H. C., chief engineer, Pacent Engineering Corporation, New York, N. Y.

MacGillivray, A. L., telephone engineer, Western Electric Company, New York, N. Y.

McDowell, L. G., assistant engineer, New York and Queens Electric Light and Power Company, Flushing, N. Y.

Petit, F. W., assistant engineer, Brooklyn Edison Company, Inc., Brooklyn, N. Y.

Platt, C. J., Jr., superintendent, service inspection bureau, New York Edison Company, Inc., New York, N. Y.

Siskind, R. P., assistant professor of electrical engineering, Harvard University, Cambridge, Mass.

Smith, W. A., consulting engineer, Jacksonville, Fla.

Sommerman, G. M. L., research engineer, American Steel and Wire Company, Worcester, Mass.

Underhill, J. E., assistant engineer, British Columbia Electric Railway Company, Vancouver, B. C., Canada.

Van Sickle, R. C., engineer, switchgear engineering department, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

**19 to Grade of Member**

## Applications for Election

Applications have been received at headquarters from the following candidates for election to membership in the Institute. If the applicant has applied for direct admission to a grade higher than Associate, the grade follows immediately after the name. Any member objecting to the election of any of these candidates should so inform the national secretary before February 28, 1937, or April 30, 1937, if the applicant resides outside of the United States or Canada.

Abbott, E. G., General Electric Company, Chicago, Ill.

Andersen, J. R. (Member), New York and Queens Electric Light and Power Company, Flushing, N. Y.

Anderson, H. C., Oregon State Highway Commission, Salem, Ore.

Anderson, N. E., Homestake Mining Company, Lead, S. D.

Angevine, O. L. Jr., Stromberg-Carlson Telephone Manufacturing Company, Rochester, N. Y.

Ashe, F. C. (Member), Carnegie Institute of Technology, Pittsburgh, Pa.

Atwood, E. M., Washington Water Power Company, Troy, Idaho

Bacon, F. S., Jr., Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

Baranovsky, C., J. R. Longstaffe, Ltd., Toronto, Ont., Canada

Barrows, W. M., Public Service Electric and Gas Company, Hackensack, N. J.

Bennett, R. M., General Electric Co., Schenectady, N. Y.

Bernhard, G. K., Ohio Power Company, Canton, O.

Bissiri, A. Jr., 2409 Silver Lake Drive, Los Angeles, Calif.

Blaese, A. C., Porcelain Products, Inc., Chicago, Ill.

Boast, W. B., Iowa State College, Ames, Iowa.

Bobe, C. P. (Member), 1530 Olive Street, St. Louis, Mo.

Boehmer, F. D., Louis Allis Company, Milwaukee, Wis.

Bosworth, P. N., General Electric Company, Schenectady, N. Y.

Bower, G. L., Crane Company, Chicago, Ill.

Brandenburger, L., Wagner Electric Corporation, Salt Lake City, Utah.

Brigham, F. W., Washington Pulp and Paper Company, Port Angeles, Wash.

Bromley, J. E., Public Service Commission, New York, N. Y.

Brown, C. A., Southern California Telephone Company, Los Angeles, Calif.

Brown, S. S., Brown Brockmeyer Company, Dayton, O.

Bullock, E. S., Federal Power Commission, Atlanta, Ga.

Capy, P. L., 725 Paulus Street, Dallas, Texas.

Carlson, A. B., Southern New England Telephone Company, New Haven, Conn.

Carlson, H., Associated Press, New York, N. Y.

Casiano, L. J., Carnegie Illinois Steel Corporation, Youngstown, O.

Clasgens, A. E., New York State Electric and Gas Corporation, Brewster, N. Y.

Clifford, L. V., General Electric Company, Philadelphia, Pa.

Collings, L. W. Jr., General Electric Company, Schenectady, N. Y.

Coons, T., Potomac Electric Power Company, Washington, D. C.

Crates, R. R., Memphis Light and Water Commission, Tenn.

Craven, W. D., New York and Queens Electric Light and Power Company, Flushing, N. Y.

Croden, W. T., Metropolitan Water District, Banning, Calif.

Cutler, L. B., Armstrong Cork Products, Boston, Mass.

Davies, M. (Member), Langley Manufacturing Company, Ltd., Vancouver, B. C., Canada

Davis, E. W. (Member), 1478 Municipal Building, New York, N. Y.

Davis, M. F., Young Men's Christian Association, Zanesville, O.

Davis, P. C., Donnelly Electric and Neon Company, Boston, Mass.

de Anda, E., El Paso Electric Company, El Paso, Texas

Decker, H. D., Consolidated Edison Company, New York, N. Y.

Dillon, D. A., Century Electric Co., St. Louis, Mo.

Dorey, F. M., General Electric Company, Schenectady, N. Y.

Dumser, W. T., International Business Machines Corp., Chicago, Ill.

Durst, N. J., Cincinnati and Suburban Bell Telephone Company, Ohio.

Ellis, E. A., Boston and Maine Railroad, Billerica, Mass.

Emery, W. L., University of Utah, Salt Lake City, Utah.

Esval, O. E., Sperry Gyroscope Company, Inc., Brooklyn, N. Y.

Evans, A. J., Public Service Commission, New York, N. Y.

Evans, L. M., Worthington Pump and Machinery Corporation, Buffalo, N. Y.

Everest, F. A., Oregon State College, Corvallis.

Eysenbach, H. A., Crouse-Hinds Company, Syracuse, N. Y.

Fein, H., Belyea Company, Inc., New York, N. Y.

Ferrell, J. T., Brooklyn Edison Company, Brooklyn, N. Y.

Finley, A. R., Reliance Electric and Engineering Company, Cleveland, Ohio.

Fisher, R. L., Emerson Electrical Manufacturing Company, St. Louis, Mo.

Forsyth, W. H., Florida City, Fla.

Fowles, G. A., Anaconda Wire and Cable Company, Pawtucket, R. I.

Fox, E. L., 715 Sanford Street, Peoria, Ill.

Fraser, J. D., Jersey Central Power and Light Company, Allenhurst, N. J.

Frieseke, A. H., Southern Line Material Company, Birmingham, Ala.

Frith, J. M., American Telephone and Telegraph Company, New York, N. Y.

Fuller, J. L., Reliance Electric and Engineering Company, Cleveland, O.

Gago, F. J., University of Florida, Gainesville, Fla.

Gallagher, F. W., Franklin Institute, Philadelphia, Pa.

Ganzar, J. A., Carnegie Illinois Steel Corporation, Gary, Ind.

Gaynor, A. M., I. Gaynor, Inc., New York, N. Y.

Getting, M., Jr., Allis-Chalmers Manufacturing Company, Pittsburgh, Pa.

Gissel, E. A., Central Arizona Light and Power Company, Phoenix, Ariz.

Glas, F. J., New York and Queens Electric Light and Power Company, Flushing, N. Y.

Gordy, T. D., General Electric Company, Pittsfield, Mass.

Gosney, W. A., Trumbull Electrical Manufacturing Company, Ludlow, Ky.

Greentree, C. D., General Electric Company, Schenectady, N. Y.

Griesinger, F. D., Buffalo General Electric Company, Buffalo, N. Y.

Hamilton, J. P., Tennessee Valley Authority, Wilson Dam, Ala.

Hamilton, R. A., University of British Columbia, Vancouver, Canada.

Hansen, A. Jr., General Electric Company, Schenectady, N. Y.

Harris, C. S., Federal Telegraph Company, Newark, N. Y.

Hemmerich, F. J., New York and Queens Electric Light and Power Company, Flushing, N. Y.

Hepler, M. M., Textile Machine Works, Reading, Pa.

Hertel, R. F., General Electric Company, Schenectady, N. Y.

Higbee, C. W. (Member), United States Rubber Company, New York, N. Y.

Hillman, E. C., 815 Crotona Park North, New York, N. Y.

Hine, C. R., Pennsylvania Railroad, Wilmington, Del.

Houle, A. U., University of Toronto, Ont., Can.

Howell, J. C., Public Service Electric and Gas Company, Irvington, N. J.

Hufford, G. V., Century Electric Company, St. Louis, Mo.

Hughes, B. T., Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

Hunt, F. B., Green Mountain Power Corporation, Wells River, Vermont

Hunt, R. McP., General Electric Company, Schenectady, N. Y.

Hutchcraft, H. W., Tennessee Valley Authority, Wilson Dam, Ala.

Imle, H. R., Carter Oil Company, Tulsa, Okla.

Johnson, J. S., Iowa State College, Ames.

Johnson, S. E., General Electric Company, Oakland, Calif.

Jones, J. N., Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

Kaup, J. A., Doble Engineering Company, Medford Hillside, Mass.

Kelly, C. M. Jr., Guided Radio Corporation, New York, N. Y.

Kennedy, L. F., General Electric Company, Philadelphia, Pa.

King, H. W., New York (N. Y.) Edison Company, Inc.

Kirby, R. N., Deming Ice and Electric Company, Deming, N. M.

Kirkpatrick, P. E., Montreal Engineering Company, Ltd., Regina, Sask., Canada.

Kyle, W. D. Jr., Milwaukee, Wisconsin Electric Railway and Light Company.

Lank, W. J., Potomac Electric Power Company, Washington, D. C.

Larson, S. R., Jackson and Moreland, Boston, Mass.

Lear, T. J., New York and Queens Electric Light and Power Company, Long Island City, N. Y.

Lester, S. L., Transducer Corporation, New York, N. Y.

Levine, L. J., Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

Lightfoot, T. C. (Member), General Electric Company, Philadelphia, Pa.

Lillybridge, C. R., U. S. Bureau of Reclamation, Boulder City, Nevada.

Lockett, H. E., General Electric Company, Philadelphia, Pa.

Logan, J. E., Jersey Central Power and Light Company, Allenhurst, N. J.

MacCutcheon, R. H., Western Reserve University Law School, Cleveland, O.

Marsh, R. H., Southern California Edison Company, Ltd., Los Angeles, Calif.

Martens, J. J., New York and Queens Electric Light and Power Company, Jamaica, N. Y.

Matson, D. L., Jr., 101 Fifth Avenue, New York, N. Y.

Matthew, M. P., General Electric Company, Schenectady, N. Y.

Mauritz, F. E., General Electric Company, Schenectady, N. Y.

Maxwell, A. (Fellow), Edison Electric Institute, New York, N. Y.

McGee, H. M., Pennsylvania Power and Light Company, Sunbury, Pa.

McLean, L. V., Louisiana State University, Baton Rouge.

McNamara, C., Commonwealth Edison Company, Chicago, Ill.

Meehan, J. M. Jr., 12-14 West 37th Street, New York, N. Y.

Meudell, A. Y. Jr., General Electric Company, Schenectady, N. Y.

Miller, E. F., American Telephone and Telegraph Company, New York, N. Y.

Misenheimer, H. N. (Member), Bell Telephone Laboratories, Inc., New York, N. Y.

Mohan, A. R., 58 Hammond Street, Cambridge, Mass.

Montgomery, W. D., Cincinnati and Suburban Bell Telephone Company, Norwood, O.

Moon, A. W., New York State Transit Commission, New York, N. Y.

Moore, P., Hancock Brothers, San Francisco, Calif.

Muller, H. N. Jr., Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

Mundt, O. T., Montana Dakota Utilities Company, Williston, N. D.

Nason, H. E., Westinghouse Electric & Manufacturing Company, Chicago, Ill.

Nicholson, J. R., General Electric Company, Schenectady, N. Y.

Norton, V. E., General Controls Company, Minneapolis, Minn.

Oldfield, R. T. (Member), Public Service Commission, New York, N. Y.

Osborn, R. M., Allis-Chalmers Manufacturing Company, Milwaukee, Wis.
Osenbaugh, C. L., Light and Water Division, City of Memphis, Tenn.
O'Shea, C. L., Curtis Lighting, Inc., New York, N. Y.
Palmer, L. T., Burns and McDonnell Engineering Company, Kansas City, Mo.
Parrott, J. A. (Member), American Telephone and Telegraph Company, New York, N. Y.
Partington, R. M., General Electric Company, Pittsfield, Mass.
Pawluk, J., Sarvas Electric Company, Brooklyn, N. Y.
Pipes, L. A., Rice Institute, Houston, Texas.
Poey, C. D. (Member), New York and Queens Electric Light and Power Company, Long Island City, N. Y.
Pollyea, M. H., C. J. Tagliabue Manufacturing Company, Brooklyn, N. Y.
Pope, R., Bell Telephone Laboratories, Inc., New York, N. Y.
Pugh, H. C., Cast Iron Pipe Company, Birmingham, Ala.
Ratliff, A. H., Oklahoma Gas and Electric Company, Shawnee, Okla.
Razovsky, A. M., Laclede Gas Light Company, St. Louis, Mo.
Relson, M., National Park Service, Washington, D. C.
Rhodes, W. E., Stone and Webster Engineering Company, Richmond, Va.
Rowe, I., 652 Lafayette Avenue, Brooklyn, N. Y.
Roby, F. H., 710 South 3rd Street, Milwaukee, Wis.
Roehmann, L. F. (Member), 310 West 113th Street, New York, N. Y.
Rogers, E. T., Bishop Wire and Cable Corporation, New York, N. Y.
Rutledge, G. A., Allis-Chalmers Manufacturing, Company, Pittsburgh, Pa.
Sanders, J. W., Long Island Lighting Company, Roslyn Heights, N. Y.
Santiago, F., Aldrich Pump Company, Allentown, Pa.
Schroedel, H. E., Chicago, Milwaukee, St. Paul, and Pacific Railroad, Milwaukee, Wis.
Simmons, H., Georgia Power Company, Atlanta.
Sitkin, A., Century Lighting Equipment, Inc., New York, N. Y.
Skoog, A. W., Kingsbury Machine Tool Corporation, Keene, N. H.
Slusser, J. A., National Broadcasting Company, Inc., Denver, Colo.
Smith, P. D., Cansfield Electrical Works, Toronto, Ont., Canada.
Sokasits, F. M., Gibbs and Hill, New York, N. Y.
Sparrow, K. M., Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.
Stafford, A. B., Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.
Steinmetz, C. L., General Controls Company, Minneapolis, Minn.
Stratford, J. P., 821 North Normandie Avenue, Los Angeles, Calif.
Sukava, L., Reno Gold Mines, Ltd., Salmo, B. C., Canada.
Swanson, M. C. W., American Locomotive Company, Schenectady, N. Y.
Taborelli, R. V., 512 14th Street, Union City, N. J.
Taylor, O. L., Arrow-Hart and Hegeman Electric Company, Hartford, Conn.
Tyvand, J. A. (Member), Iowa Farm Bureau Federation, Des Moines, Iowa.
Upham, N. C., General Electric Company, Lynn, Mass.
Van Winkle, E. W., Best Manufacturing Company, Inc., Irvington, N. J.
von Roeschlaub, F., General Electric Company, Schenectady, N. Y.
Wagner, E., 6235 West Roosevelt Road, Berwyn, Ill.
Walter, J. H., Milwaukee (Wis.) Electric Railway and Light Company.
Watkins, D. L., American Steel and Wire Company, Worcester, Mass.
Way, K. J., Bell Telephone Laboratories, Inc., New York, N. Y.
Wells, F. B., Stone and Webster Engineering Corporation, Richmond, Va.
Wells, R. M., New York and Queens Electric Light and Power Company, Flushing, N. Y.
West, F. L., Niagara, Lockport, and Ontario Power Company, Buffalo, N. Y.
White, J. C., Air Reduction Sales Company, Corning, N. Y.
Wilcox, H. L. (Member), Electric Controller and Manufacturing Company, Cleveland, O.
Wilke, E. A., 6025 Melrose Avenue, Chicago, Ill.
Williams, S. B. (Member), *Electrical World*, New York, N. Y.
Winkelman, H. T., Jr., City of Memphis (Tenn.), Water and Light Division.
Wuerch, L. W., City of Tacoma, (Wash.), Public Utilities.
Wopat, R. M., Iowa Continental Telephone Company and Interior Telephone Company, Grinnell, Iowa.
Wyckoff, P. H., California Institute of Technology, Pasadena.
Zimmer, C. S., Bussmann Manufacturing Co., St. Louis, Mo.

## Addresses Wanted

A list of members whose mail has been returned by the postal authorities is given below, with the addresses as they now appear on the Institute record. Any member knowing of corrections to these addresses will kindly communicate them at once to the office of the secretary at 33 West 39th St., New York, N. Y.

Burns, Arthur B., 1958 E. 29th St., Brooklyn, N. Y.
Eller, E. E., 101 Brookline Court, Upper Darby, Pa.
Godoy, Ernesto R., Cia. Tel. y Tel. Mex., 16 de Septiembri No. 13, Mexico, D. F., Mex.
Jones, Harry Kenneth, 5511 Kenmore Ave., Chicago, Ill.
Koch, Joseph Stanley, 11 Howe Ave., New Rochelle, N. Y.
Little, Leroy C., 3414—17th St., N., Cherrydale, Va.
Ludwig, Leon R., 434 Burling Road, Forest Hills, Pittsburgh, Pa.
Millheisler, Charles A., 1417 Catalpa Ave., Chicago, Ill.
Miyota, Nath S., 916½ Howell St., Seattle, Wash.
Moore, Everett, 821 Sunset Blvd., Los Angeles, Calif.
Peach, Paul S., Upperville, Va.
Pollastro, John B., Helper, Utah.
Sawyer, Fred E., 811 E. Wisconsin Ave., Milwaukee, Wis.
Wong, Harry Y. L., 771 Broadway, West New York, N. J.

14 Addresses Wanted

# Engineering Literature

## New Books in the Societies Library

Among the new books received at the Engineering Societies Library, New York, recently, are the following which have been selected because of their possible interest to the electrical engineer. Unless otherwise specified, books listed have been presented gratis by the publishers. The Institute assumes no responsibility for statements made in the following outlines, information for which is taken from the preface of the book in question.

ELECTRICAL ENGINEERING in RADIOLOGY. By L. G. H. Sarsfield and V. E. Pullin. Pittsburgh, Instruments Publishing Co., 1936. 284 p., illus., 9x6 in., cloth, $6.00. Deals exclusively with the electrical engineering aspects of X-ray equipment for engineers not familiar with the work.

CONTROL of ELECTRIC MOTORS. By P. B. Harwood. N. Y., John Wiley and Sons, 1936. 390 p., illus., 9x6 in., lea., $4.50. Describes the characteristics of various types of motors and explains how they are used for purposes of control. Discusses the design, construction, and operating characteristics of controllers.

PHYSICAL CONSTANTS of PURE METALS. Ed. by National Physical Laboratory. Lond., His Majesty's Stationery Office, 1936. 27 p., tables, 10x6 in., paper, 6d. (obtainable from British Library of Information, New York, $0.20.) Presents results prepared by the National Physical Laboratory.

**Engineering Societies Library**
29 West 39th Street, New York, N. Y.

MAINTAINED as a public reference library of engineering and the allied sciences, this library is a co-operative activity of the national societies of civil, electrical, mechanical, and mining engineers.

Resources of the library are available also to those unable to visit it in person. Lists of references, copies or translation of articles, and similar assistance may be obtained upon written application, subject only to charges sufficient to cover the cost of the work required.

A collection of modern technical books is available to any member residing in North America at a rental rate of five cents per day per volume, plus transportation charges.

Many other services are obtainable and an inquiry to the director of the library will bring information concerning them.

NATURE of PHYSICAL THEORY. By P. W. Bridgman. Princeton (N. J.) University Press, 1936. 138 p., 9x6 in., cloth, $2.00. Presents a critical analysis of the points of view and methods in trying to understand the simpler aspects taken to be within the domain of physics.

TELEVISION RECEPTION, Construction and Operation of a Cathode Ray Tube Receiver for the Reception of Ultra-Short Wave Television Broadcasting. By M. von Ardenne, translated by O. S. Puckle. Lond., Chapman and Hall, 1936. 121 p., illus., 9x6 in., cloth, 10s. 6d. Intended to stimulate the interest of amateurs in experimentation with television.

TELECOMMUNICATIONS, Economics and Regulation. By J. M. Herring and G. C. Gross. N. Y. and Lond., McGraw-Hill Book Company, 1936. 544 p., illus., 9x6 in., cloth, $5.00. Deals with the economic and public service aspects of the telegraph and telephone industries. Presents the background of development of these industries, deals with the sources of revenue and the factors affecting costs and rate structures. Includes a detailed analysis of the Communications Act of 1934.

ORGANIZATION and MANAGEMENT in Industry and Business. By W. B. Cornell. N. Y., Ronald Press Company, 1936. 802 p., illus., 8x5 in., cloth, $4.50. Aims to provide a course of training in the organization, management, and operation of every department of a business concern.

OLD WIRES and NEW WAVES, the History of the Telegraph, Telephone, and Wireless. By A. F. Harlow. N. Y. and Lond., D. Appleton-Century Company, 1936. 548 p., illus., 9x6 in., cloth, $5.00. A popular history of the origins and development of the telegraph and telephone systems of America. The human side of the story is emphasized.

LESSONS and PROBLEMS in ELECTRICITY. By N. C. Page. N. Y., Macmillan Company, 1936. 356 p., illus., 9x6 in., cloth, $2.75. Based upon a course in the fundamentals of electricity which has been given to sophomore students at Massachusetts Institute of Technology. Planned for students with some training in mechanics and calculus.

HANDBOOK of CHEMISTRY and PHYSICS, 21 ed. Cleveland, Ohio, Chemical Rubber Publishing Company, 1936. 2023 p., 7x4 in., lea., $6.00. The latest annual edition of a well-known reference book.

ELECTRICITY: For Use or for Profit. By B. Ostrolenk. N. Y. and Lond., Harper Brothers, 1936. 211 p., tables, 8x5 in., cloth, $2.00. Discusses one aspect of the power problem: the influence of private utility companies on the standard of living. Considers the social and economic significance of present rate policies.

AUTOMATIC VOLUME CONTROL. ed. and published by J. F. Rider, N. Y., 1936. 94 p., illus., 8x5 in., cardboard, $0.60. Affords a description of the general principles of automatic volume control in radio receivers and of their use in current commercial sets.

ELECTRICAL ENGINEERS' HANDBOOK, 2 volumes (Wiley Engineering Handbook Series, volumes 4 and 5) ed. by H. Pender, W. A. Del Mar and K. McIlwain. 3 ed. N. Y. and Lond., John Wiley and Sons, 1936. illus., 9x5 in., lea. (volume 1, $6.00; volume 2, $5.00). A new edition in 2 volumes; one on power, the other on communications, which may be purchased separately.

# Industrial Notes

**General Electric Report for 1936.**—Orders received by General Electric Co. during the year 1936 amounted to $296,748,219, compared with $217,361,587 during 1935, an increase of 37 per cent. Orders for the quarter ended December 31 amounted to $84,857,181, compared with $58,417,822 for the last quarter of 1935, an increase of 45 per cent.

**Reward for "Lost" Meter Socket.**—A reward of $50.00 has been offered by the Westinghouse Elec. & Mfg. Co., for the return of the two-millionth type S meter socket. It is properly marked and identified as the two-millionth socket. The finder will be rewarded upon return of the socket to the company at Newark, N. J.

**New Cable Accessory.**—To meet a widespread demand for a simple and effective device for interconnecting single conductor secondary insulated cables in manholes and vaults, the G & W Electric Specialty Co., Chicago, has developed the "Multitap" which eliminates the use of tape and solder. This splicing device is suitable for cables with or without lead sheath. The copper bus is covered with molded G & W "Resistoyl" oil and moisture resistant rubber compound. The connectors and cable ends are covered with a molded Bakelite insulator sealed at the ends by means of a Resistoyl bushing compressed on the cable with a gland nut. Cable heads are interchangeable and made for all conductor sizes up to 500 mcm. A wrench is the only tool required for installation.

**General Electric Expands in Texas.**—A 3-story, concrete and brick addition to the General Electric building at Dallas is under construction, adjoining the present office and warehouse building and will provide all departments of the company with permanent headquarters in Dallas. It is expected construction will be completed about June 1. The annex will front 80 ft on Lamar Street and extend 174 ft on Corbin Street. A new $200,000 building in Houston, located on the block recently purchased by the company, bounded by Polk, St. Charles, Clay, and Live Oak Streets, is being erected. The building, of brick and steel construction, will be 2 stories in height and will be used to house the offices, warehouses, and service shops of the General Electric Co., the General Electric Supply Corp., and the General Electric X-Ray Corp.

**Factory Built Switchgear Units.**—A standard line of factory-built, metal enclosed switchgear, for shipment as a complete assembly, has been announced by the Westinghouse Elec. & Mfg. Co. Suitable for small industrial installations or auxiliary circuits in steam power stations, the units are factory assembled and tested so that cross connections do not have to be made in the field. This metal enclosed switchgear consists of cubicles in which are mounted circuit breakers, buses, disconnecting switches, instrument transformers and similar auxiliaries. On the front panels, which are hinged, are mounted required relay and meter equipment.

**New Electric Flow Meters.**—The Bristol Co., Waterbury, Conn., announces the addition of a complete line of electric flow meters for steam, liquids, and gases to its line of mechanical flow meters. These flow meters operate on the Bristol Metameter principle of telemetering, which the company has used for several years in instruments to transmit readings of pressure, liquid level, temperature, and motion from the point of measurement to a distant point where they are recorded or indicated on a dial. The electric flow meters can be furnished for recording, integrating, and indicating flow. The readings are transmitted over a simple 2-wire circuit, telephone circuits included, which does not enter into the calibration of the instruments.

**Condit Now Allis-Chalmers Unit.**—The Allis-Chalmers Mfg. Co., Milwaukee, announces that its subsidiary company, Condit Electrical Mfg. Corp., of Boston, is now operating as a company unit and known as Allis-Chalmers Mfg. Co.—Condit Works. It will continue to specialize in the manufacture of switchgear products as a division of the electrical department under R. S. Fleshiem, manager. The personnel, with headquarters at Hyde Park, will be as follows: George A. Burnham, assistant manager of the electrical department in charge of sales and engineering of the switchgear division; W. S. Edsall, manager of sales, switchgear division; and H. V. Nye, engineer in charge of the switchgear division, with headquarters at Milwaukee. Frank W. Young is works manager.

# Trade Literature

**Motors.**—Bulletin 2-1, 8 pp. Describes single phase motors, repulsion start induction, brush lifting, 1/8 to 40 horsepower. Century Electric Co., 1806 Pine St., St. Louis, Mo.

**Connectors.**—The "Burndy News," 16 pp., in the form of a tabloid newspaper, profusely illustrated, describes numerous applications of various forms of electrical connectors. Burndy Engineering Co., Inc., 459 East 133rd St., New York City.

**Network Equipment.**—Bulletin 1184, 8 pp. Describes a complete line of low-voltage, a-c network apparatus, comprising transformers of both vault and subway types, disconnecting and ground switches, and network protectors for all applications. Allis-Chalmers Mfg. Co., Milwaukee, Wis.

**Motors.**—Illustrated folder, "Making Commutators," describes methods for manufacture, testing and inspection of commutators for d-c motors and generators. Folder, "Making Bobbin-Type Field Coils," illustrates manufacture of field coils for the same apparatus. The Reliance Electric & Engg. Co., 1086 Ivanhoe Road, Cleveland, O.

**Insulator Tester.**—Catalog 11, Sec. 2, 6 pp. Describes a new device, the "Hipot" insulator tester, a portable outfit for live line testing of individual porcelain insulators in a string or pin type insulator assembly; for operating voltages of 11,000 to 132,000 volts and higher. The equipment consists of three Bakelite sections and a handle section which screw together, an indicating instrument, a ground prod and the necessary cable and connectors. Roller-Smith Co., 233 Broadway, New York City.

**Time Delay Relay.**—Bulletin 362, 2 pp. Describes a new motor driven time delay relay, in which time ranges start with a maximum of 35 seconds and include 1 3/4, 5 1/4, 12 1/4, 26 1/4, 42 and 63 minutes. Differential gearing eliminates the use of troublesome clutches and a magnetically operated brake has been designed for the differential gear train. A standard midget relay, built into the device, provides various load contact combinations including double pole, double throw. The relay is designed for 110 and 220 volt a-c operation, and is immediately recycling. Quick make-and-break contacts are furnished with all contact combinations. Ward Leonard Electric Co., Mt. Vernon, N. Y.

**Electrostatic Voltmeters.**—Bulletin, 4 pp. Describes a new line of electrostatic voltmeters for a-c and d-c measurements, available in full scales ranging from 150 to 25,000 volts. The instruments are suitable for direct connection on either alternating or direct current for readings up to 3500 volts and are entirely independent of wave form, frequency and temperature. Flush, projecting and portable types may be had in all ranges up to 3500 volts. Applications include cable testing, determining insulator leakage, insulation testing, measuring high impedance circuits, etc. Ferranti Electric, Inc., 30 Rockefeller Plaza, New York City.

**Equipment Depreciation Analysis.**—A 176-page bulletin on the determination of the probable lives of various types of railroad, public utility and other physical equipment has been published by the Iowa Engineering Experiment Station as Bulletin 125, "Statistical Analyses of Industrial Property Retirements" by Robley Winfrey, research engineer, and will be sent free of charge on request to the Station at Iowa State College, Ames, Iowa. Five methods of constructing survivor curves for the determination of probable life are explained and compared with the "turnover" method. The method of comparison with type curves is simple, accurate, and quickly applied, all in contrast to involved mathematical methods. The bulletin will be helpful to those engaged in depreciation studies.

**Induction-Motor Constants.** The constants of single-phase induction motors usually are computed by means of polyphase formulas, with special adaptations to single-phase motor construction. A method of calculating electrical constants has been developed specifically for the single-phase capacitor motor, but is equally applicable to other types of single-phase motors (*pages 333–8*).

**Flux Locus.** A concept for the locus of rotor flux in a single-phase induction motor has been suggested in which the flux is referred to axes fixed with respect to the rotor; this concept is said to be less involved than either the cross-field or revolving-field theories although it does not lend itself to quantitative mathematical treatment (*pages 331–2*).

**Inductance of Solenoids.** A paper in this issue presents the derivation of series expansion formulas for calculating the mutual inductance of solenoids. The new formulas are derived from basic formulas of the National Bureau of Standards, and replace some of the older absolute formulas that require exacting numerical computations (*pages 347–53*).

**Train Heating.** Weather conditions have marked effects on the electrical energy requirements for traction and heating of trains, cold weather causing considerable increase in operating expense when power is purchased. A study of the relations of energy and temperature is reported in this issue (*pages 361–2*).

**Rectifier Circuit.** Measurement of transient oscillations of small angular swing in synchronous machines, when made by the method employing a pilot alternator connected to the main machine, may be simplified by a circuit employing rectifier tubes that enables the oscillograph to plot the actual displacement curve directly (*pages 339–40*).

**Copper-Oxide Rectifiers.** An equivalent circuit has been developed for representing copper-oxide rectifiers by replacing the rectifier element with 2 constant resistances effective during the 2 directions of current flow. Circuits are analyzed and the computed results obtained by this method are compared with oscillograms (*pages 354–60*).

**Carbon Arcs.** Low-intensity, high-intensity, and flame arcs, 3 distinct types of carbon arcs, have individual characteristics, and each is affected differently by variations in arc conditions. Effective application requires consideration of these characteristics, and adaptation of operating conditions to them (*pages 319–24*).

**Railway-Motor Standards.** Advancements in railway motor design, and the development of new types of equipment for which no standards have existed, have made necessary a revision of the AIEE standards in this field; the new standards have been adopted as "American Tentative Standards" (*pages 312–13*).

**Lightning Protection.** Some 75 per cent of all interruptions on overhead electric power transmission circuits are attributed to lightning. To reduce these interruptions and thus improve service, several methods of protecting power lines against lightning have been developed (*pages 314–18*).

**Committee Meetings.** During the Institute's 1937 winter convention, meetings of many Institute committees and subcommittees were held (*pages 380–2*). Four technical conferences also were held at the convention under auspices of Institute committees (*pages 383–4*).

**Nominations for Institute Officers.** In accordance with the AIEE by-laws, the national nominating committee met during the recent winter convention. At that meeting, nominees for Institute offices for the year 1937–38, were designated (*page 375*).

**Report on Dues.** The final report of the special committee appointed several years ago to consider dues and related matters was presented to the Institute's board of directors at its meeting held during the recent winter convention; the committee recommended no change in dues (*pages 388–9*).

**Vehicle Lighting.** Railroad cars, trolley cars, and motor coaches are now being equipped with decorative and highly effective lighting installations that greatly improve reading conditions for passengers; illumination levels are from 10 to 20 foot-candles at the reading plane (*pages 302–04*).

**Core Loss.** The magnitude of intersheet eddy-current loss in laminated cores, which may be important in large cores and with high clamping pressure, has been investigated, and a more rigorous formula for eddy currents in rectangular sections has been derived (*pages 344–6*).

**Current Loci.** The variation of currents and voltages in a general linear a-c network connected to a single adjustable branch in which the current is adjusted under some given restriction is considered in a paper in this issue; the various loci are shown (*pages 325–30*).

**Circular Loci.** The method of circular loci may be conveniently applied in the calculation of the variation of currents and voltages when self impedances are changed in various types of circuits operated at constant frequency. This method has been applied to the delta-star connection (*pages 341–3*).

**Lamme Medal Awarded.** The Institute's Lamme Medal for 1936 has been awarded to Frank Conrad of the Westinghouse company, for "his pioneering and basic developments in the fields of electric metering and protective systems" (*page 388*).

**Edison Medal Presented.** The 1936 Edison Medal, highest award of the AIEE, was presented to Alex Dow, president, Detroit Edison Company, at a special session of the Institute's recent winter convention (*pages 378–80*).

**Institute Members Honored.** Five Institute members were honored recently by Eta Kappa Nu, honorary electrical engineering society, in connection with the naming of America's outstanding young electrical engineer for 1936 (*pages* 389–90).

**Capacitance.** Calculation of the capacitance of a parallel-plate air capacitor may be made exact by a method that takes into account the fringing of the flux; several approximate formulas are also useful (*pages 363–6*).

**Power and People.** Social relations of technical advances, considered from the aspect of the arts of energy production and distribution, are discussed in an address delivered upon the occasion of the presentation of the Edison Medal for 1936 (*pages 305–11*).

**Winter Convention.** Reports of the various activities at the Institute's 1937 winter convention held during the last week in January are given in this issue (*pages 371–87*).

**Directors Meet.** For the first time, the AIEE board of directors met on 2 successive afternoons during the 1937 winter convention; many matters of importance to the Institute were acted upon (*pages 374–5*).

**North Eastern District Meeting.** Plans for the Institute's North Eastern District meeting to be held in Buffalo, N. Y., May 5–7, 1937, are progressing (*page 390*).

**Discussions.** Some of the papers presented at the AIEE South West District meeting at Dallas, Texas, in October 1936 are discussed in this issue (*pages 367–70*).

# DISCUSSIONS

Appearing in this issue are discussions of the following papers:

A Disturbance Duration Recorder—Frier . . . 367
Electrical Features of the Texas Centennial Central Exposition—Fies . . . . . 368
Experiences With a Modern Relay System—Gerell 369

Statements and opinions given in articles and papers appearing in ELECTRICAL ENGINEERING are the expressions of contributors, for which the Institute assumes no responsibility. Correspondence is invited on all controversial matters. ¶ Subscriptions—$12 per year to United States, Mexico, Cuba, Porto Rico, Hawaii, Philippine Islands, Central and South America, Haiti, Spain, Spanish Colonies; $13 to Canada; $14 elsewhere. Single copy $1.50. ¶ Address changes must be received by the fifteenth of the month to be effective with the succeeding issue. Copies undelivered because of incorrect address cannot be replaced without charge. ¶ ELECTRICAL ENGINEERING is indexed annually by the Institute, weekly and monthly by *Engineering Index*, and monthly by *Industrial Arts Index*: abstracted monthly by *Science Abstracts* (London).

# Speaking of Conventions—

## A Message From the President

AN almost universal characteristic of the human family is the desire "to come together"—"*con venio*"—"convene." Twice in the last month have I seen this demonstrated: once in New York at the winter convention of the AIEE; and again in a far different way at Colon, Panama, where the picturesque natives of the Isthmus dropped every regular occupation that they might fittingly celebrate the annual carnival just prior to the beginning of Lent. I am told that the term "carnival" is derived from 2 Latin words, *vale* (farewell) and *carnus* (meat). In gay, picturesque, and sometimes ludicrous costumes, by parades through colorfully decorated streets, and enlivened by bands, the throng bade a merry farewell to meat.

With the convention closing January 29, and an Institute trip through the South scheduled to begin at Miami, Fla., on February 12, Mrs. MacCutcheon and I feel that Providence must have arranged that the French liner "Lafayette" should sail at 11 p.m. on the 29th, and touch at Havana on the morning of the 12th. The Pan American Airways ship at 3 p.m. should have delivered us at Miami in ample time for the Florida Section meeting in the evening, but a storm prevented this. On the trip the ship touched at Martinique, Trinidad, Grenada, La Guayras, Caracas, and the Canal Zone. Of course, we traveled in an electrically equipped ship and at each port we found that the electrical engineer had preceded us and provided lights, railways, pumping stations, and refrigeration.

As the delightful cruise drew to a close we thought of the many Institute conventions we have been privileged to attend, the 1937 New York convention in particular; and the conventions of the future, the 1937 Milwaukee convention in particular.

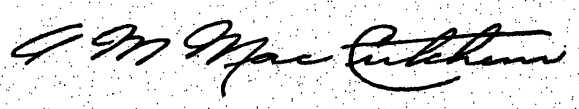
The 1937 winter convention seemed one of the busiest, most stimulating, and most interesting that we have attended. Our only regret is that every member of the organization could not be there. The outstanding feature was the presentation of papers at the 14 technical sessions. There is a mental stimulus through the authors' personal presentation, which cannot be realized by reading alone; and the resulting discussion is sometimes more valuable than the paper itself. Frequently the discussions were continued outside the meeting long after it had closed. Next was the opportunity offered, through the many inspection trips, for observing the most modern electrical installations. The presentation of the Edison Medal to Doctor Alex Dow, outstanding pioneer and president of the Detroit Edison Company, was a memorable and impressive occasion fittingly climaxed by an inspiring address from Doctor John C. Parker, vice-president of the Consolidated Edison Company of New York, Inc.

During the convention an unusual number of committee meetings filled every available room at headquarters. Carefully arranged, these committee meetings appeared to stimulate rather than detract from the interest in the technical sessions. Because of the committee meetings many were present who otherwise would not have been able to attend. Some committees met on the first day, presented their recommendations to the board of directors at its meeting on Tuesday, and at a second meeting late in the week took steps to initiate the activity which had received the board's approval.

It has become customary to hold the meeting of the national nominating committee during the convention week. This plan brings to the convention a prominent, enthusiastic, and active Institute member from every District. Opportunity is also offered to each member of the nominating committee to consult many other Institute members relative to the most important work of the nominating committee.

For the first time in our history, the board of directors devoted 2 afternoons in a single week to the affairs of the Institute.

Those who attend a New York convention see our efficient headquarters' staff in operation and realize what a busy place headquarters is.



Each day I overheard or took part in discussions relative to Section activities, Section membership, Section management. Plans were discussed and final details completed as to visits by national officers to the various Sections. Ideas were exchanged and enthusiasm given and received.

Last and not least acquaintances were formed and strengthened, friendships renewed, new friendships started. The electrical engineers were meeting on a common ground and with a common purpose.

Great credit is due Chairman C. R. Beardsley, and all his committee chairmen, and the members of the committees for the excellent handling of all of the tremendous amount of planning and detail so essential to a successful convention.

The members of the AIEE enjoy and profit by convening. This year 4 invitations were received for the 1938 summer convention and one for 1939. It was indeed difficult to choose between these invitations, but Washington, D. C., was finally selected since the Section there is very active, has not previously been our host, can offer unusually adequate accommodations, and is located in a city we would all like to visit.

The next national convention will be at Milwaukee, Wis., next June, cooled by the breezes from Lake Michigan. In last December, I visited the hotel that has been selected for convention headquarters and saw one of the finest convention floors to be found in this country, with every provision for assembly and meeting rooms. The Milwaukee committee was organized over 7 months ago and has planned an unusual convention of broad general interest. In spite of a recent story in *Saturday Evening Post* I believe in conventions of the type we hold and wish the author of that story might be with us in Milwaukee and observe how a real engineering convention is carried on. I hope to meet a large number of you at Milwaukee.

# Improved Lighting in Passenger Vehicles

THE SCIENCE OF SEEING differs somewhat from the science of vision with which most of us are generally familiar. The science of vision is a relatively old subject and deals with the eyes, their functions and limitations. The science of seeing, however, treats the human being as a seeing machine, particularly as regards its behavior, efficiency, and welfare.

Years of research, from which grew this new science, definitely prove that lighting values and conditions of the past, and especially in the realm of transportation, are totally inadequate for what may be termed comfortable or easy seeing. Such ideas or beliefs as that 4, 6, or even 8 footcandles represent adequate lighting have been literally blasted.

It is obvious that of those passengers who attempt to read while patronizing transportation systems today, all but a very small percentage are 20 years of age or more. A recent survey indicates that of those at the age of 20 years 23 per cent have defective eyesight; at age 30, 39 per cent; at age 40, 48 per cent; at age 50, 71 per cent; while at 70 years of age 95 per cent have impaired eyes.

Furthermore, investigations covering several occupational groups show that in the farmer and laborer class, where work is usually carried out under daylight conditions only (500 to 8,000 footcandles), less than 20 per cent have defective eyes. In the carpenter and painter groups, a percentage of from 20 to 40 is noted; the machinist and printing occupation from 40 to 60; housewife and textile worker from 60 to 80; and in the drafting and stenographic field from 80 to 100.

The foregoing is mentioned for the purpose of bringing out the great need for more and better lighting, not only for the purpose of aiding those eyes that are already defective but also to serve to protect those millions of eyes that are as yet unimpaired.

It is encouraging to note that recently the several transportation agencies, in their earnest efforts to serve the needs of the public, have begun to give serious thought to this subject of lighting.

The modern day coach shown in figure 1 is indicative of the strides being made by the more progressive railroads. It is lighted by means of a combination indirect and direct louvered system. The indirect, which provides a low general illumination, is delivered from a single row of lamps spaced along the center line of the ceiling. Direct view of these lamps is prevented by the unique baffle which not only directs their light toward the ceiling but also serves as the duct for air conditioning.

This system is supplemented by individual seat-lighting fixtures of the direct type properly louvered, which are incorporated within the rolled edge of the continuous basket or baggage rack. Approximately 12 footcandles are obtained at the reading plane. About 5 watts per square foot of floor area are provided.

No discussion of rail transportation would be complete without presenting some of the lighting treatments which are being incorporated in the new Diesel-electric streamline trains. Figure 2 shows a portion of a truly modern observation lounge car. The lighting here is delivered from a semi-indirect open-top louvered-bottom aluminum trough containing small-wattage lamps located on approximately 7-inch centers. The general illumination is secured by light reflected from the ceiling and the reading-plane illumination derived mainly from the direct light from the lamps. The front edge of the trough and the transverse louvers in the bottom of the trough protect the eyes of those seated from direct view of the lamps. Approximately 12 footcandles of illumination are provided at the reading plane.

Another example of modern train lighting which is quite worthy of note is that of a recently built Pullman sleeping car shown in figure 3. The general illumination

**Fig. 1. Combination indirect and direct louvered lighting systems in a modern stream-lined day coach**

Indirect lighting system consists of 15-watt 60-volt lamps located above air-conditioning baffle; individual seat lighting is from 60-watt 60-volt tubular lamps located above transverse louvers in edge of bag rack

An article written especially for ELECTRICAL ENGINEERING, based upon an address by H. H. Helmbright of the incandescent lamp department of the General Electric Company, Nela Park, Cleveland, Ohio, before a meeting of the transportation group of the New York Section, April 9, 1936; recommended for publication by the AIEE committee on production and application of light.

**Fig. 2 (above). Semi-indirect louvered-trough lighting in an observation lounge car**

Each trough contains 10-watt 32-volt lamps spaced 7 inches apart

is furnished from a continuous trough of the direct lighting type, in which are also incorporated the air-conditioning outlets. The semicylindrical glass sections diffuse the light from the single row of lamps which are mounted within a reflector recessed into the ceiling. A night lighting circuit consisting of low-wattage blue-colored lamps is also included to facilitate reading the section numbers and also to insure safe passage along the aisle after berth sections are "made up" for occupancy.

A new type of berth-lighting fixture furnishing approximately 10 footcandles is installed at both ends of the section. This fixture is also equipped with the blue night-lighting feature.

Train-lighting systems of the totally indirect type, although possessing many virtues, are rapidly being abandoned, partly because of their extremely low efficiency (from 8 to 15 per cent) and the rapid depreciation of their reflecting surfaces under railroading conditions. Furthermore, a totally indirect system that would produce footcandles in keeping with modern standards would probably produce uncomfortable ceiling brightness that would be annoying to the eyes.

Strange as it may seem, the electric street-railway industry, which until recently seemed doomed to be replaced by the motor bus, has taken a "new lease on life." The industry has joined with the various manufacturers of electric railway equipment in staging a "comeback." A distinctly new type of vehicle has been developed that differs in many respects from the general conception of the street car. Lighting, consisting of a relatively large number of bare lamps studded throughout the car ceiling,

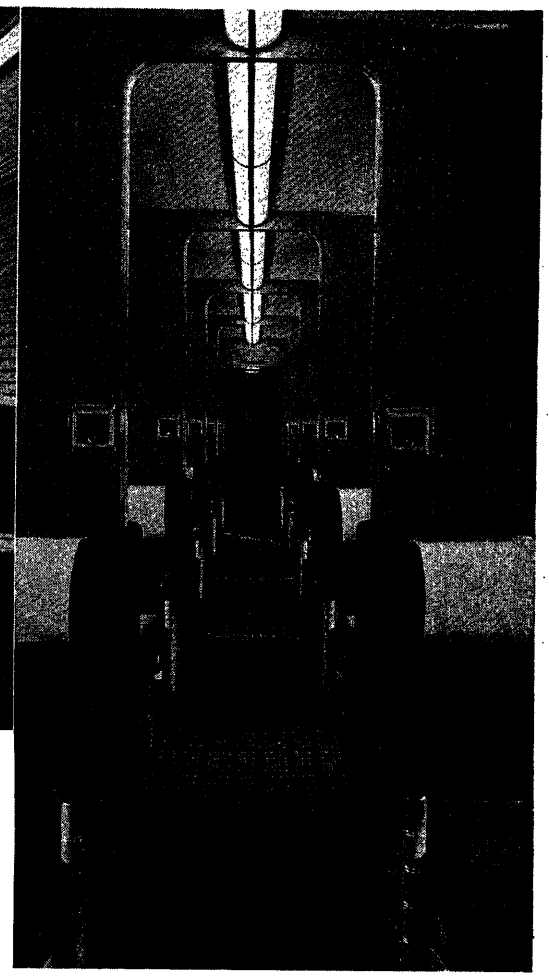


**Fig. 3. A modern Pullman sleeping car lighted by central lighting system and new berth-lighting fixtures; night-lighting circuits are incorporated within fixtures**

The ceiling fixture of the continuous direct type contains 10-watt 32-volt lamps on approximately 7-inch centers above semicylindrical flashed opal glass; small 6-watt blue-coated lamps are provided for night-lighting use

has been replaced by more efficient and less glaring systems giving the passenger from 10 to 20 footcandles of lighting. Figure 4 shows one type of street car that has been equipped with the semi-indirect louvered trough producing an average of 18 footcandles throughout the car. This replaced a direct system delivering from 8 to 10 footcandles at the reading plane.

Another continuous louvered system in which the greater portion of the light is directed toward the reading plane has been produced and installed in trolley busses (figure 5). This design also delivers approximately 18 footcandles at the reading plane, but permits a spacing of lamps 50 per cent greater than in the semi-indirect trough shown in the street car (figure 4).

Other modern and efficient types of lighting systems recently produced have fixtures of the direct type placed directly above each transverse seat. In general, the design is such that accurate control is obtained, thus preventing direct glare from reaching the reader's eyes. This control may be secured by means of lenses or by glass-

**Fig. 4 (above). Street car equipped with open-top louvered-bottom aluminum trough for lighting**

Trough contains 30-volt 1-ampere automatic-cutout lamps spaced on 10-inch centers

**Fig. 5 (right). A modern trolley coach with recessed louvered trough for lighting**

Trough contains 30-volt 1-ampere automatic-cutout lamps spaced on approximately 15-inch centers

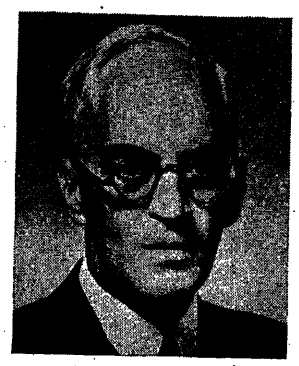
enclosed reflectors. The lighting efficiency of these systems, in terms of footcandles at the reading plane, is slightly greater than that obtained from either the semi-indirect or direct louvered trough.

The gasoline-motor-coach field, desiring to maintain its present position in city transit and also to compete successfully with the new-type street car and the electric trolley coach, is making rapid progress in the art of lighting. Power supply has been increased from approximately 150 watts to 750 watts and in extreme instances to 1,200 and 1,500 watts. Present day practice results in one fixture containing a 21-candlepower lamp being placed above each transverse seat or its equivalent. Until recently, one fixture containing a 15-candlepower lamp and in some cases only a 6-candlepower lamp, placed above each alternate seat, was considered adequate.

Here again the lens or the reflector design is used to obtain high output efficiency and to avoid objectionable glare. By the use of the 21-candle power lamp as mentioned, it is possible to obtain approximately 10 footcandles at the reading plane. In figure 6 a good example of modern motor coach lighting is shown.

Judging from the intense interest in illumination that is being displayed by transportation officials, it is believed that the time is not far distant when transportation lighting conditions will be quite in keeping with those obtaining in other fields where usual seeing tasks are performed. Lighting still remains one of the most important tools available to the transportation field in furthering the development of passenger travel.

**Fig. 6 (below). Modern lighting in a motor coach**



Open louvered-type fixtures are used with a 12–16-volt 21-candlepower lamp in each

# Power and People

By JOHN C. PARKER
FELLOW AIEE

**The application of technical advances to the welfare of mankind is held to be the true contribution of engineering to civilization, rather than the advances themselves; power together with tools to use it, and not power alone, led to American industrial development. More than merely the availability of large amounts of power is necessary in order that standards of living may be raised, and maintained.**

BECAUSE I know a little more about power engineering than about any of the other varied aspects of our profession, it seems suitable in large part, in attempting an inquiry into the social relations of our more mechanical performances, to use some aspects of the arts of energy production and distribution as typical rather than as the exclusive subject matter of our discussion. I suspect that we are in essential agreement as to all that will be said here this evening. Certainly I do not believe that I shall be bringing any new ideas to you, nor is what I have to say any recently inspired product of the vigorous or violent sequence of events in this decade. I hope to suggest for your reconsideration things already well known to you, but which, under the pressure of necessity in material things, all of us are likely to get into a wrong perspective or even entirely to forget.

Doctor Parker

I approach a discussion of the relation of technology to humanity with a greater hesitation because today it seems increasingly convenient to seek implications behind explicit terms. Will you accept my assurance that no suggestions are intended beyond the things actually discussed? Whatever applications to engineering conduct may be suggested, it would be most improper before a society of professional engineers to attempt to preach at other elements in society. I think it may fairly be said that however vivid our professional imagination and however sound our social conduct, we engineers are not characteristically possessed of an extraordinary degree of social imagination.

This comes about through the very nature of our training and more particularly of our engagements. Probably there is no calling more definitely social in its character than is that of the engineer. The engineer does not live a life of isolation but on the contrary works with and through other men. His work, whether it be in research or design or construction or production or commercial distribution, involves understanding of, and adjustment to and co-operation with other men. A community of effort is necessary to the complete realization of his undertakings. He has then a high reality of contact within a closely articulated social unit. In this his work is definitely more social than that of the physician or of the lawyer or of the minister of souls or of the exponent of the creative arts, each of whom, in a large degree, works as an individual. In that very fact, however, the engineer has at once a satisfaction and a limitation of his social contacts. With other men, largely of identical or at least of closely related interests and limitations, he finds satisfaction for his desires for human contact and such satisfaction easily enough so preoccupies his time that he can easily fail of social understanding of the people whom his profession serves or of the social significances of his own works.

The profession perhaps is not unlike the cloistered monastic orders, living their intensely intimate and interrelated lives, out of touch with the world immediately about them. The physician or the lawyer, on the other hand, carrying on an individual practice even with people in their less normal temper or physical state, does have of necessity a vividness and reality of contact with people other than his coprofessors, and properly to do his work must have the imagination broadly to interpret their lives, their needs, and the significance of his professional efforts in their behalf.

These individual service professions do come closer to the people served than do we.

In consequence of engineering remoteness, we perhaps become obsessed with the technical beauties and interests of our work and with the human problem of co-ordination with our fellows in creation and miss some perspective of how our works touch on the larger interests of society. Not infrequently, it seems to me, we have missed entirely the large significances of engineering and perhaps as frequently, in the fashion so common among self-deprecatory people, we have put up a certain defensive insistence on importances which simply do not exist.

If at both extremes the world has taken us at our own depreciated valuation, there can be little complaint on our part, nor can there be any great surprise if the less ponderable and less obvious values in us and in our works are not spontaneously accepted. Of course, it hurts our finer professional sense if people think of us as mere technicians of unimportant arts, whether the niceties of sound engineering analysis are appraised merely as necessary contributions to a socially unimportant technique, or, as might be inferred from lay references in the news columns

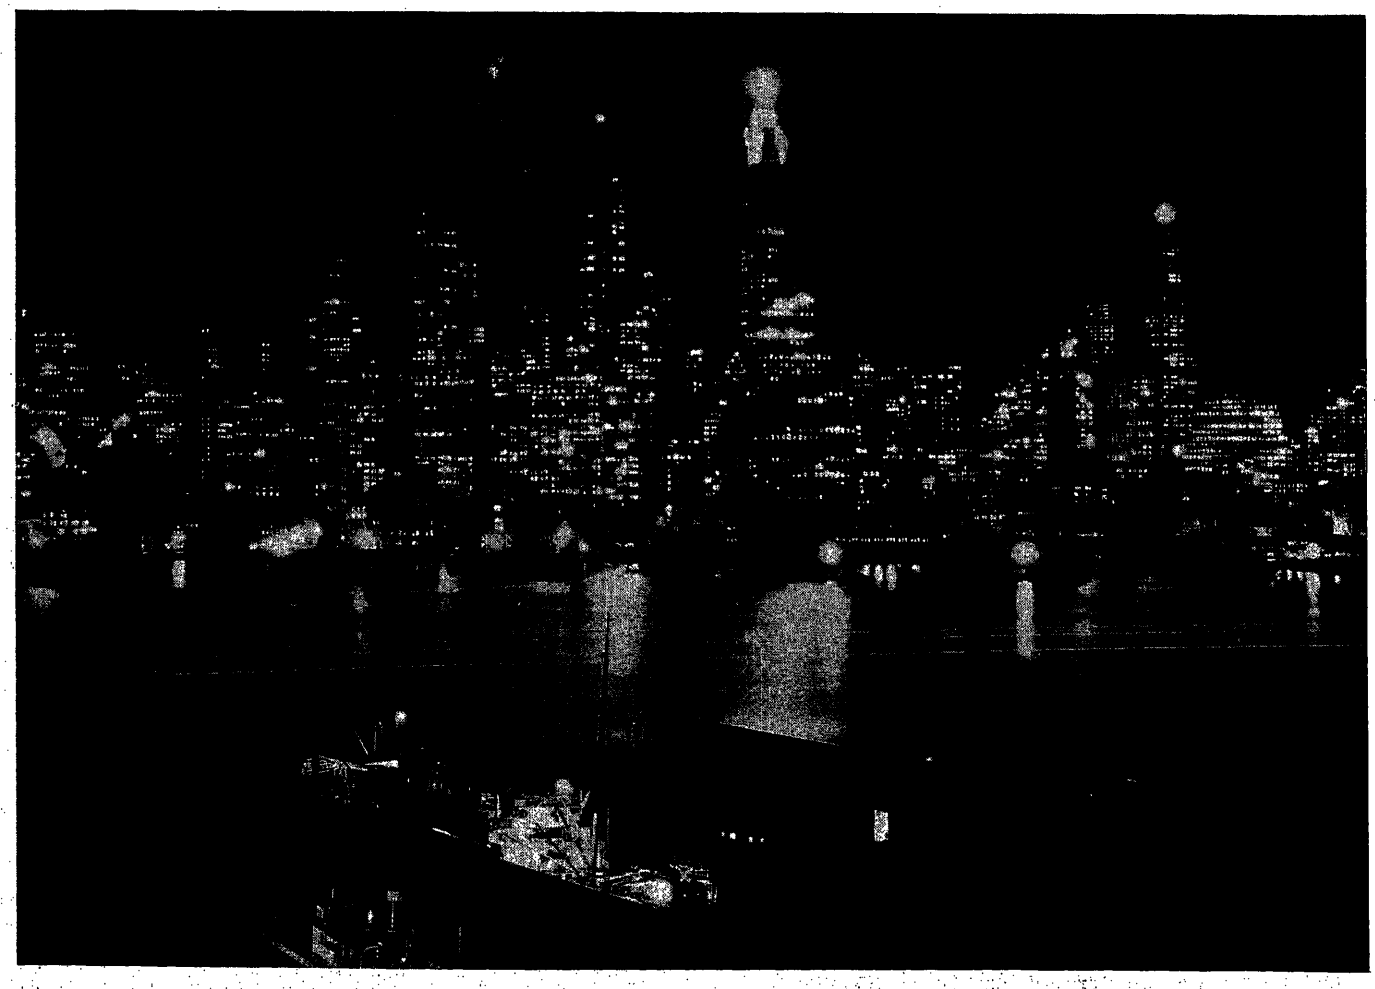
An address presented January 27, 1937, upon the occasion of the presentation of the Edison Medal, during the AIEE winter convention, New York, N. Y.

JOHN C. PARKER is vice-president of the Consolidated Edison Company of New York, Inc.

and in the advertising space, the engineer is esteemed as only a slightly sublimated form of mechanical handyman.

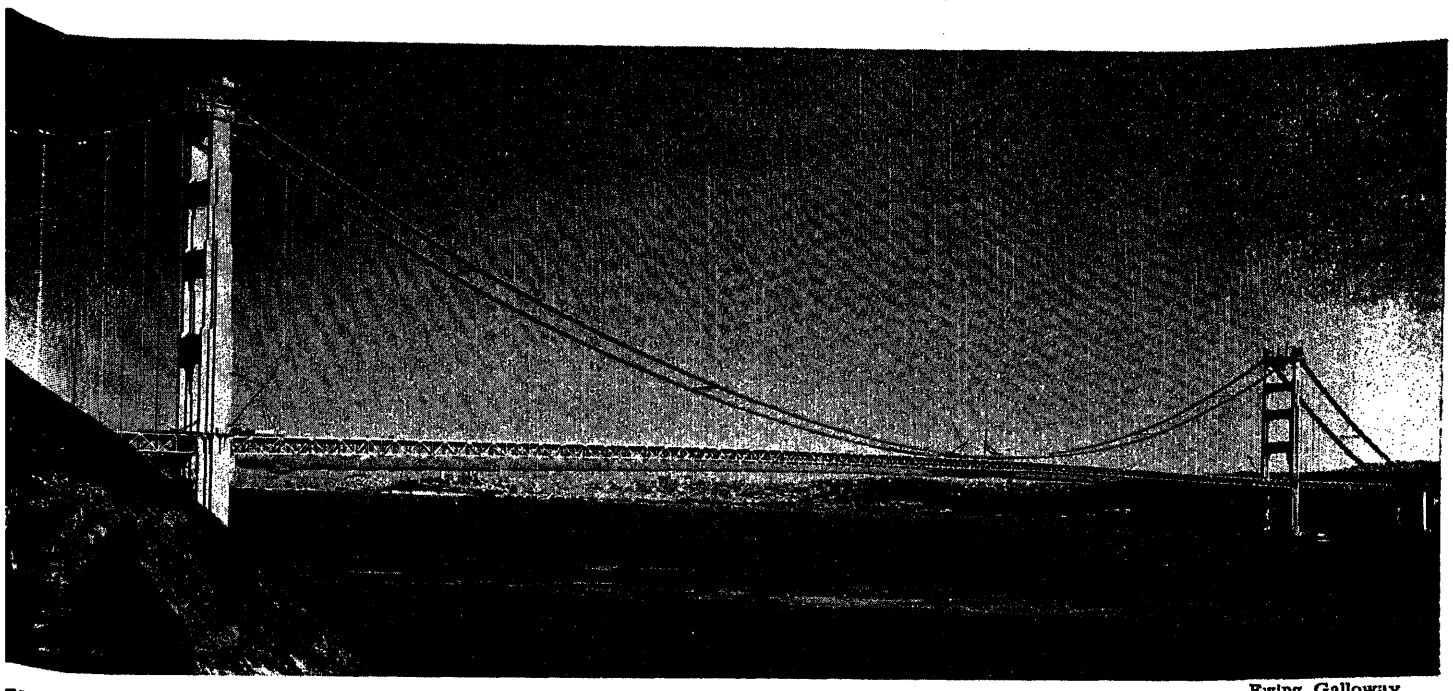
On the other hand, when laymen, editorial writers, and public officials agree with us in adulation of our works and hail engineering achievement as the be-all and the end-all of social progress, it is easy for us smugly to agree with what is at once too narrow a conception of the value of our work and too great an emphasis on its place in a world of human beings. When such a philosophy becomes characteristic of a nation or of a period, we may well be in desperate danger.

There is not exaggeration in the belief that a disproportionate acclaim is given to mere mechanical achievement.



A few days ago an eminent traveler expressed his belief that the hazards of life were great in this country because we were the most highly civilized, the cause or the evidence of our civilization being, in his mind, the fact that we have so many machines. The extraordinary thing is that that remark did not produce any comment in disclaimer of mechanisms as either an origin or an evidence of civilization, though in all truth an essentially barbaric people might produce as great engineering works as did the uncivilized Romans in their crudest period of material well-being.

The truth is that our engineering activities are not necessarily evidences of civilization, nor, although they are almost essential, are they by themselves the means to civilization. On the contrary, when pursued too narrowly they can be destructive of the real values in living.



The engineer does not need to arrogate to his works an undue or an undeserved importance in order to find a splendid justification for his calling. Reasonable social awareness will disclose paramount reasons for a fine professional pride.

These lie in 2 categories, of which the first, and the one which can be a most extraordinary contribution to the welfare of the race and to the progress of our times, lies in the engineer himself. I need not develop at great length all those characteristics which most mark the men who have been the pride of our profession.

The engineer who is an engineer approaches his work without bias and with a mind freely open to conviction. He cannot be a special advocate and remain in any professional sense an engineer. Whatever may be the limits of his vision, he does at least possess a fine objectivity in his imagining. For him no sentimentality or wishful thinking will conjure up visions different from the world of things as they are. His creative thinking is the finer ability to project the observed facts of today into principles and rules of conduct and a clear picture of possibilities that are certainties because their origins are actual.

"Extra hours redeemed from darkness"

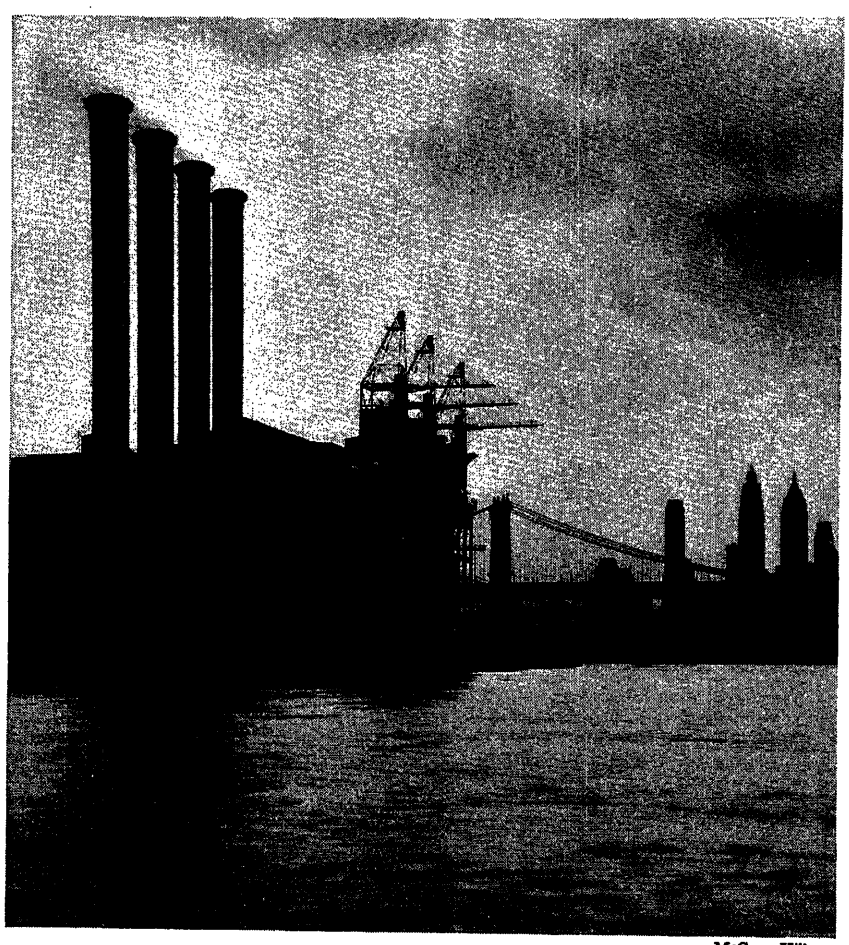
Ewing Galloway

**The pure lines of the catenaries spanning the Golden Gate and the rhythmic proportions of their supporting towers are a glorious outward expression symbolic of the courage and dignity of the conception and of the long period of painstaking and anxious preparation"**

Because of his freedom from bias and the objectivity of s thinking, he must of necessity be possessed of integrity, id because he is intellectually honest and open-minded e is tolerant of judgments that do not conform with his vn, while courageous and firm when he gets out of the ld of opinion and into that of fact.

If as a profession we can gain acceptance by the world the personal qualities of the engineer as freely as it has en willing to accept his works, society's debt to us will enormously greater.

Secondly, the works as well as the character of the gineer give him a right to claim a great place in the teem of mankind, not for the things themselves but r these things in their relation to civilized living and inking. There is a profound and important difference re and one which in practical effect needs the most pains- king care to avoid damaging, if not fatal, error. The stinction is that between sterile virtuosity and a vital tistry which reaches into the very fibers of men, or again is not much different from the contrast which exists tween a flippant self-indulgence in metaphysical acro- tics and the beneficent philosophy which gives us God, edom, and immortality.



To get down to cases, the production of the electric ht or the development of an industry about it means thing or less than nothing except as it may be related an over-all improvement in the welfare of mankind. uly this art has enabled men of good purpose to live eir lives in greater security and nobly to employ extra urs redeemed from darkness. I think it is not at all reasonable to claim that the writing and the wide blication of fine literature have tremendously been mulated by the possibilities created by this one art of e engineer.

The important thing to recognize, however, is that the technical achievement has gained much of its significance as an adjunct to the arts. The production of a minute lighting unit is only a slightly more advanced form of achievement than that of the man who writes the Lord's Prayer within the space of a postage stamp, but the production and adaptation of such a luminant for the nicety of a surgical operation becomes a service very real indeed.

What is important here is, of course, how people use the power that we place in their hands. Quite as easily, if humanness of feeling and cultivation of mind do not go along with our technical possibilities, these can become curses rather than beneficences.

So, if we please, the telephone and the telegraph, interesting inventions, marvelous expressions of research and energy and co-operation and faith, still remain things of little importance except as they bring people into more familiar intercourse and closer understanding one of another, except as they remove the narrowness of isolation and contribute to the genuine happiness and welfare of men.

Our great railroad systems would not be worthy of the sacrifices that have gone into creating them were it not for what they have done in enabling men to push out into freer and more intelligent lives and to grow, and themselves, through the agencies of transportation, to be of service to other men in distant parts of the world. The automobile merely as a device for speed and restlessness would be a wonderful mechanical achievement and a curse to the race, but men have been able to relate themselves to, and to appropriate, these engineering achievements for a more decent living and as aids to something more than merely material happiness. In all these real values our engineering works have gained their significance be-

McGraw-Hill

"The power engineers of this country have done, as the engineers have done in practically every field of American endeavor, a glorious job"

cause of uses ancillary to other functions of living, and doing so have become vastly greater even than the engineers conceived.

I would not be thought for one moment to be deprecatory of the intrinsic romance of engineering achievement, nor would I concede that engineering structures are deficient in beauty and in nobility. The pure lines of the catenaries spanning the Golden Gate and the rhythmic proportions of their supporting towers are a glorious outward expression symbolic of the courage and dignity of the conception and of the long period of painstaking and anxious preparation. The spiritual qualities of such an engineering work may be different from those appearing in a work of poetry, art, or music, but because of difference they are no less present. All one would say is that in both the engineering and the less rigorously scientific fields of the other arts the real beauty, the real romance, the real nobility come from interrelation with life.

Indeed such things as we have spoken of—the service which engineering works render to life, and the spirit and the character with which the engineer approaches his profession—are the stuff of which the arts and philosophy are made.

Even in the narrowly technical sense, our portions of the arts are portions and not the whole, and a great deal of disappointment and some social disturbance can be avoided by recognition of that. A specific instance may illustrate the way in which absence of realistic social awareness may lead to dangerous implications.

There is a general public interest in the problems of power production and distribution that is way out of proportion to any significance even so important an art has in the affairs of men. This would be puzzling if it were only a recent phenomenon. It is not the less disturbing because of the fact that it has been developed over a period of years by an ill-considered but perfectly honest enthusiasm which has mistaken simultaneity of occurrence for a relation of cause and effect.

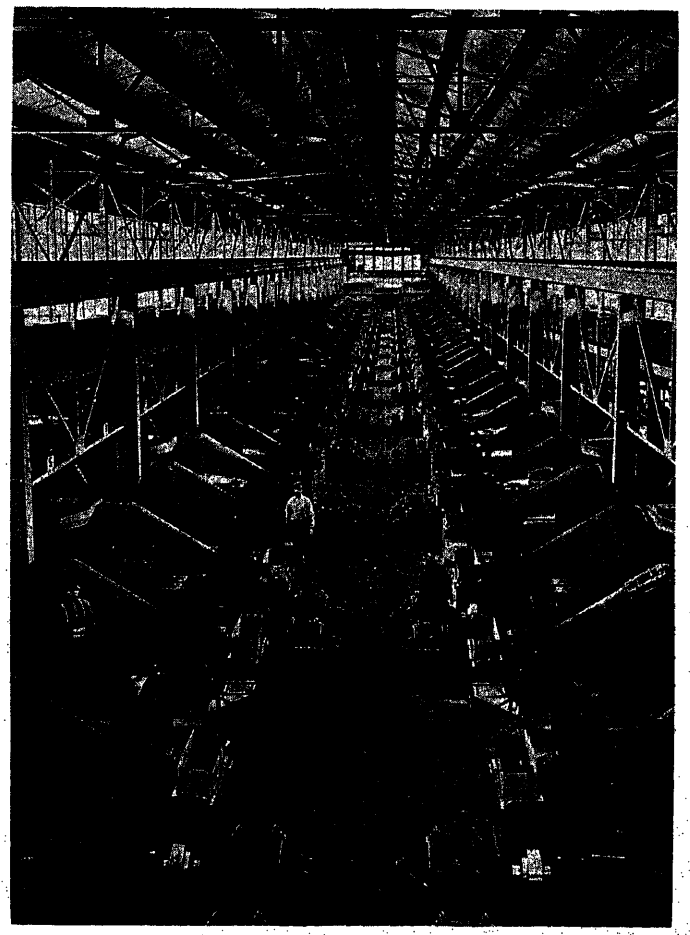
When in the middle and late '20's the rest of the world was suffering the economic aftermaths of war and we in this country were riding on the full tide of what we believed to be prosperity, we explained to ourselves that we had so many horsepower back of the elbow of every American working man. The *Daily Mail* sent an English commission to discover that mechanically developed power was the great secret of American prosperity; the Soviet Union initiated its series of 5-year plans with an emulation of the great American electrical industry, while Fascist Italy sought to develop the backbone of the peninsula through a superpower system. I have no quarrel with these things, but I had then and have today a profound disagreement with a wrong emphasis.

The power engineers of this country have done, as the engineers have done in practically every field of American endeavor, a glorious job and they continue to do so. We have produced and distributed a superlative quality of service at extraordinarily low prices. It has been made available to the largest feasible percentage of the population and is used in a degree almost unrivaled throughout the world. Yet this much vaunted power use did not suffice to keep us from plunging headlong and with characteristic American vigor into the world depression. There is no reasonable basis for believing that power development on an even greater scale in this country is going to pull us into the prosperity which the secret of American well-being a dozen years ago was not able to preserve for us. Claiming all the territory in sight at that time was a result of rather superficial thinking. Power engineers today would be foolish if they accepted the responsibility implied in the theory that dynamic development is a thing precedent to social or economic uplift. Acceptance of any such idea will simply find the power people again discredited.

Let us see what the actual fact is in regard to the place of power development in the American industrial picture of the predepression days. There was more power at the

command of the worker in industry than existed anywhere else in the world. It is so rudimentary as to be almost trite to say that the factory worker did not take $x$ kilowatts into his hands and apply them directly to a bunch of steel ingots and have a freight car emerge from the process. Not only that, but American industry did not set out with the idea of trying to apply power to industrial production and thereafter discover the means for utilizing power. Ingenuity, energy, and the courage of conviction produced the machine tool, the turret-lathe, the automatic screw machine, punch presses, and drop hammers. These called for power and for power in ever increasing quantities. Without an ample supply of dependable power at modest prices we should have had carefully to restrict the use of power in manufacture and the hand processes would have persisted here as they have elsewhere.

The power industry saw a commercial opportunity and observed a social responsibility. Its place in the picture is sufficiently great in that it did supply that which was necessary to the operation of the machine tool.



Neither power nor the machine tool without the other could have established the American methods in industry, nor could both of them together have done very much without the development of elemental metals and of alloys and plastics which should lend themselves to the processes of quantity production. These again would have been of little use had it not been for the development of design directed quite as much to the working of modern materials through the power driven machine tool as to the functioning of the product after it was made. An entirely new technique of design was called for, a technique superb in its philosophic simplicity, in its intellectual straightforwardness, in its impatience with artifice or dissimulation. But neither design for production, nor modern materials, nor machine tools, nor the power to drive them, or any of them in combination would have been of the slightest use without one of the greatest contributions that America has made to industrial progress. That contribution may be described in any one of its aspects as the use of tolerance limits, interchangeability of parts, standardization, the use of limit gauges. Again there is a whole philosophy of moral conduct suggested in the conception of units interchangeably and excellently adapted to correlation with other units for the production of a whole, no one being required to be perfect but each one being limited to a tolerable excess or deficiency from a working ideal.

When all of this is said and done we have not yet quite approached the full story of the place of power in the business of satisfying the needs of the people. Engineers well understand that the process of industrial production, whether it be in machines or textiles, in meats or magazines, is a function of quantity. Below a rather large minimum an enterprise cannot develop the methods of interchangeability which make the machine tool tolerable or which bring power into the service of the workman. Enterprise and courage and a reasonable assurance of success are necessary as inducements to the people who risk their savings in enterprises which may become obsolete on a whimsical turn of fashion or impotent through a major economic disturbance. This is the part of the entrepreneur who, in a very real sense and working outside the fields of power development, has been necessary to the development of the industrial uses of power in this country.

All these elements put together might have accomplished nothing had it not been for the superb achievements in distribution which have brought the end results of industry to the final user.

Some engineers and a certain sentimental type of social scientist occasionally deprecate the function of commercial distribution and find it quite without use. I am not at all sure that advertisers and merchants are perfect or even intelligent in their processes, but I do know that it is something to have persuaded several millions of people to want a new agency of transportation and to promote such construction of roads as would make it possible for those millions to reorganize their living about an automobile, and to persuade those same millions to accept an at least currently standard type of machine rather than individualistically to insist on going without through devotion to the fetish of tailor-made cars.

I am not permitting my enthusiasm to enlarge the importance of the nonengineer in this whole sequence of development. I know perfectly well that salesmen and capitalists did not in the first instance plan all that they have produced any more than the power engineer, when

Ewing Galloway

**"Power at the command of the worker in industry"**

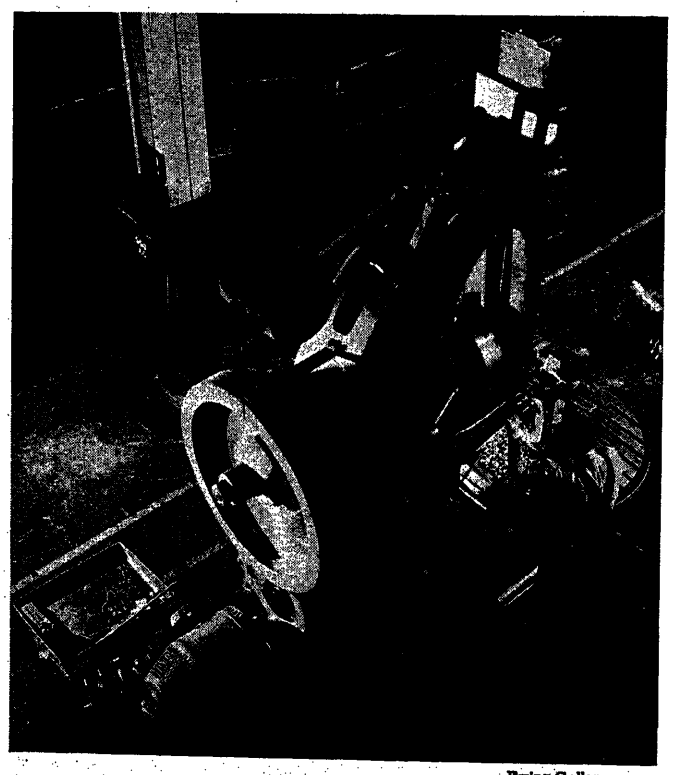
he developed his induction motor, had any idea of applying it to the gargantuan rolls of a steel mill. I am simply saying that these people, like ourselves, recognized facts as they came along and had imagination to build from them a little at a time until from gradual progress there developed a philosophy of commercial existence. Indeed, had they tried to devise an economic or industrial system out of their own imaginings they would probably have come off very badly.

The machine tool itself was a product of necessity. It probably never would have come into at all substantial use had it not been that the cost of supporting the typical American workman made necessary some means tremendously of increasing his productivity.

Note well that every one of these elements which we have sketched has been essential to modern industrial life as we know it; even more than that, has been essential to modern nonindustrial living. Our enthusiasm for one of these elements in which we may happen to be particularly interested—let us say power—should not run away with our sense of proportion. On the contrary, it seems to me that our pride in our own service becomes greater if we have an adequate picture of where it fits in as an essential and considerable element of something enormously bigger than itself.

We need not be at all deprecatory of the importance of our power developments as service to the home or to the farm merely because we may be realistic in our apprehension of the fact that many other things enter into life and that the life is more than meat and the body more than raiment. It is understandable, though not by virtue of that at all defensible, that the specialist should develop an unrestrained enthusiasm for his particular field of human endeavor and that his extreme loyalty might communicate his zeal to others. What is not perhaps quite so clear is that economic, social, and political injuries may result from these widespread and exaggerated enthusiasms. Not alone as a matter of humane consideration, but in self-defense against the reactions of disappointed hope, we must be at pains not to arouse desires that we cannot gratify or which, gratified, will be found not all that the body or the soul can crave.

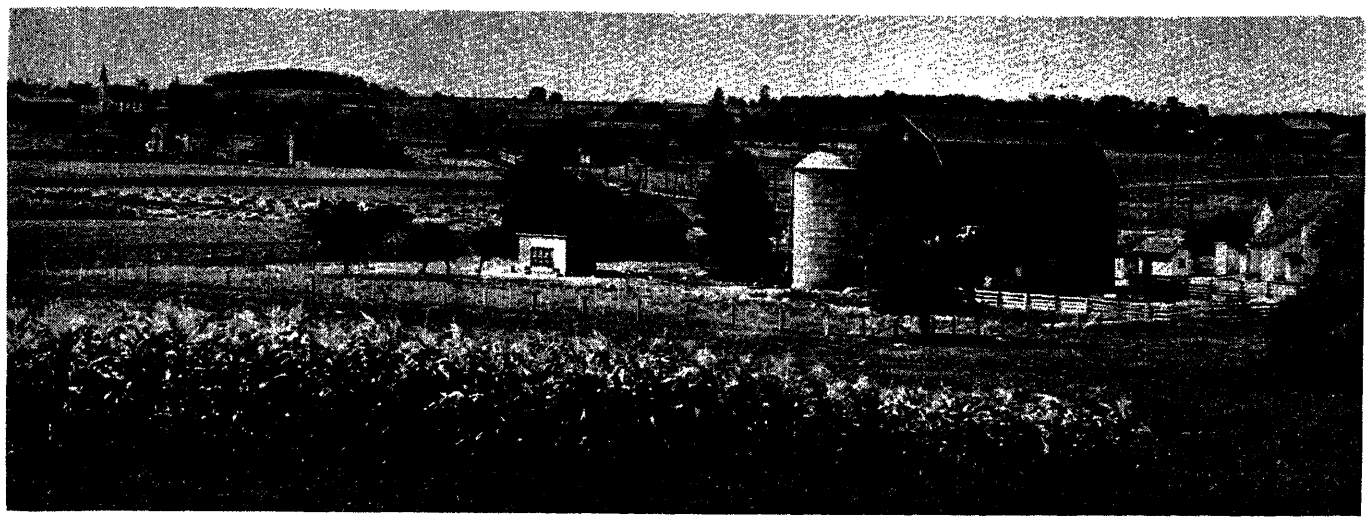
Energy available as a contribution to carrying on the amenities of domestic life is, beyond question, almost, but not quite, indispensible and a long, long way from being all-sufficient. Let me qualify this a bit. Energy in some form or other is, of course, completely necessary to human existence. For all of the necessities of life there are substitutes for those forms of energy with which you and I, as electrical engineers, are most concerned, and in some applications these other and more ancient forms may come very close to the excellences that we can offer, if indeed in some respects they may not offer facility or charm rather greater than can be developed by electric power. With this qualification, may I return to the statement that our special form of power is almost indispensible to the convenience of modern living.



Unfortunately the ultraenthusiast paints so vivid a picture of the domestic comfort created through the power agency that people in all simplicity but in no less great sincerity come to believe that electric power is at once necessary to living and a solution of all the mechanical problems of the home. I have even read claims not dissimilar to those on behalf of the $x$ horsepower at the worker's elbow—namely, that electricity can take all the guess work out of cooking and the drudgery out of domestic life.

It is perhaps reasonable to suspect that a good deal of the current abnormal interest of the people in power problems may be due to their persuasion that this, that, or the other overly exploited device is essential to civilized living if not a sure cure for all of the difficulties thereof, instead of being, as in many cases it is, a most remarkably adept contribution thereto.

So, if you please, a profound conviction of the value of extending to the farm the power use which has been so common in industry may run away with itself.



More than 25 years ago, as chairman of the committee on electricity on the farm of the association of the industry with which I was identified, I had occasion to know those early efforts at a broadened use for power. My own company in the rich farm country of western New York discovered at once the values, the difficulties, and the limitations of farm supply from contiguous distribution circuits. From such a realistic background, I have observed with much satisfaction the various well-planned efforts which, in this country of vast subeconomic areas, have saturated every section whose intrinsic economy at all approaches the productivity or the population density of western Europe.

On the other hand, I note a marked parallel between

Ewing Galloway

**"Neither power nor the machine tool without the other could have established American methods in industry"**

Ewing Galloway

**Here "rural electrification is feasible and highly developed"**

power use and the human relations. Farm use is least in those states where farm tenancy is common and progressively greater until we reach an extraordinary saturation in the lean, rock-ribbed, stubborn, but user-owned farm country of New Hampshire.

This and similar human factors make it important that we note certain limitations in this as in other desirable fields of power development.

In the first instance, the farm is not a quantity-production factory. Its functions are biologic and not mechanical, and the conditions are not repetitive nor even precisely cyclic. The economic contribution which power makes in industry cannot reasonably be expected to have any parallel in farming. The economic welfare of the rural regions is much more intimately concerned with soil quality and selection of strains and with plant and animal pathology and with market problems and transportation than with the application of mechanical power.

Success of our endeavors in industry does not necessarily indicate that we can contribute equally richly to agriculture.

Rural electricity, of course, can contribute markedly to ameliorating the conditions of rural life, but here, as in claiming too much for the economic values of farm electrification, we must be reasonably careful that we do not arouse hopes that can only result in frustration. Strangely enough, it seems not to be popularly recognized, nor even to be realized by those better informed technically, that the refinement of running water in the home is not, excepting in the least degree, related to electric wires along the highway. Yet a thumbing of the pages of any mail-order catalog will bring vivid conviction of the fact that pumps, piping, and fixtures not only are the essence of that particular evidence of civilization but that they are somewhat easily to be had. Until the essentials of sound sanitation are sought by the rural population one wonders at times about the value of the electric circuits.

The most distressingly backward of our rural communities do not in all conscience need electric power, either economically or as adjuncts to living, one-tenth as much as they need many other things closely at hand but still frightfully difficult of attainment within a farm income restricted so narrowly as to make impossible many of the mere decencies of life. I even have a suspicion that when a good job has been done in the way of aiding and advising in an improved agricultural technique and when the intimacy of human understanding offered by education and the means of communication and the means of transportation has itself ameliorated farm living as a result of the economic and social improvements, power lines will almost automatically have become extended to every part of the farm community intrinsically capable of supporting the purchase of the devices necessary to the utilization of power.

Failing of these things, which seem to me to be fundamental, there is grave danger than when experience shows electric service to be unattainable in vast stretches of this country, as it must for a long time continue to be, or when the farmer along the electric right-of-way finds his economic lot and his social outlook not essentially different than formerly, disappointed hopes will vent themselves at the expense of those who encouraged them.

A too-great desire to electrify a type of countryside unknown in those sections where rural electrification is feasible and highly developed has painted a picture of blessings enjoyed by the city dweller and believed by one all too aware of his hard lot to be denied him as a result of deliberate mischief. Thus group suspicion and aloofness have unnecessarily and unjustifiably been strengthened.

What I have been trying to say is that important as is power as an adjunct to factory, farm, and home, it, in and of itself, will not revolutionize life. We are, in our most profound relations, biologic creatures and all the conscious mechanical and technical efforts in the world are small factors in determining the essential well-being of our lives. To the extent that we have made our lives in their superficial details depart from our biologic origins, we find the mechanisms of living important. They will be the more important if our perspective keeps them in the proper relation to the other elements of living and to life itself.

# Revision of Standards for Railway Motors

By NORMAN W. STORER
FELLOW AIEE

**Higher armature peripheral speeds, better insulation, and improved ventilation of railway motors, together with the rapid development of Diesel-electric equipment for railroads, have made necessary a revision of the AIEE Standards for Railway Motors. The new standards have been adopted as "American Tentative Standards" pending further experience with the new types of machinery covered by them.**

THE STANDARDS of the AIEE for railway motors, which for many years have been accepted in the United States as the "last word" and have had an enviable reputation in all other parts of the civilized world, have been completely revised and have advanced to the status of a tentative American Standard. They will be published shortly by the AIEE as "Rotating Electrical Equipment for Rail Cars and Locomotives." Approval of this further revision was given by the AIEE board of directors at a meeting held at Pasadena, Calif., on June 24, 1936, upon recommendation of the AIEE standards committee.

Compiled by sectional committee *C*-35 of the American Standards Association under the sponsorship of the AIEE, these standards are based on many years of experience in the design and operation of railway motors and generators. They are necessary at this time not only to bring the AIEE standards for railway motors up to date, but especially to develop standards for gas and Diesel-electric equipments, the manufacture of which has grown to large proportions.

These new standards have been adopted as "American *Tentative* Standards" because the new types of machinery covered by them have heretofore had no definite standards, and such standards must therefore be developed. It is also important to leave the door open for changes if any are necessary in order to come to an agreement with the International Electrotechnical Commission.

The necessity for bringing the railway motor standards up to date will be apparent when the developments of the last few years are considered. The motor designers have been very active, and have wrought wonderful results. The problem has had the most intensive study, and advantage has been taken of every improvement in materials, processes, new discoveries, and operating experience, with the result that there has been a gradual shrinkage in the dimensions and weight of the motor that is truly remarkable.

## Reduction in Weight of Motors

Twenty years ago, the street-car motor weighed in the order of from 40 to 50 pounds per horsepower at the one-hour rating. Today street-car motors are being built weighing from 8 to 12 pounds per horsepower at the continuous rating.

Until very recently, the almost universal practice was to mount one side of the street-car motor on the axle, support the other side on the truck, and gear the armature to the axle through a single train of gears. That practice has been practically superseded for street-car motors by removing the motor entirely from the axle, carrying it on separate springs, or mounting it rigidly on the truck, and driving either through a double-reduction gear unit carried on the axle, or through a "right-angle drive" and a hypoid gear. In either case, the motor is relieved of the pounding of the track, and the track and special work are relieved of the pounding caused by the dead weight of motor on the axle, both results being very desirable.

These light-weight motors together with the light-weight car construction recently developed have given the street railway a new lease of life and made possible the high-speed stream-lined Diesel-electric trains that have recently been so much in the public eye. In the Diesel-electric trains, the weight of the power plant and motors, with the car to carry them, forms a considerable part of the total weight of the train, so that, because the weight reductions outlined apply to both motors and generators, the total reduction is a very important amount.

The question arises as to how this great reduction has been accomplished. There are 3 important factors that are directly responsible:

1. Higher armature peripheral speeds
2. Higher permissible temperatures
3. Better and more ventilation

The output of a given size of motor with a given current capacity increases as the rated voltage and speed increase, to a certain point, then more slowly as the torque begins to fall as the result of core loss and windage until maximum voltage or maximum speed is reached. Hence, other things being satisfactory, it is desirable to operate at as high a speed as is feasible with the gearing available. Higher speeds now used were made possible by refinements in the construction of armatures and commutators, perfect balance, roller bearings, and improved gears.

The rise in the temperature of a railway motor has always been one of the most important, if not the most important, limits. Of course, the motor must be strong enough mechanically and must commutate satisfactorily.

---

Essentially full text of "Revised Railroad Standard Recognizes Light-Weight Motors, New Designs," published by the American Standards Association in the February 1937 issue of *Industrial Standardization*.

NORMAN W. STORER, retired, Pittsburgh, Pa., is former consulting railway engineer of the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa. He has had many years of experience in railway work, and served on the AIEE committee on transportation almost continuously from 1914 to 1936. A biographical sketch of Mr. Storer appeared on page 1405 of the December 1936 issue of ELECTRICAL ENGINEERING.

After these features are secured, the rise in temperature fixes the rating. Hence, any increase in the permissible temperature rise will permit an increased rating. There has been a great deal of experience in the last 20 or more years with insulation made of incombustible materials such as mica and asbestos, known as class *B* insulation, which has convinced the committee that the temperature rises given in the AIEE rules can safely be raised for class *B* insulation. It has, therefore, been increased from 105 up to 120 degrees centigrade rise at the continuous rating, measured by the resistance method. This is a conservative increase based on the large number of motors which have been operating for years at such temperature rises.

Twenty-five years ago, it was the general practice to operate with street-car motors completely enclosed. Locomotive motors were in some cases cooled by forcing a stream of air through them by motor-driven blowers. The use of fans on the armature shafts, inside of the motor frames, was just beginning. Both of these methods of cooling railway motors have been carried to what appears at the moment to be the ultimate limit and have made tremendous increases in motor capacity.

## Increase in Peripheral Speeds

In no class of railway motors have speed and ventilation been carried to greater extremes than in the single-phase motors for the Pennsylvania Railroad for multiple-unit trains and stream-lined passenger locomotives. There, peripheral speeds of armature and commutator are approximately 12,000 and 9,000 feet per minute, respectively, which are about 70 per cent above the speeds of a few years ago. A veritable hurricane is blown through the motors. The weight per horsepower was brought down below that of d-c motors designed only a few years ago, which made it entirely practicable to equip a single-phase passenger locomotive with motive power capable of slipping the wheels with the maximum permissible weight on the drivers and still be able to develop the full motor rating at 90 miles per hour.

With such motors as these, the old methods of rating fall short of the requirements. The continuous rating becomes practically the same as the one-hour rating because of the rapid ventilation. The one-hour rating is of little, if any, value as a measure of the thermal capacity of the motor, and many engineers have advocated dropping it, but while admitting its small value, the committee feels that it should be continued until a better measure of thermal capacity is agreed upon.

For these reasons, the committee offers a "thermal capacity rating" in the appendix. A number of schemes have been suggested but none has yet had any extensive test. The method proposed will add very little to the cost of the usual tests and should, if properly used, give a good measure of thermal capacity, which is practically the same as overload capacity. The committee asks for a fair trial of it and the results obtained.

Altogether these rules represent the best thought of the committee that compiled them. The committee consists of 2 members each from 4 national organizations which are vitally interested. They are as follows:

AMERICAN TRANSIT ASSOCIATION

H. H. Adams (M'19) superintendent of shops and equipment, Chicago Surface Lines, Chicago, Ill.

R. H. Dalgleish (A'11) chief engineer, Capital Transit Company, Washington, D. C.

NATIONAL ELECTRICAL MANUFACTURERS ASSOCIATION

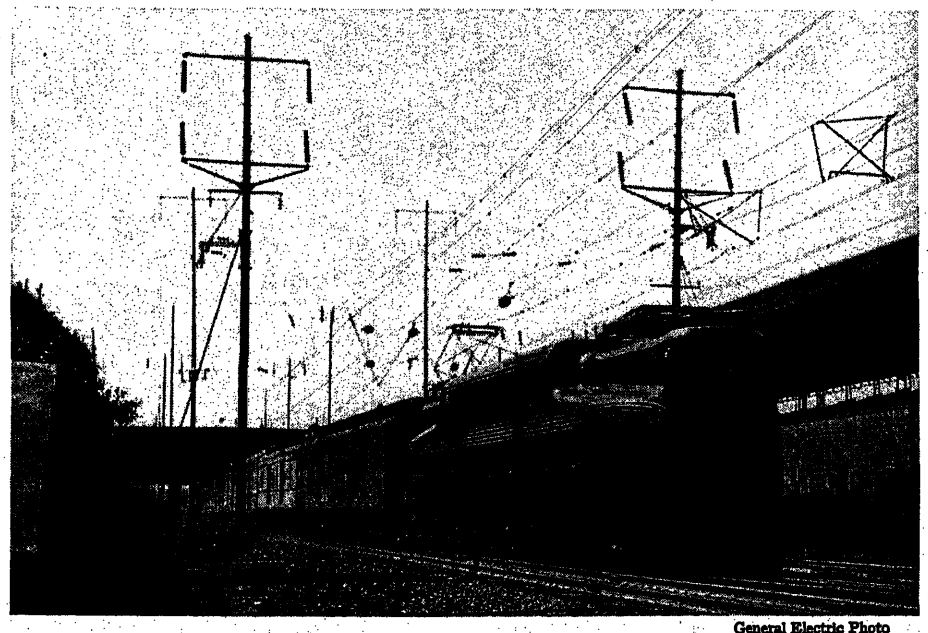
S. B. Cooper, railway sales department, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

M. R. Hanna (A'03) engineer, motor division, transportation department, General Electric Company, Erie, Pa.

AMERICAN RAILWAY ASSOCIATION

J. E. Sharpley, electrical engineer, The Virginian Railroad, Princeton, W. Va.

Sidney Withington (M'20, F'24) electrical engineer, New York, New Haven and Hartford Railroad, New Haven, Conn.



J. V. B. Duer (A'15, F'29) *alternate*, chief electrical engineer, Pennsylvania Railroad, Philadelphia, Pa.

W. S. H. Hamilton (A'19, M'26) *alternate*, equipment electrical engineer, New York Central Railroad, New York, N. Y.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

E. L. Moreland (A'11, F'21) consulting engineer, Jackson & Moreland; also head of department of electrical engineering, Massachusetts Institute of Technology, Cambridge.

# Protection of Power Lines Against Lightning

By W. W. LEWIS
MEMBER AIEE

**A brief review of the fundamentals of the lightning protection problem, and of the various common methods of protecting power transmission lines against lightning, their comparative merits, and their relative costs.**

IN THESE DAYS of intense public interest in electricity, the public utilities are making every effort to provide as continuous and dependable service as possible. They are interested therefore in those types of construction and auxiliary devices that will help them maintain a high standard of service.

It is probable that lightning can be held responsible for at least 75 per cent of all interruptions on bare-wire transmission circuits, at least in the eastern part of the United States. The other 25 per cent is caused by such things as wind, sleet, trees, failure of line insulation or structure, failure of apparatus, and mistakes in operation.

The lightning discharge from cloud-to-ground may cause induced or direct potentials to appear between conductors and ground. If such potential is sufficiently high, flashover may result; and if the lightning flashover is followed by dynamic current, tripout may follow.

There are several ways in which the effect of lightning upon transmission lines may be minimized: by the use of (1) overhead ground wires, (2) expulsion protective gaps, (3) Petersen coils, or (4) immediate initial reclosure. In the following paragraphs these methods are discussed in detail.

## Line Without Overhead Ground Wires

When lightning strikes a conductor on a line not equipped with overhead ground wires, the current divides and flows in both directions toward the towers. Only a small amount of current passing through the surge impedance of the conductor is necessary to built up sufficient potential to flash over the insulator string.

When lightning strikes a tower, the total current passes down or up the tower, encounters the tower-footing resistance, and raises the potential of the tower above ground potential. This potential is roughly the product of the current and the tower-footing resistance. If this product is high enough, an insulator string or strings will flash over. In some instances the normal-frequency voltage added to or subtracted from the transient voltage may determine which strings flash over. Flashover of an insulator string places the impedance of the conductor in multiple with that of the tower and tends to relieve the potential of the tower and thus may prevent other strings from flashing over.

Where wood poles are used, the resistance to ground is so high that flashover between conductors may take place instead of flashover to ground.

## Line With Overhead Ground Wires

One ground wire is usually not sufficient to shield the conductors effectively from direct strokes, either on single-circuit horizontal arrangements or double-circuit vertical arrangements. Two ground wires placed above and mid-

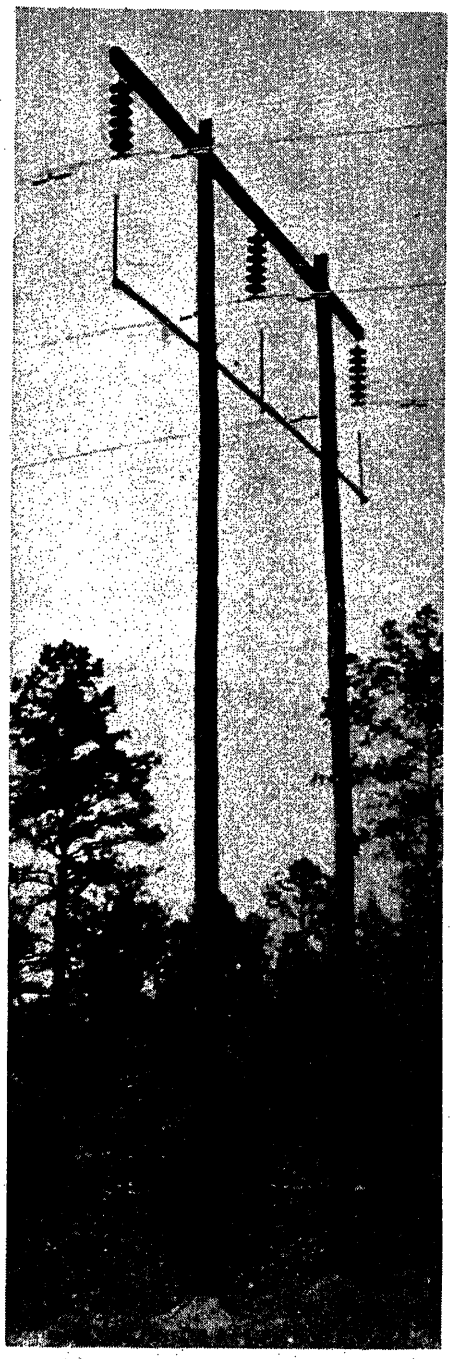
Essential substance of a paper presented at a meeting of the AIEE Philadelphia (Pa.) Section, January 11, 1937.

W. W. LEWIS is electrical engineer in the central station engineering department of the General Electric Company, Schenectady, N. Y. He is the author or co-author of several Institute papers on lightning protection, and is serving on 4 Institute technical committees.

way between the conductors on horizontal arrangement or over the outermost conductors on vertical arrangement have proved adequate in practice to shield the conductors.

When the conductors are properly shielded, a direct stroke will strike either the ground wires or the tower. If it strikes the ground wires, the current will divide and flow toward the towers at the ends of the span. At the tower the current will divide again, part passing down the tower and part continuing on the ground wire. The part passing down the tower will encounter the footing resistance, the tower will be raised in potential by the product of current and resistance, and flashover will result if this product exceeds the strength of the insulation. Coupling between the ground wires and conductors and the normal-frequency voltage may sometimes determine which insulator strings flash over.

When lightning strikes the top of a tower, the current divides, part going down the tower and part going out on the ground wires in both directions. Again, the part going down the tower encounters the footing resistance, raises the potential of the tower above that of the conductor, and may cause flashover if the potential is sufficiently high.



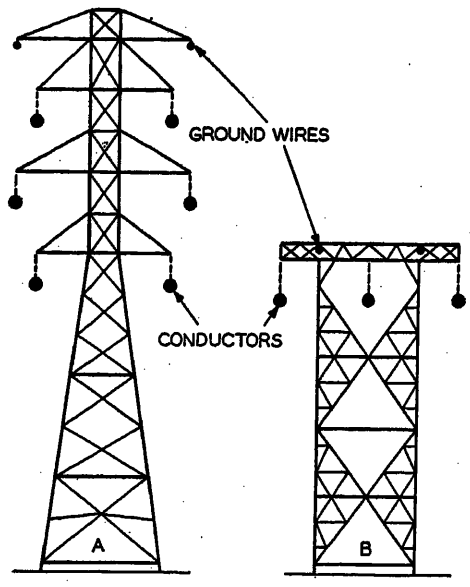
Where wood poles are used with overhead ground wires and down leads, the action is exactly the same as for steel-tower lines, except that the wood crossarm may add extra insulation and allow the potential to rise somewhat higher before flashover. Where the insulator hardware is bonded and grounded, the action of wood-pole lines is identical with that of steel-tower lines.

## Tower-Footing Resistance

From the previous discussion it is apparent that the prevention of flashover resulting from direct strokes to overhead ground wires or towers, depends largely on the tower-footing resistance. Assuming a knowledge of the magnitude of current in towers due to direct strokes and of the strength of the line insulation, then it is possible to arrive at a limiting value of tower-footing resistance for a given line. For example, if the highest current expected is 100,000 amperes and the line insulation is 1,000 kv, then the highest permissible footing resistance is 10 ohms.

Several devices have been used to reduce tower-footing resistance, among which are driven rods, driven wells, ground plates, and buried conductors or counterpoises. Among the questions still to be answered are: the relative effectiveness of a given resistance obtained by 2 different methods, such as driven rods or counterpoise wires; the relation between resistance measured by Megger at low current and voltage and that encountered by lightning current of high intensity and at high voltage; also the most effective length of counterpoise.

Evidence gathered during the past few years attests to the great effectiveness of the continuous tower-to-tower counterpoise wire. A section of line 2.6 miles long equipped with tower-to-tower counterpoise has operated 8 years without flashover, as against an average of 10 flashovers per year in the 3 years previous to the installation of the counterpoise wire.



**Installation of expulsion protective gaps on 115-kv H-frame line**

A continuous counterpoise is, of course, a conductor or conductors buried under the transmission line from end to end of the line or certain sections of the line and connected to all tower feet. Some engineers believe that if the same amount of conductor were used as a radial or crowsfoot counterpoise, where several conductors merely radiate outward from the foot of each tower with no connection between towers, it will give more effective protection.

Short radial counterpoise wires also have improved the operation of lines. On the Glenlyn-Roanoke (Va.) line of the Appalachian Electric Power Company certain towers are equipped with 150-foot counterpoise wires running parallel with the line and from diagonally opposite legs of the towers, with 40-foot wires running at right angles to the line from the other 2 legs. A number of records obtained in 1935 showed the sum of the current readings in the long wires to have a ratio of 4.3 times the current in the short wires; the ratio of the lengths is 3.75. In 1936, a large number of readings on this line showed the sum of the current readings in the long wires to have a ratio of 2.9 times the current in the short wires.

On the Wallenpaupack-Siegfried line of the Pennsylvania Power and Light Company, certain towers were equipped, in 1936, with one 250-foot and 3 50-foot radial counterpoise wires. The summation of readings of currents in the long and one short wire gave a ratio of 7.5, as

compared with a ratio of lengths of 5. Simultaneous readings of current at several different points along the 150- and 250-foot counterpoise wires indicated an almost uniform current distribution along the wires, but with different rates of current connection or dissipation at different current levels. It has been suggested that figures

**Arrangement of overhead ground wires to give good shielding against direct strokes, for vertical and horizontal configuration of conductors**

of this sort for several different lengths and ratios of length might give some indication of the effective minimum length of counterpoise wires.

## Expulsion Protective Gaps

Another way of attacking the problem of continuity of service is to direct the flashover through gaps or tubes set for a slightly lower flashover potential than the insulators, not attempting as in the previously discussed solution to prevent flashover altogether.

The expulsion protective gap is a tube with an internal gap, connected to the line through an external gap, the whole having a flashover potential lower than that of the insulator string. The tubes are selected for the range of short-circuit currents expected. The short-circuit current that follows the lightning flashover produces a pressure within the tube and the arc is extinguished within a half cycle.

For continuity of service, it has been customary to build double-circuit lines. However, even with 2 circuits a large proportion of the faults may involve both circuits, because when lightning current passes down a tower, the tower potential may be raised above that of all 6 conductors, and the probability is that more than one conductor will flash over at a time. On wood-pole lines, faults frequently spread between circuits because of the high resistance of the pole, which does not relieve the potential due to a direct stroke.

For the foregoing reason some power companies now are building single-circuit lines equipped with expulsion protective gaps, instead of double-circuit lines. Among these may be mentioned the Pennsylvania Power and Light Company's 66-kv wood-pole lines, the Carolina Power and Light Company's 115-kv wood-pole lines, and the American Gas and Electric Company's 132-kv steel-tower lines. In the limited time they have been in operation, such lines have had very good service records.

Expulsion protective gaps were placed on one circuit of the Glenlyn-Roanoke double-circuit line in 1933, and on the Roanoke-Danville single-circuit line in 1934. In the 3 years, 1933, 1934, and 1935, a total of 339 gap operations occurred, with 30 cases of incorrect operation. The outages on the 2 circuits of the Glenlyn-Roanoke line averaged 10 per year during the 3 years of expulsion-gap operation, against an average of 18 per year during the previous 7 years. On the Roanoke-Danville line the outages for the 2 years of gap operation averaged 4.5 per year against an average of 19.5 per year for the 7 previous years.

The Pennsylvania Power and Light Company and the Pennsylvania Water and Power Company installed, in 1935, expulsion protective gaps and Deion gaps on about 98 miles of 66-kv line, consisting of 81 miles of single-circuit wood H-frame line and 17 miles of double-circuit steel-tower line. Out of a total of 944 structures, 543 were equipped with gaps. During the 1935 season there were 374 tube operations, with 8 tube flashovers or failures. There were 18 tripouts on these lines during this period.

Data given for the lines of the Appalachian Electric Power Company indicate that for the Glenlyn-Roanoke line the outages on the double-circuit were reduced about 45 per cent after the installation of expulsion protective gaps on one circuit. On the Roanoke-Danville single-circuit line the outages were reduced about 75 per cent after the installation of the expulsion protective gaps. Approximately 9 per cent of the gap operations on both lines were incorrect.

Data at hand for the 66-kv Pennsylvania lines do not permit of an evaluation of the improvement in operation due to the gaps, except perhaps in case of 2 of the lines. On these 2 lines gaps were installed to guyed structures only, which comprise about 25 per cent of the structures on the Northumberland-Williamsport line and about 14 per cent on the Berwick-Bloomsburg line. The operating record of these lines showed 1 tripout on each line in 1935 as compared with a yearly average of 7 tripouts on the Northumberland-Williamsport line and 5 on the Berwick-Bloomsburg line during the previous 4 years. There were many correct gap operations (the incorrect gap operations were slightly over 2 per cent on these lines).

It cannot be said that each correct gap operation saves a tripout. It must be remembered that the flashover potential of the expulsion-gap assembly is considerably less than that of the insulation assembly which it is designed to protect (10 to 15 per cent less for the 132-kv steel-tower lines and about 40 per cent less for the 66-kv wood-pole lines considered in this discussion). It is obvious therefore that the number of expulsion-gap operations will be greater than the number of insulator flashovers that would have occurred if the gaps had not been installed. Nevertheless, it is probably true that the

gaps saved a large number of tripouts on these lines during the period of their operation.

## Petersen Coils

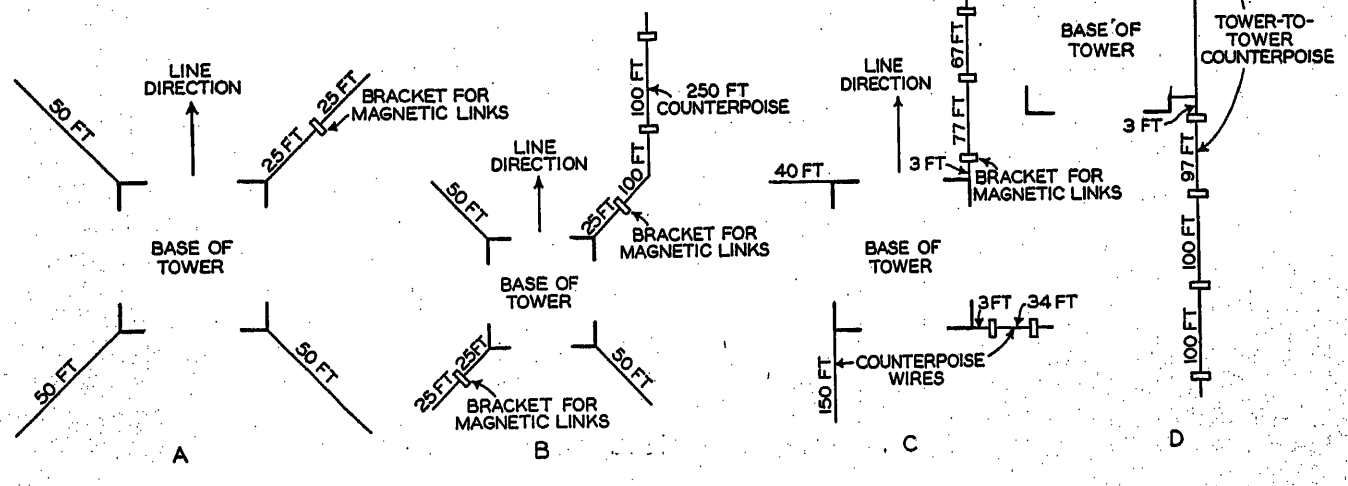
Briefly, the Petersen coil is a reactance coil connected between the system neutral and ground and specially proportioned in relation to the capacitance of the system. Upon the occurrence of a line-to-ground fault on one conductor, a lagging current will flow through the coil which is equal in magnitude and opposite in phase to the charging current at the fault. Under this condition the resultant current at the fault becomes zero and the fault is cleared.

In some instances there is a residual in-phase component of current at the fault, which cannot be neutralized by the Petersen coil. This current is due to corona on the line conductors, leakage over insulators, and other factors. If large enough to be important, the in-phase component may be neutralized by special auxiliary means. It is obvious that the Petersen coil cannot neutralize a line-to-line fault.

The use of the Petersen coil in Germany and other European countries has been very extensive. Approximately 1,000 coils have been installed on systems varying in voltage from 5 to 220 kv. In the United States the solidly grounded neutral system has been very popular, and therefore Petersen coils and other grounding devices have not received wide acceptance.

At the present time there are 5 coils in operation in the United States as follows: an 800-kva continuous-rated coil on the 44-kv system of the Georgia Power Company; 2 10,000-kva 10-minute-rated coils on the 140-kv system of the Consumers Power Company, Mich.; a 3,000-kva 30-minute-rated coil on the 33-kv system of the Central Maine Power Company; and a coil rated 800 kva for 30 minutes on the 33-kv system of the Public Service Company of Indiana. A 10,000-kva 10-minute coil will be installed during the spring of 1937 on the 100-kv system of the Public Service Company of Colorado.

The first Petersen coil in the country was an 800-kva continuous-rated coil installed on the Lock 12-Vida-Selma-Montgomery section of the Alabama Power Company's 44-kv system in 1921. This coil operated successfully until early in 1924 when it was removed because the system mileage had practically doubled and greatly outgrown the capacity of the coil. The coil was moved to the Georgia Power Company's system and installed on the 130-mile Marietta section of the 44-kv system, where it has been in successful operation for about 6 years.



The Consumers Power Company's coils were installed late in 1931. The system consists of 275 miles of line on steel towers, all but about 40 miles of which is single circuit. There are no overhead ground wires on this line. The coils are rated 10,000 kva for 10 minutes and are installed one at Saginaw and one at Alcona. Operation on this system shows approximately 70 per cent of all faults in about 5 years' service cleared without oil circuit-breaker operation.

The Central Maine system consists of 560 miles of 33-kv line on wood poles with pin insulators and no overhead ground wires. The Petersen coil was installed in the fall of 1935. In the 14 months from August 1, 1935 to October 1, 1936 the Maine coil operated 54 times and cleared all faults that were not permanent, without a service interruption. In the Gulf Island Station in the 6 years before the coil was installed, there were 27 insulator or bushing flashovers associated with faults at other points on the system. Since the coil has been in service flashovers of this type have not occurred.

It is probable that the majority of faults start as single-phase-to-ground disturbances and that later other phases may become involved. It is also probable that high tower-footing resistance, by allowing the tower potential to rise above that of the conductors, is responsible for the other phases becoming involved. Consequently, a reduction in tower-footing resistance will decrease the number of phase-to-phase faults, and allow the single-phase faults to be cleared by Petersen-coil operation.

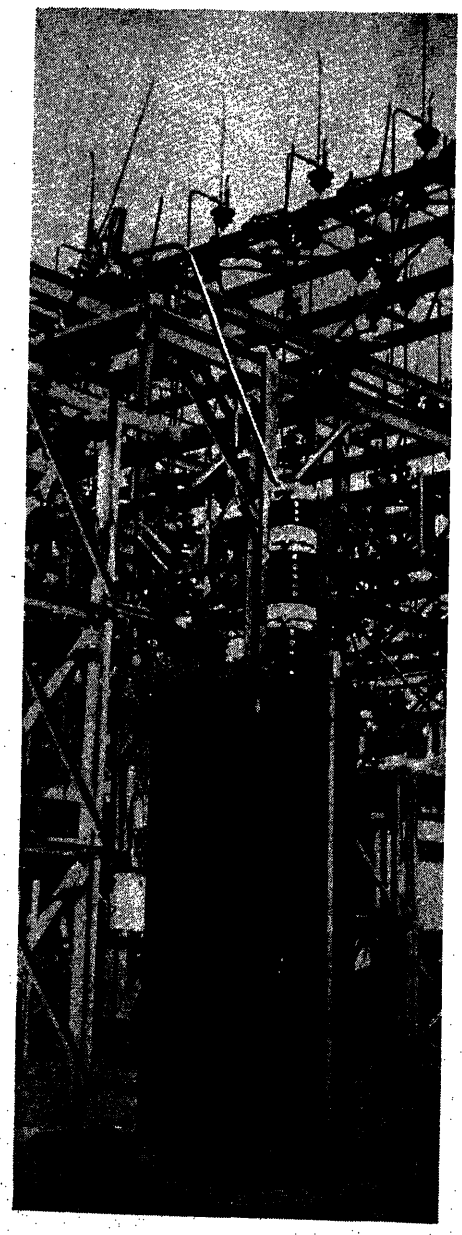
## Immediate Initial Reclosure

During the last few years an operating procedure has been developed to improve continuity of service on feeders and tie lines: The practice of immediate initial reclosure of a circuit-breaker that has been tripped automatically. Many of the causes of short circuits have disappeared by the time the controlling breaker can be reclosed. Experience has demonstrated that immediately returning voltage to a circuit not only does no harm, but completely neutralizes the effects of interruption on most types of load.

All motors connected to an immediately reclosed circuit must have time delay on their undervoltage releases, if full benefit is to be derived from this procedure. Otherwise the motors having an instantaneous under-voltage device will be disconnected during the period of no voltage, and it then makes no difference whether the voltage is reestablished immediately or later. Provided under-voltage devices, when used, have time-delay features, it is possible to open the circuit-breaker and immediately reclose it with no detrimental effect on many kinds of load. The value of this procedure increases with the prevalence of lightning on a system, for then a smaller proportion of faults arises from causes that are permanent.

Some companies, especially in the Southeast, have applied immediate reclosure to their systems with significant improvement in their service. On one system it has been found that a circuit can be returned immediately to service after nearly 90 per cent of the tripouts, and remain closed with no loss of load and no detriment to service.



Immediate reclosure does not benefit all types of loads. Where it is applicable, and where many of the outages result from transitory causes, such as lightning, immediate reclosure is usually a simple, inexpensive, and very effective means of improving the service. In addition, immediate reclosure reduces service interruptions from certain causes from which the other protective means may not. These include temporary conductor contact from wind, sleet, or foreign materials on the line, such as kite strings, tree branches, and birds, which often leave the line clear after the first tripout.

## Summary

None of the means of lightning protection considered here has shown a perfect record. In some instances, however, overhead ground wires, when properly installed to shield the conductors from direct strokes and when accompanied by adequate insulation and low tower-footing resistance, have shown an almost perfect record.

The expulsion protective gap has shown good performance, especially on wood-pole H-frame lines. Improvements in the tubes may be expected as a result of past operating experience. This will tend further to improve the performance of these gaps. There is some evidence that equipping one circuit of a double-circuit line is beneficial, and on the Pennsylvania systems equipping only the guyed structures was apparently beneficial.

In the limited experience with Petersen coils in the United States, this equipment has shown a record of suppression of faults of the order of 70 to 80 per cent. Low tower footing resistance is of importance here in limiting the number of phase-to-phase flashovers, thus giving the Petersen coil full opportunity of taking care of the line-to-ground flashovers for which it is adapted.

**Petersen coil installed on a 33-kv system**

Immediate initial reclosure has been applied mainly to radial feeders and tie lines of medium voltages (up to 66 kv), although trial installations have been made on higher-voltage lines (up to 132 kv). A certain amount of maintenance is involved in the oil circuit-breakers, relays, and other equipment.

It is difficult to evaluate in general terms the cost of applying the various methods mentioned, so that the following figures should be considered as only very rough: For a 115- or 138-kv double-circuit steel-tower line, the cost of 2 overhead ground wires plus a continuous tower-to-tower counterpoise wire would be roughly $1,500 or $1,600 per mile. The cost of expulsion protective gaps plus installation would be roughly $1,200 to $1,400 per mile for both circuits or $600 to $700 if only one circuit is equipped. The cost of a Petersen coil for a 100-mile line plus installation would be roughly $10,000, or $100 per mile. Immediate initial reclosure is probably the least expensive of any of the methods mentioned, assuming that suitable breakers and relays are already available and that only the automatic reclosing device is required.

Each method has its advantages and disadvantages, and the best method for a particular case can be selected only after a study of all the circumstances.

# Further Characteristics of the Carbon Arc

By W. C. KALB
MEMBER AIEE

*In this paper the carbon arc is considered in its 3 characteristic forms, the low intensity arc, the high intensity arc, and the flame arc. The influence of arc current on the energy emission is discussed in relation to each of the 3 types, as well as the effects of variation in arc voltage.*

*The discussion covers characteristics which should be given consideration in order to make most effective application of the various types of arcs.*

IN THE course of a previous paper, which discussed the general characteristics of the carbon arc, it was pointed out that there are 3 distinct types of carbon arcs, the low-intensity neutral-core arc, the flame arc, and the high-intensity arc. The characteristic features distinguishing these 3 types of arcs were also described. Each of these types has its own peculiar characteristics and is affected in different manner or degree by variations in arc conditions. It is the purpose of the present paper to present further data on the characteristics of these arcs and to consider the effect of certain variables on the character and intensity of the light emitted.

## Distribution of Radiant Energy

The quality of light from the high-intensity arc is inherently whiter than that from the low-intensity neutral-core arc. This might be anticipated from the much higher intrinsic brilliancy of the crater. Spectral energy distribution curves for all carbon arcs show 2 characteristic peaks, one of moderate intensity at about 2,500 Angstrom units and a dominant band of emission, commonly called the "cyanogen peak," at about 3,800-3,900 Angstrom units. Except for the influence of this cyanogen peak, the energy emission from the d-c low-intensity neutral-core arc at full brilliancy tends to follow the theoretical black-body radiation curve for 3,810 degrees Kelvin, the brightness temperature of carbon at the point of vaporization. The emission from the d-c high-intensity arc, on the other hand, comes nearer to the black-body curve for 5,600 degrees Kelvin. This difference is illustrated in figure 1, in which all curves have been adjusted to a maximum value of 100 (exclusive of cyanogen peak) on an arbitrary scale of intensity. It is obvious from the energy distribution shown by these curves that the light from the high-intensity arc has a substantially even balance of all colors and comes close to our conception of a pure white light. It is equally obvious that the light from the low-intensity arc has a yellowish tint resulting from the higher intensity of the longer wave lengths within the visible range.

The distribution of radiant energy from the flame arc is dependent largely on the composition of the core. This is illustrated, for the visible range, by figure 2 where the output from a 30-ampere 50-volt a-c arc between neutral-core carbons is compared with that from carbons burned under the same conditions and having identical outer shells but whose cores contain, respectively, cerium, calcium, and strontium. Figure 3 shows the effect of variation in core composition on the ultraviolet emission. The respective core compositions in this case contain the elements listed below the curves. Many elements, other than those whose effects are illustrated in figures 2 and 3, have pronounced influence on the quality of emission in both the ultraviolet and the visible portions of the spectrum. This fact makes the flame arc a highly flexible source of radiation, capable of adaptation to a wide range of requirements in radiation characteristics.

## Effects of Increasing Arc Current

In all types of arcs, one effect of increasing arc current is to increase the light output. This result, however, is subject to certain practical limitations characteristic of the various types. For a given type and size of trim there is a certain range of current within which best results are obtained. Operation at lower currents allows the arc to wander over the face of the carbon with resulting unsteadiness of light. Currents above this optimum range likewise produce an unsteady arc due to the effects of overloading the carbons. Carbon manufacturers have carefully determined the optimum range of current for the several types and sizes of carbons, and their instructions should be followed. As long as proper arc conditions are maintained, operation within the recommended range of current can be depended on to produce satisfactory arc performance.

In the d-c low-intensity arc the light produced is largely dependent on the area and intrinsic brilliancy of the positive crater. Only a small percentage of the total light comes from the arc stream and the less brilliant tip of the negative carbon. Mott and Kunzmann (reference 2) have shown that the relation between arc current and crater area may be expressed by an equation of the form

$$A = 7 + 0.47 I^e$$

where

$A$ = crater area in square millimeters
$I$ = arc current in amperes
$e$ = 1.4 for carbons of large diameter
= 1.35 for carbons of small diameter

More recent observations (reference 3) on positive carbons of 10 to 13 millimeters diameter, designed for use in low-intensity d-c projection lamps of the reflecting type,

A paper recommended for publication by the AIEE committee on production and application of light. Manuscript submitted August 20, 1936; released for publication October 22, 1936.

**Table I—Influence of Arc Current on Low-Intensity D-C Arc at 55 Volts, SRA Trim**

| Diameter Positive Carbon, Millimeters | Arc Current, Amperes | Crater Area Square Millimeters | Maximum Intrinsic Brilliancy, Candle Power per Square Millimeter | Candle Power Directly in Front of Crater | Candle Power per Arc Watt |
|---|---|---|---|---|---|
| 10 | 21 | 34.8 | 174 | 5,720 | 4.95 |
| 10 | 24 | 39.2 | 175 | 6,650 | 5.04 |
| 12 | 28 | 49.0 | 171 | 7,900 | 5.12 |
| 12 | 34 | 60.0 | 175 | 9,800 | 5.24 |
| 13 | 32 | 61.0 | 171 | 9,100 | 5.16 |
| 13 | 44 | 77.9 | 172 | 13,200 | 5.45 |

**Table II—Influence of Arc Current on High-Intensity D-C Arc With Rotating Positive**

| Diameter of Positive Carbon, Millimeters | Arc Current, Amperes | Average Arc Voltage | Crater Area, Square Millimeters | Intrinsic Brilliancy, Candle Power per Square Millimeter | Candle Power of Crater Light | Candle Power per Arc Watt |
|---|---|---|---|---|---|---|
| 9 | 50 | 44 | 29.3 | 430 | 12,500 | 5.68 |
| 9 | 75 | 54 | 35.4 | 705 | 25,000 | 6.17 |
| 11 | 90 | 60 | 56.0 | 750 | 42,000 | 7.78 |
| 13.6 | 100 | 63 | 73.3 | 535 | 39,000 | 6.20 |
| 13.6 | 125 | 68 | 92.0 | 815 | 75,000 | 8.82 |
| 16 | 135 | 70 | 132.0 | 570 | 75,000 | 7.94 |
| 16 | 155 | 72 | 145.7 | 695 | 101,000 | 9.05 |

support the substantial accuracy of this formula. The measured values of crater area represent values of $e$ ranging from 1.32 to 1.35.

The vaporizing temperature of carbon having been approached in the low-intensity arc, further increase in arc current results in little increase in intrinsic brilliancy of the positive crater. The increase in crater area, however, does result in an increase of total light emission. The optical systems used in most projection lamps and projectors place limitations on the area of the positive crater face from which the light can be effectively focused within the dimensions of the aperture plate and projected onto the screen. For this reason, when a projector carbon has been raised to its maximum intrinsic brilliancy, further increase in current produces little, if any, increase in screen illumination. Table I shows the influence of arc current on the crater characteristics and light output of the d-c low-intensity arc with the type of carbons now extensively used in reflecting type projection lamps.

Mott and Kunzmann (2) found that the candle power of low-intensity searchlight carbons, within the range of 20 to 150 amperes, followed substantial y the curve expressed by the equation,

$$CP = 51.4\ I^{1.4}$$

The carbons now used in the d-c low-intensity reflector arc show higher efficiency in light production. The candle power measurements given in table I are closely approximated by the equation $CP = 164.0\ I^{1.165}$.

In the d-c high-intensity arc, increase of current increases both the area and the depth of the positive crater. The increase in crater area with increasing current is shown by the curves in figure 4. It is apparent from these curves that, at the same current, 2 carbons of different diameters will show a substantially larger crater on the larger carbon. The influence of arc current on the intrinsic brilliancy of the positive crater is shown by the curves in figure 5. Here it is apparent that, of 2 carbons of different diameters operated at the same current, the

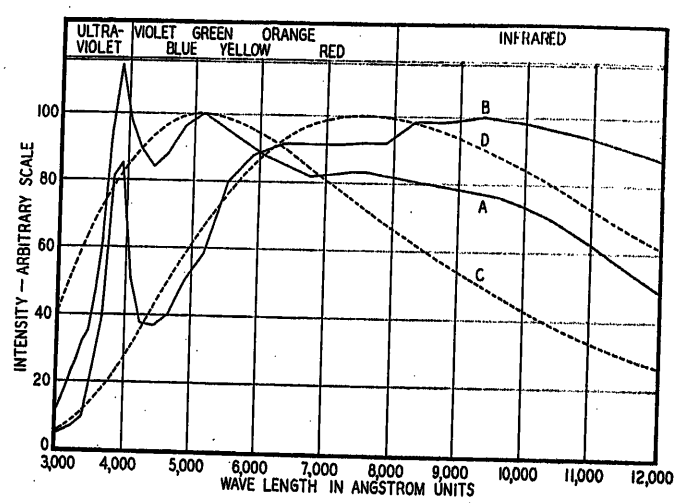

**Fig. 1. Spectral energy distribution curves**

*D*—Theoretical black-body radiation at 3,810 degrees Kelvin

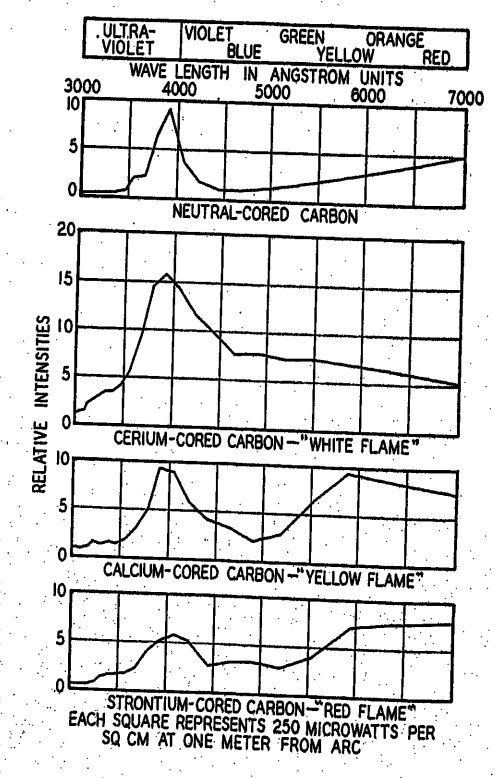

**Fig. 2. Effects of core composition on near ultraviolet and visible radiation—30 amperes, 50 volts, a-c**

smaller will have the higher intrinsic brilliancy. This is the natural result of concentrating the energy of the arc within a smaller area. It is evident, from a comparison of these curves with the data given in table I, that much higher intrinsic brilliancies are available from the high-intensity arc than are possible to obtain from the low-intensity arc.

Table II shows the effect of arc current on the crater light from the d-c high-intensity arc with rotating positive electrode and also shows the arc-voltage representative of average operating conditions at the specified arc currents. The figures in this table do not include the light from the tail flame of the arc, which represents about 32 per cent of the total light output but cannot be properly

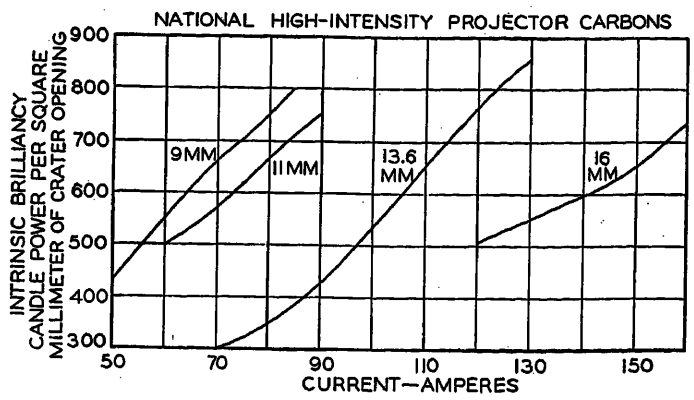

**Fig. 5. Intrinsic brilliancy versus arc current—d-c high-intensity arc**

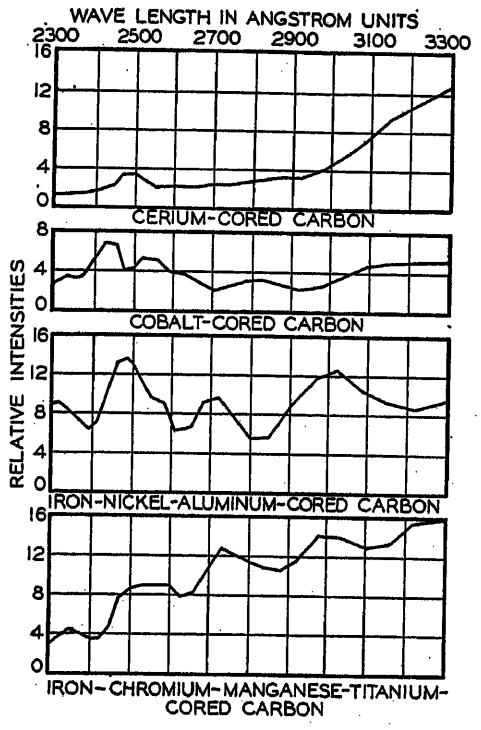

**Fig. 3. Effects of core composition on short ultraviolet radiation—60 amperes, 50 volts, a-c**

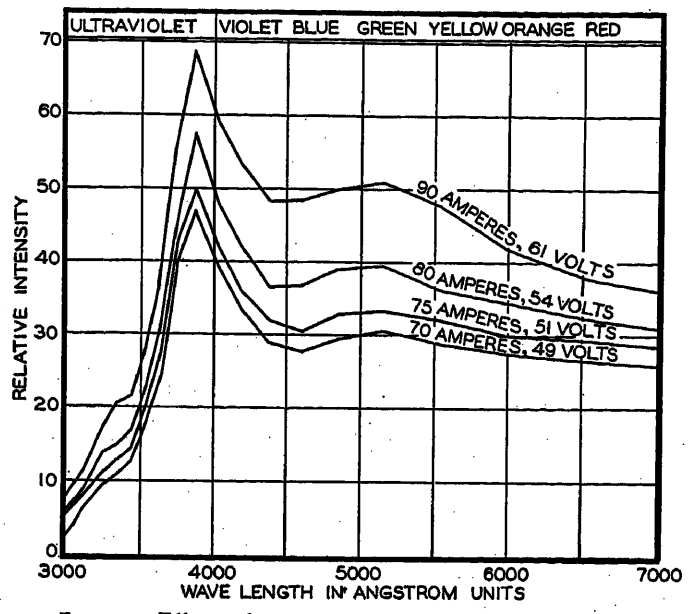

**Fig. 6. Effect of arc current on energy distribution d-c high-intensity arc—9-millimeter positive**

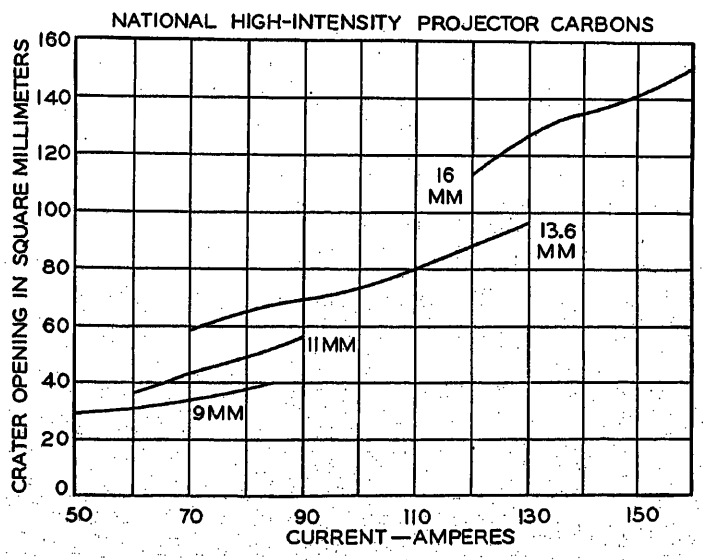

**Fig. 4. Crater area versus arc current—d-c high-intensity arc**

focused by the optical system of projection lamps and therefore does not add to the screen illumination.

Increasing current does not greatly affect the quality of light emitted by the high-intensity arc. This is shown in figure 6 by the energy-distribution curves for a high-intensity arc with 9-millimeter positive operated in a reflecting type projection lamp at arc currents of 70, 75, 80, and 90 amperes. Over this range of current the increase in arc watts and the increase in radiant energy are in approximately the same ratio, the effect of increasing current being slightly more pronounced in the blue and green bands of the spectrum than in other portions.

With flame arcs the effects of increasing arc current are decidedly complex. They vary with the composition of the flame supporting core, with the range of current in which comparison is made and with the portion of the spectrum in which intensity of radiation is observed. A few examples are cited to illustrate the effects of arc current under specific conditions.

The increase in intensity of ultraviolet radiation, between the limits of 2,900–3,100 Angstrom units, which

results from increasing arc current, with voltage constant, is shown by the curves in figure 7. The upper curve shows the effect on a carbon having iron, nickel, and aluminum in the core and the lower curve the effect on one containing cerium. The curves in figure 8 show the corresponding effects on total radiation over a broad band of the spectrum, from 1,700 to 6,500 Angstrom units. This includes practically all ultraviolet emission from the arc and a major portion of the visible light. In this case, the upper curve represents the cerium-cored carbon and the lower curve the carbon containing iron, nickel, and aluminum.

The effect of current increase at different wave lengths can be illustrated by curves showing the variation in mean exponential relation between changes in arc current and resulting changes in intensity of radiation. These curves, presented in figure 9, are based on the equation

$$\frac{W_2}{W_1} = \left(\frac{I_2}{I_1}\right)^e$$

where

$W$ = intensity of radiant energy
$I$ = arc current in amperes
$e$ = exponential relation between current and intensity

Curves are drawn for 2 ranges of arc current, 30–60 and 60–90 amperes, and for the 2 types of carbons shown in figures 7 and 8. The complexity of the relationship between arc current and resulting energy emission at different wave lengths is evident from these curves.

A series of observations of more practical application, relating to the light output of the flame arc under varied conditions of operation is given in table III. These observations were made with white flame (cerium cored) photographic carbons in the lamp mechanism of a photo-engraving lamp of standard make.

The data in table III disclose that, under the same conditions of arc voltage and current, the d-c arc between flame carbons gives higher light output than the a-c arc; the d-c arc with upper carbon positive gives higher light output than with upper carbon negative; and, the d-c arc with cerium-cored negative gives higher light output than with neutral-cored negative.

While the foregoing figures show a decided advantage for the d-c arc over the a-c arc on the basis of candle power per arc watt, this advantage is more than offset when the comparison is made on a basis of candle power per line watt between a single d-c arc on a 115-volt circuit and a transformer-operated a-c arc. It is common practice, however, particularly in twin-arc lamps, to operate 2 d-c arcs in series from the standard-voltage d-c circuit at a somewhat lower arc voltage than that used in obtaining the data given in table III. Under these conditions comparison on the basis of candle power per line watt favors the d-c arc when no reflectors are used. This was the condition under which data was obtained for the comparison given in table IV.

The use of reflectors may and, in most designs, does more than offset the primary advantage of the d-c twin arc over the single, transformer-operated a-c arc. This is because higher efficiency in reflector design is possible with the single arc which can be centered in a reflector of symmetrical form.

## Effects of Arc Voltage

The d-c low-intensity arc with neutral-cored carbons gives optimum performance over a rather limited range of arc length and arc voltage. For this reason it is customary to maintain approximately constant arc voltage and to vary the light output by adjustment of arc current. The d-c low-intensity reflecting arc is usually operated with 54–57 volts at arc. Curve *A* in figure 10 is representative of the average relationship between arc voltage and current in other types of lamps using the d-c low-intensity arc.

The d-c high-intensity arc, under given conditions of trim and arc current, should also be operated at essentially constant arc voltage. In fact, arc voltage is often used as the control factor for operating the carbon-feeding

Table III—Light Output of Cerium-Cored Flame Arc at 55 Volts

| Upper Carbon | Lower Carbon | Power | Arc Current, Amperes | Mean Spherical Candle Power | Mean Spherical Candle Power per Arc Watt |
|---|---|---|---|---|---|

mechanism. Nevertheless, arc voltage alone does not afford a sufficient basis for adjustment of the carbons in the high-intensity arc. Joy and Downes (reference 4) have published the results of a thorough investigation of this subject. They have shown that it is possible to operate a high-intensity arc at 120 amperes with 70 volts drop across the arc at arc lengths ranging from $^5/_8$ inch to $1^1/_8$ inches. However, widely divergent results as to steadiness and quantity of crater light are encountered over this range of arc lengths. Relative position of positive and negative carbons is probably a factor of greater importance than arc voltage in maintaining correct arc conditions. Without discussing theories of the action taking place within the crater of the high intensity arc, it will here suffice to say that steady burning, uniform light output and characteristic extreme brilliancy are dependent on the maintenance of uniform crater depth and form and uniform conditions within the crater. It is obvious that these factors will be influenced to a marked degree by the manner in which the negative arc stream impinges on the positive crater. Detailed instructions for obtaining optimum performance are contained in a handbook which has been made available to projectionists and other users of high-intensity arcs. Values representing average arc voltage for the d-c high-intensity arc with rotating positive, under correct operating conditions, are indicated by curve *B* in figure 10.

There has recently come into extensive use in motion picture projection a carbon arc which our present knowledge indicates to be a true high-intensity arc but which is operated at much lower arc voltage than the older types of high-intensity arcs. This arc is known in the motion picture industry as the Suprex type arc. Among several points of difference from the older types is the fact that it is operated at a relatively short arc length with a drop of 31 to 40 volts across the arc. Due to this low arc voltage, it is desirable that the Suprex arc should be operated from a low-voltage source of power. This is necessary to obtain best performance as well as good power economy.

It has been demonstrated that the crater depth of the high-intensity positive increases with increase of arc current; that the voltage drop in the arc stream is com-

paratively low and does not materially increase with increased current; and, on the other hand, that the voltage drop within the positive crater is comparatively high and does increase materially as current and crater depth increase (reference 5). When some disturbance to the "high intensity effect" takes place, crater form, depth and voltage are affected, as well as light output. Normal crater conditions and light output are re-established by the increase in current resulting from the drop in arc voltage and the time required to restore normal conditions depends on the amount of current increase. When this low-voltage arc is operated with heavy ballast on a 115-volt power circuit, so much of the total energy is consumed in the ballast that relatively large changes of arc voltage produce only slight changes in arc current. It therefore takes considerable time for restoration of normal crater conditions to be effected. On the other hand, when the voltage of the power source is not greatly above that of the arc, and the ballast correspondingly small, much larger fluctuations in arc current occur in response to a disturbing influence so that normal crater conditions and light output are restored more quickly.

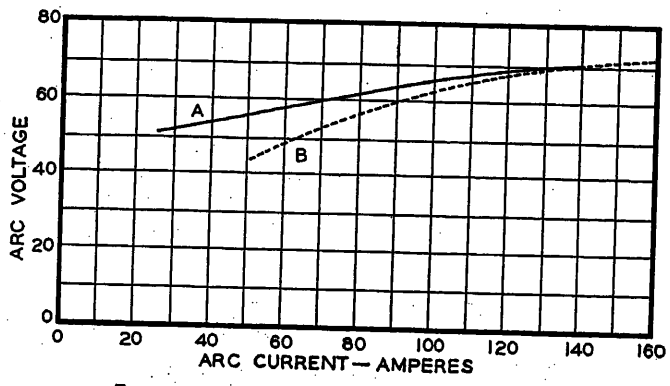

**Fig. 10. Arc voltage versus arc current**

*A*—D-c low-intensity arc
*B*—D-c high-intensity arc

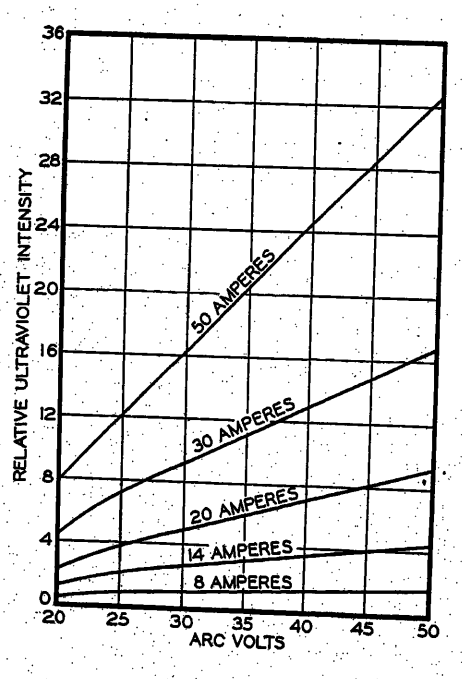

**Fig. 11. Ultraviolet output (2,900 – 3,100 Angstrom units) versus arc voltage, iron - nickel - aluminum core**

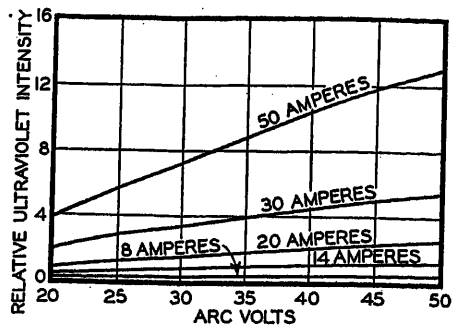

**Fig. 12. Ultraviolet output (2,900–3,100 Angstrom units) versus arc voltage, cerium core**

The operator of a Suprex type of arc, using a low-voltage power source, should therefore expect to see wider fluctuations of current than are customary with other types of arcs. Furthermore, it should be recognized that fluctuation of current is not necessarily associated with corresponding fluctuation of light but is, rather, a stabilizing factor by means of which uniform light output is maintained.

The flame arc can be operated satisfactorily over a considerable range of arc voltage although, under certain conditions or in some particular lamp, best results may be obtained over a relatively narrow voltage range. The effect of changes in arc voltage on ultraviolet output from 2,900 to 3,100 Angstrom units is shown by the curves in figures 11 and 12. The former is for a carbon containing iron, nickel, and aluminum in the core and the latter for a cerium-cored carbon. Relative effect of changes in arc current and in arc voltage can be observed by comparing these curves with those in figure 7.

## Conclusion

The carbon arc is firmly established as a powerful, efficient, and highly flexible source of radiation, possessing certain advantageous characteristics which make it a most useful source of radiant energy for many purposes. It is true of the carbon arc, as it is of all types of light sources, that effective application requires consideration of the inherent characteristics of the source and adaptation of operating conditions to these characteristics. Each type of arc has its own peculiar advantages and fields of application. The foregoing discussion covers some of the features of the various types of arcs to which attention should be given in making the initial application as well as in subsequent operation.

# Current Loci in the General Linear A-C Network

By ALAN HAZELTINE
FELLOW AIEE

OUR PROBLEM is to find the way in which the currents and voltages vary in a general linear a-c network connected to a single adjustable branch, when the current of that branch is adjusted under some given restriction. In a general linear network, each branch has a fixed impedance; and the impressed voltages and currents (of which there may be any number, but usually is only one) are also fixed.* The impressed voltages and currents are supposed sinusoidal and of the same frequency; and we are concerned only with the steady state. So all voltages and currents are sinusoidal and may be represented analytically by complex numbers and graphically by plane vectors.

If we write for the network a complete set of circuit equations, these will be linear in the unknown voltages and currents, together with the current $I_L$ of the adjustable branch. If we are interested in a certain current $I_M$, we may eliminate all other unknown currents and voltages successively in the usual way, by multiplying the equations by suitable constants and adding them. At each step the resulting equations then remain linear; and we shall finally arrive at a linear equation connecting only $I_M$ and $I_L$:

$$I_M = I_{M0} + K_M I_L \qquad (I_{M0}, K_M \text{ are constants}) \tag{1}$$

Evidently $I_{M0}$ is the value of $I_M$ when $I_L = 0$ and is due to the impressed voltages and currents. While $K_M$ is the value of $I_M$ when $I_L = 1$ and all impressed voltages and currents are removed (making $I_{M0} = 0$): here the unit current $I_L$ must be supplied from a source in its branch; and the impressed voltages must be removed by short-circuiting them, the impressed currents by opening their circuits, so as not to alter the impedances of the network.

If we had been interested in a voltage $E_M$, instead of a current $I_M$, a similar equation would have been found:

$$E_M = E_{M0} + z_M I_L \qquad (E_{M0}, z_M \text{ are constants}) \tag{2}$$

Evidently $E_{M0}$ is the value of $E_M$ when $I_L = 0$; and $z_M$ is the value of $E_M$ when $I_L = 1$ and the impressed voltages and currents are removed. In particular, we have for the voltage $E_L$ across the adjustable branch

$$E_L = E_{L0} - z_S I_L \qquad (E_{L0}, z_S \text{ are constants}) \tag{3}$$

Here $E_{L0}$ is the value of $E_L$ when $I_L = 0$ (i.e., the *open-circuit voltage* of the adjustable branch) and is due to the impressed voltages and currents of the network. While $z_S$ is the value of $E_L$ when $I_L = -1$ and the impressed voltages and currents are removed. If we restrict ourselves (as we shall) to an adjustable branch connected to the network *only through 2 terminals* (in particular, having no mutual inductance to the network), then $z_S$ is the impedance *looking into the network* between these terminals, since $-I_L = 1$ represents the current sent *into* the network by the voltage $E_L$ due to a source in the adjustable branch.†

In place of an *open-circuit* calculation to determine $I_{M0}$ (or $E_{M0}$) and $E_{L0}$, or in place of an *impedance* calculation to determine $K_M$ (or $z_M$) and $z_S$, we may use a *short-circuit* calculation, in which the adjustable branch is short-circuited, making $E_L = 0$. If $I_M$, $E_M$, and $I_L$ under this condition are denoted by $I_{MS}$, $E_{MS}$, and $I_{LS}$, equations 1, 2, and 3 give

$$\left.\begin{aligned} I_{MS} &= I_{M0} + K_M I_{LS} \\ E_{MS} &= E_{M0} + z_M I_{LS} \\ 0 &= E_{L0} - z_S I_{LS} \end{aligned}\right\}, \text{ whence } \left\{\begin{aligned} I_{M0} &= I_{MS} - K_M I_{LS} \\ E_{M0} &= E_{MS} - z_M I_{LS} \\ E_{L0} &= z_S I_{LS} \end{aligned}\right\} \text{ or}$$

$$\left.\begin{aligned} K_M &= \frac{I_{MS} - I_{M0}}{I_{LS}} \\ z_M &= \frac{E_{MS} - E_{M0}}{I_{LS}} \\ z_S &= \frac{E_{L0}}{I_{LS}} \end{aligned}\right\} \tag{4}$$

If not restricted, the current $I_L$ would be represented by a vector whose extremity could lie anywhere in its plane. When, however, $I_L$ is restricted by a single real equation, the extremity of its vector will in general lie on a curve, called the *locus* of $I_L$ for this restriction. For example, if the restriction is that the apparent power of the variable branch be constant, $E_L I_L = A_L$, the locus of $I_L$ will be one of those shown in figure 1*a*, according to the value of $A_L$.** Now multiplying $I_L$ by the complex constant $K_M$ will change its magnitude in a fixed ratio and its phase by a fixed angle; so the loci of $K_M I_L$ will be similar to those for $I_L$ and similarly related to one another, but will in general be changed in scale and rotated, as represented in figure 1*b*, with $O'$ as the origin. Then adding the complex constant $I_{M0}$, to give $I_M$ according to equation 1, merely shifts the origin to a new point $O$, figure 1*b*. That is, *every variable current $I_M$ (and every variable voltage $E_M$) of the network will have loci similar to those of $I_L$.*

A paper recommended for publication by the AIEE committee on education. Manuscript submitted September 15, 1936; released for publication January 11, 1937.

ALAN HAZELTINE is professor of physical mathematics at Stevens Institute of Technology, Hoboken, N. J.

* We do not exclude amplifiers, which involve one-way action; so our treatment is more general than the usual network theories, in which amplifiers are supposed absent, resulting in certain symmetries in the circuit relations. Voltages and currents in amplifiers which are proportional to other voltages or currents are, of course, not considered as *impressed*, even though they are derived from separate sources of energy; for they are taken into account by transfer *impedances*. A similar consideration applies to voltages and currents of negative-resistance devices.

† Equation 3 together with this statement constitutes Thévinin's theorem.

** These curves are the *ovals of Cassini*, each of which is characterized by the property that the product of the distances from any point on it to 2 fixed points is a constant. As may be seen from the discussion immediately following (figure 2*b*), the distance from any point to the "short-circuit point" $A$ represents $E_L/z_S$; and $(E_L/z_S)I_L = A_L/z_S$, which is constant. A special case is the *lemniscate*, drawn heavily in figure 1*a*.

Our problem is thus reduced to that of finding the loci of $I_L$ under various restrictions. The restrictions that we shall consider are that each of the 10 following real quantities in the adjustable branch shall in turn remain *fixed* at various values: current, $I_L$; voltage, $E_L$; their phase difference, $\phi_L$; active power, $P_L = E_L I_L \cos \phi_L$; reactive power, $Q_L = E_L I_L \sin \phi_L$; impedance, $z_L = E_L/I_L$; resistance, $r_L = z_L \cos \phi_L$; reactance, $x_L = z_L \sin \phi_L$; conductance, $g_L = (1/z_L) \cos \phi_L$; susceptance, $b_L = (1/z_L) \sin \phi_L$. We shall find that the loci in each case form a set of circles and that all of these sets of circles are related to a *single framework* (figure 2) made up of 4 fixed points ($O$, $A$, $B$, $C$) and the 6 straight lines joining them, as follows: for fixed $I_L$, $E_L$, $P_L$ or $Q_L$, the centers of the circles lie on one of the 4 points; while for fixed $\phi_L$, $z_L$, $r_L$, $x_L$, $g_L$, or $b_L$, the centers of the circles lie on one of the 6 straight lines. (Figure 2 is drawn for the case where $r_S$ and $x_S$, the rectangular components of $z_S$, are both positive, as is most usual.)

The locus for any fixed magnitude $I_L$ of *current* $\boldsymbol{I}_L$ is obviously a circle having its center at the origin $O$ and the radius $I_L$, figure 2*b*.

The locus for fixed magnitude $E_L$ of *voltage* is found almost as directly: If we write equation 3 in the form,

$$\boldsymbol{I}_L = \frac{\boldsymbol{E}_{L0}}{\boldsymbol{z}_S} - \frac{\boldsymbol{E}_L}{\boldsymbol{z}_S}, \quad \text{or} \quad \boldsymbol{I}_L = \boldsymbol{I}_{LS} - \frac{\boldsymbol{E}_L}{\boldsymbol{z}_S}, \tag{5}$$

we see that the vectors corresponding to the 3 terms form a triangle, as in figure 2*b*, of which the vertex $A$ also is fixed, since the short-circuit current, $\boldsymbol{I}_{LS} = \boldsymbol{E}_{L0}/\boldsymbol{z}_S$, is fixed. Then if the magnitude $E_L$ is fixed, the magnitude of $\boldsymbol{E}_L/\boldsymbol{z}_S$ will also be fixed; so the locus will be a circle having its center at the short-circuit point $A$ and the radius $E_L/z_S$.

The *active power* $P_L = E_L I_L \cos \phi_L$ is found by multiplying $I_L$ by the projection of $\boldsymbol{E}_L$ upon $\boldsymbol{I}_L$. If $\phi_{L0}$ is the phase difference between $\boldsymbol{E}_{L0}$ and $\boldsymbol{I}_L$ and if $r_S$ is the real part of $\boldsymbol{z}_S$, this projection is $E_{LS} \cos \phi_{LS} - I_L r_S$, as illustrated by the usual vector diagram, figure 2*a*. So

$$P_L = I_L(E_{L0} \cos \varphi_{L0} - I_L r_S), \text{ whence } \cos \varphi_{L0} = \frac{I_L^2 + P_L/r_S}{I_L E_{L0}/r_S} \tag{6}$$

To show that with fixed $P_L$ this gives a circular current locus, we may derive the general polar equation of a circle, as illustrated in figure 3. There the well-known "cosine law" of trigonometry gives

$$\cos(\theta - \alpha) = \frac{R^2 + a^2 - b^2}{2Ra} \tag{7}$$

This is of the same form as equation 6, the correspondence being as follows:

$$\text{Variables, } I_L = R, \varphi_{L0} = \theta; \text{ constants, } \frac{P_L}{r_S} = a^2 - b^2, \frac{E_{L0}}{r_S} = 2a, \quad 0 = \alpha.$$

Hence the locus for fixed $P_L$ is a circle whose center is on the $\boldsymbol{E}_{L0}$ vector ($\alpha = 0$) at the fixed distance

$$a = \frac{E_{L0}}{2r_S} \tag{8}$$

and whose radius is

$$b = \left(a^2 - \frac{P_L}{r_S}\right)^{1/2} = \left(\frac{E_{L0}^2}{4r_S^2} - \frac{P_L}{r_S}\right)^{1/2} \tag{9}$$

Such a set of circles is illustrated in figure 2*c*, with centers at $B$. If $P_L$ is positive (power input into the adjustable branch), then $a > b$ and the circle does not enclose the origin. If $P_L$ is negative (power output), then $a < b$ and the circle encloses the origin. If $P_L = 0$, then $a = b$ and the circle passes through the origin, as shown by the heavily drawn circle $C_P$ in figure 2*c*. There will be a maximum possible value of $P_L$, corresponding to $b = 0$, which is

$$P_{Lm} = \frac{E_{L0}^2}{4r_S} \tag{10}$$

This corresponds to the common center $B$, which may thus be called the *maximum-active-power point.*

The loci for fixed *reactive power* $Q_L$ are found in exactly similar fashion, $Q_L$ being given (figure 2*a*) by the equation,

$$Q_L = I_L(E_{L0} \sin \varphi_{L0} - I_L x_S), \text{ whence } \sin \varphi_{L0} = \cos\left(\varphi_{L0} - \frac{\pi}{2}\right) = \frac{I_L^2 + Q_L/x_S}{I_L E_{L0}/x_S}, \tag{11}$$

where $x_S$ is the imaginary part of $\boldsymbol{z}_S$. The loci are again concentric circles, their centers being at the distance

$$a = \frac{E_{L0}}{2x_S} \tag{12}$$

on the line lagging 90 degrees behind $\boldsymbol{E}_{L0}$, and their radii being

$$b = \left(a^2 - \frac{Q_L}{x_S}\right)^{1/2} = \left(\frac{E_{L0}^2}{4x_S^2} - \frac{Q_L}{x_S}\right)^{1/2} \tag{13}$$

as also illustrated in figure 2*c*, with centers at $C$. If $Q_L$ is positive (inductive), the circle does not enclose the origin; if it is negative (capacitive), the circle does enclose the origin; and if $Q_L = 0$, the circle passes through the origin, as shown by the heavily drawn circle $C_Q$, figure 2*c*. There will be a maximum possible value of $Q_L$, corresponding to $b = 0$, which is

$$Q_{Lm} = \frac{E_{L0}^2}{4x_S} \tag{14}$$

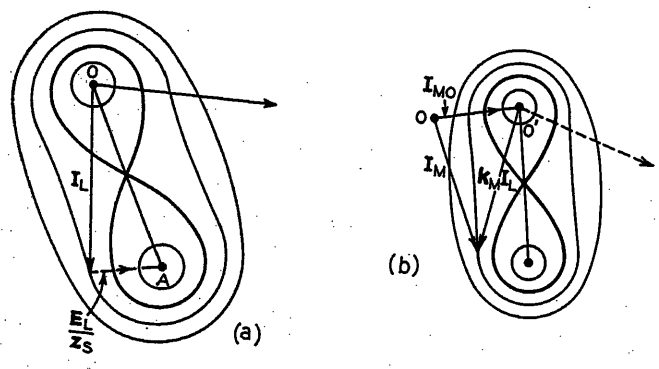

Fig. 1

This corresponds to the common center $C$, which may thus be called the *maximum-reactive-power point.*

The 4 fixed points $O$, $A$, $B$, $C$, which we have now located, and the 6 straight lines joining them make up the framework to which we referred earlier. In the subsequent loci (figure 2*d*, *e*, *f*), each of these straight lines will appear as a special locus itself and also as bearing the centers of a set of circular loci. The circles $C_P$ and $C_Q$ also reappear as loci in each of figures 2*d*, *e*, *f*, and are heavily drawn throughout.

The remaining sets of loci all depend on the property of a circle that its *inverse* with respect to a point is also a circle (including the limiting case of a straight line as a circle of infinite radius). Let a complex variable, $\boldsymbol{R} = Re^{j\theta}$, have a circular locus $C$, so that $R$ and $\theta$ are related by equation 7. The reciprocal, $\boldsymbol{R}' = R'e^{j\theta'} = 1/\boldsymbol{R} = (1/R)\epsilon^{-j\theta}$, then has the magnitude $R' = I/R$ and the phase angle $\theta' = -\theta$. If $a > b$, so that the circle $C$ does not enclose the origin $O$, figure 4*a*, equation 7 may be written in the form,

$$\cos(\theta - \alpha) = mR + \frac{n}{R} \tag{15}$$

where $m = 1/(2a)$ and $n = (a^2 - b^2)/(2a)$ are positive constants.

Putting $\theta = -\theta'$ and $R = 1/R'$, we have

$$\cos(-\theta' - \alpha) = \frac{m}{R'} + nR' \quad \text{or} \quad \cos(\theta' + \alpha) = nR' + \frac{m}{R'} \tag{16}$$

which is of the same form as (15) but with $\alpha$ replaced by $-\alpha$ and with $m$ and $n$ interchanged. The locus of $\boldsymbol{R}'$ is therefore also a circle, as represented by $C'$, figure 4*a*. (The dotted circle $C_t$ is conveniently found first; it is the inverse of $C$ with respect to $O$, only the magnitude having been changed from $R$ to $R'$, not the angle $\theta$.)

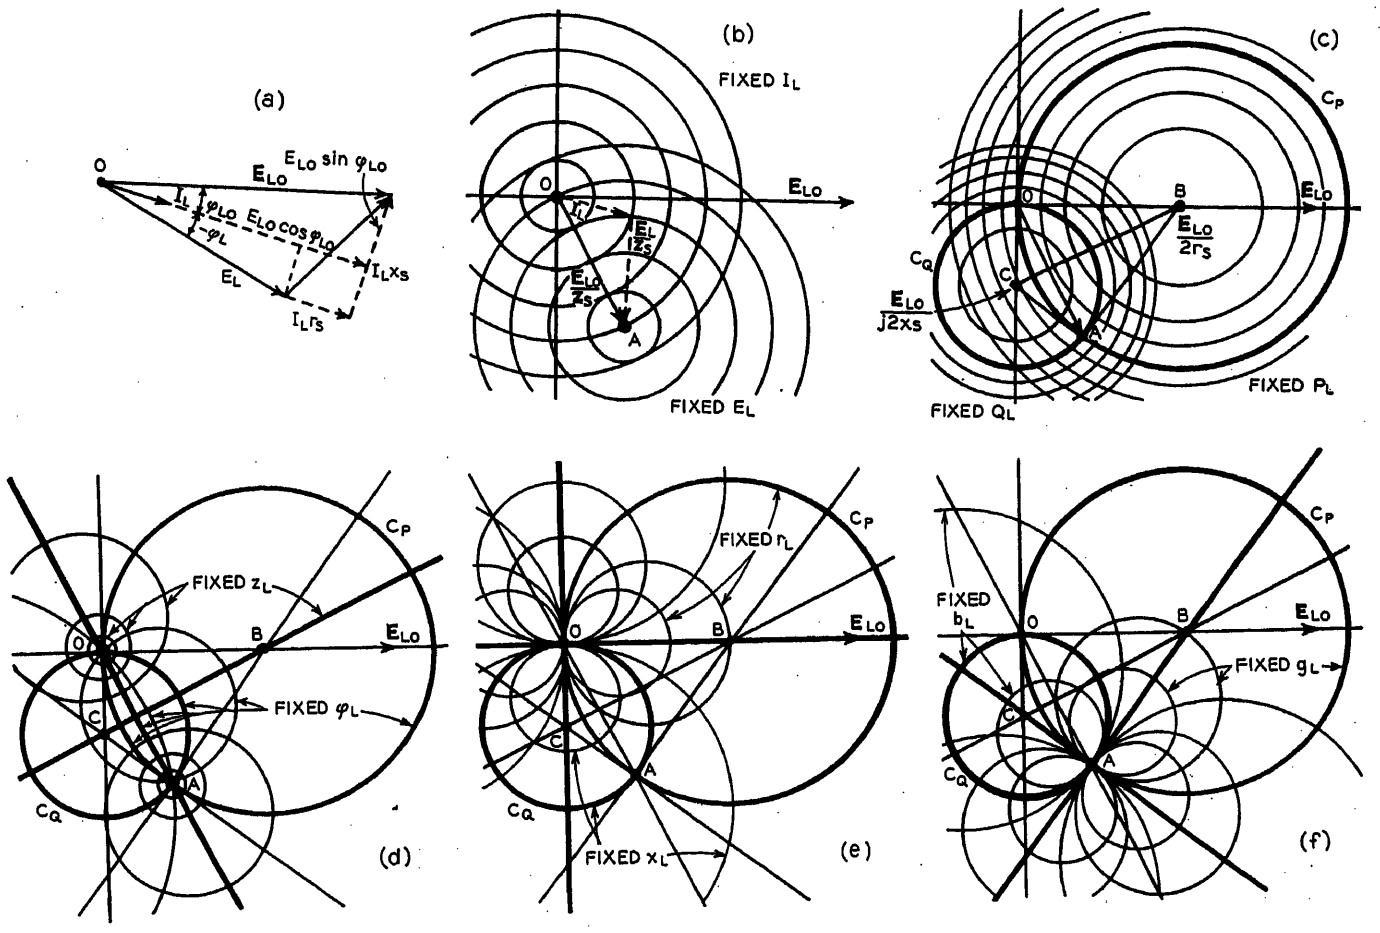

Fig. 2

If $a < b$, so that the circle $C$ encloses the origin $O$, figure 4*b*, equation 7 may be written in the form,

$$\cos(\theta - \alpha) = mR - \frac{n}{R} \tag{17}$$

where $m = 1/(2a)$ and $n = (b^2 - a^2)/(2a)$ are again positive constants. Then, putting $\theta = -\theta'$ and $R = 1/R'$, as before, we have

$$\cos(-\theta' - \alpha) = \frac{m}{R'} - nR' \text{ or } \cos(\theta' + \alpha - \pi) = nR' - \frac{m}{R'} \tag{18}$$

which is of the same form as (17) but with $\alpha$ replaced by $\pi - \alpha$ and with $m$ and $n$ interchanged. The locus of $\boldsymbol{R}'$ is therefore again a circle, as represented by $C'$, figure 4*b*.

If $a = b$, so that the circle $C$ passes through the origin $O$, figure 4*c*, equation (7) becomes

$$\cos(\theta - \alpha) = \frac{R}{2a} \tag{19}$$

So

$$\left.\begin{aligned} &\cos(-\theta' - \alpha) = \frac{1}{2aR'} \\ &\text{or} \\ &R'\cos(\theta' + \alpha) = \frac{1}{2a} \end{aligned}\right\} \quad (20)$$

which is evidently the equation of the straight line $C'$, figure 4*c*.

(The theorem that the inverse of a circle is a circle can also be proved by elementary geometry, using the fact

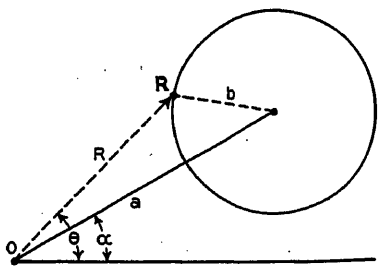

Fig. 3

that an inscribed angle is measured by its subtended arc to prove the similarity of certain triangles.)

The above theorem can be generalized to show that *if* $\boldsymbol{R}$ *has a circular locus, then so has the general linear fraction,*

$$w = \frac{dR + e}{fR + g} \left(d, e, f, g \text{ are complex constants such that } \frac{d}{f} \neq \frac{e}{g}\right) \quad (21)$$

For this equation may be reduced by division to

$$w = \frac{d}{f} + \frac{e - dg/f}{fR + g} \quad (22)$$

Thus $w$ is derived from $R$ by the following steps, each of which turns one circle into another: multiplying by the constant $f$ and adding the constant $g$, thus changing the scale, rotating and translating the circle; inverting, giving a new circle as proved above; and multiplying by the constant $e - dg/f$ and adding the constant $d/f$, thus changing the scale, rotating and translating the new circle.

Now returning to our problem of finding the loci of $I_L$, we may put $E_L = I_L z_L$ in equation 3, giving

$$I_L = \frac{E_{L0}}{z_S + z_L} \quad (23)$$

where

$$z_L = z_L \epsilon^{j\varphi_L} = r_L + jx_L = \frac{1}{g_L - jb_L} \text{ is variable} \quad (24)$$

Evidently $I_L$ is a linear fraction with respect to any of the components $z_L$, $\epsilon^{j\varphi_L}$, $x_L$, $r_L$, $b_L$, or $g_L$ when the associated component is held fixed. Hence in each case the locus of $I_L$ will be a circle, as we have just proved. We proceed to consider each case in turn.

If the *phase difference* $\varphi_L$ is fixed, and $z_L$ varies, the vector $z_L \epsilon^{j\varphi_L}$ will have a straight-line locus (circle of infinite radius). The current is expressed in terms of $\varphi_L$ and $z_L$ by the equation,

$$I_L = \frac{E_{L0}}{z_S + z_L \epsilon^{j\varphi_L}} \quad (25)$$

As $z_L$ varies from 0 to $\infty$, $I_L$ will vary from $E_{L0}/z_S$ to 0, for any $\varphi_L$; so all circular loci will pass through the origin $O$ and the short-circuit point $A$, as drawn in figure 2*d*. Their centers will therefore lie on the line $BC$, which is the perpendicular bisector of $OA$. For very large $z_L$, the term $z_S$ becomes vanishingly small in comparison with $z_L \epsilon^{j\varphi_L}$; so $I_L$ starts off from $O$ at the phase angle $-\varphi_L$, which is thus the inclination of the tangent to the circle at the origin. When $\varphi_L = 0$, we have the zero-active-power circle $C_P$; when $\varphi_L = 90$ degrees, we have the zero-reactive-power circle $C_Q$; and when $\varphi_L = \varphi_S$ (the phase angle of $z_S$), we have the straight line $OA$.

If the *impedance* $z_L$ is fixed and $\varphi_L$ varies, the vector $z_L \epsilon^{j\varphi_L}$ will have a circular locus (since $\epsilon^{j\varphi_L}$ is a vector of unit length and variable angle). The current, given by 25, will then have a circular locus which is most easily located by finding its center and radius. Evidently $I_L$ will have its minimum and maximum magnitudes when $z_L$ is respectively in phase with, and in opposition to, $z_S$; it then becomes

$$\left.\begin{aligned} I_{L\,\min} &= \frac{E_{L0}}{z_S} \cdot \frac{1}{1 + \frac{z_L}{z_S}} \\ &\text{and} \\ I_{L\,\max} &= \frac{E_{L0}}{z_S} \cdot \frac{1}{1 - \frac{z_L}{z_S}} \end{aligned}\right\} \quad (26)$$

The center of the circle is then the extremity of the vector.

$$\frac{I_{L\,\min} + I_{L\,\max}}{2} = \frac{E_{L0}}{z_S} \cdot \frac{1}{2}\left(\frac{1}{1 + \frac{z_L}{z_S}} + \frac{1}{1 - \frac{z_L}{z_S}}\right) = \frac{E_{L0}}{z_S} \cdot \frac{1}{1 - \frac{z_L^2}{z_S^2}} \quad (27)$$

so all centers lie on the line $OA$, which is the vector $E_{L0}/z_S$ produced. And the radius of the circle is the length of the vector,

$$\begin{aligned} \frac{I_{L\,\max} - I_{L\,\min}}{2} &= \frac{E_{L0}}{z_S} \cdot \frac{1}{2}\left(\frac{1}{1 - \frac{z_L}{z_S}} - \frac{1}{1 + \frac{z_L}{z_S}}\right) \\ &= \frac{E_{L0}}{z_S} \cdot \frac{z_L/z_S}{1 - \frac{z_L^2}{z_S^2}} \end{aligned} \quad (28)$$

For $z_L = 0$ and $z_L = \infty$, respectively, the circles shrink to the points $A$ and $O$. For $z_L = z_S$, the circle has an infinite radius and becomes the straight line $BC$.

Inspection of figure 2*d* suggests that the 2 sets of circles are *orthogonal* (cross at right angles). To prove this, we may differentiate (23):

$$dI_L = \frac{-E_{L0}}{(z_S + z_L)^2} dz_L \quad (29)$$

Now if $dz_L$ is given in turn 2 values at right angles, $dI_L$ will also have 2 values at right angles, since the factor $-E_{L0}/(z_S + z_L)^2$ is the same for both. But when $z_L$ varies first with $\varphi_L$ fixed and then with $z_L$ fixed, $dz_L$ will first be radial and then tangential. Hence the corresponding values of $dI_L$ will be at right angles. This relation affords a ready means for locating the constant-$z_L$ circle passing through any point $P$ in the plane: the constant-$\varphi_L$ circle is first drawn (through $P$, $O$, and $A$) and then its tangent is drawn at $P$; the intersection of this tangent with $OA$ is the center of the required circle.*

If the *resistance* $r_L$ is fixed and $x_L$ varies, the vector $z_L = r_L + jx_L$ will have a straight-line locus (vertical). The current is expressed in terms of $r_L$ and $x_L$ by the equation,

$$I_L = \frac{E_{L0}}{z_S + r_L + jx_L} = \frac{E_{L0}}{(r_S + r_L) + j(x_L + x_L)} \tag{30}$$

where $z_S = r_S + jx_S$.

If $x_L = \pm\infty$, $I_L = 0$ for all $r_L$; so all circular loci will pass through the origin $O$. Evidently $I_L$ will have its maximum magnitude when $x_L = -x_S$ and is then

$$I_{L\max} = \frac{E_{L0}}{r_S + r_L} \tag{31}$$

The center of the circle is then the extremity of the vector,

$$\frac{1}{2} I_{L\max} = \frac{E_{L0}}{2(r_S + r_L)} \tag{32}$$

so all centers lie on the line $OB$, which is the vector $E_{L0}$ produced, as drawn in figure 2*e*. For $r_L = \pm\infty$, the circles shrink to the point $O$. For $r_L = 0$, the circle is the zero-active-power circle $C_P$, whose radius was found to be $E_{L0}/(2r_S)$. Positive values of $r_L$ correspond to circles inside $C_P$, negative values to circles outside. For $r_L = -r_S$, the circle has an infinite radius and becomes the straight line $OC$.

If the *reactance* $x_L$ is fixed and $r_L$ varies, the vector $z_L = r_L + jx_L$ will again have a straight-line locus (now horizontal). The current, expressed by (30), will have a similar set of circular loci, all passing through $O$ (for $r_L = \pm\infty$). It will have its maximum magnitude when $r_L = -r_S$ and is then

$$I_{L\max} = \frac{E_{L0}}{j(x_S + x_L)} \tag{33}$$

The center of the circle is then the extremity of the vector,

$$\frac{1}{2} I_{L\max} = \frac{E_{L0}}{j2(x_S + x_L)} \tag{34}$$

so all centers lie on the line $OC$, which is in quadrature with $E_{L0}$, as drawn in figure 2*e*. For $x_L = \pm\infty$, the circles shrink to the point $O$. For $x_L = 0$, the circle is the zero-reactive-power circle $C_Q$, whose radius was found to be $E_{L0}/(2x_S)$. Positive (inductive) values of $x_L$ correspond to circles inside $C_Q$, negative (capacitive) values to circles outside. For $x_L = -x_S$, the circle has an infinite radius and becomes the straight line $OB$.

The 2 sets of circles in figure 2*e* are orthogonal, for the same reason as in figure 2*d*. Equation 29 still applies; and $dz_L$ will first be vertical and then horizontal when $z_L$ is varied first with $r_L$ fixed and then with $x_L$ fixed.

If the *conductance* $g_L$ is fixed and $b_L$ varies, the vector $1/z_L = g_L - jb_L$ will have a straight-line locus (vertical). It will now be conveniently to temporarily shift our origin to $A$ and to consider the locus of the vector (extending *from* $A$, figure 2*b*),

$$-\frac{E_L}{z_S} = -\frac{E_{L0}}{z_S}\cdot\frac{z_L}{z_S + z_L} = -\frac{E_{L0}}{z_S^2}\cdot\frac{1}{\frac{1}{z_S} + \frac{1}{z_L}}$$

$$= -\frac{E_{L0}}{z_L^2}\cdot\frac{1}{(g_S + g_L) - j(b_S + b_L)} \tag{35}$$

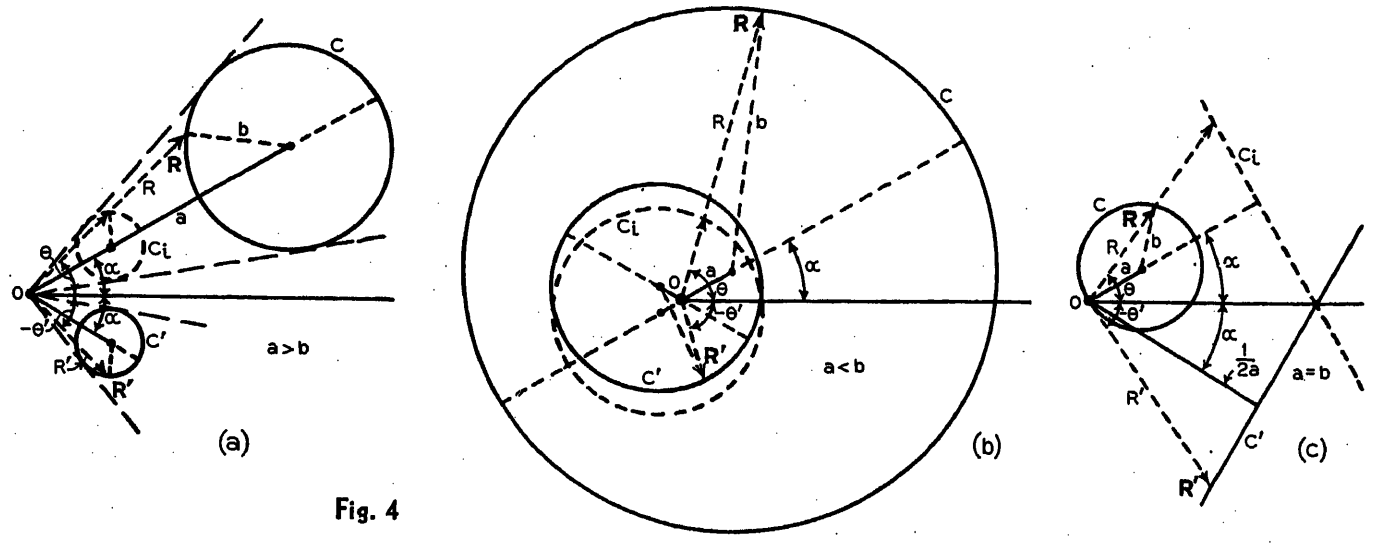

Fig. 4

* If we imagine $z_L$ *mapped* in its plane by drawing radial lines (fixed $\varphi_L$) and concentric circles (fixed $z_L$), these lines will constitute a figure *conformal* with the loci of figure 2*d*. Conformal mapping of one figure on another requires that all corresponding angles be equal. It always results when corresponding loci are drawn for 2 complex variables one of which is an analytic (differentiable) function of the other; for then differential figures will be similar. (Finite figures, however, will be similar only in the special case where the function is *linear*, as in equation 1 and figure 1.)

where $1/z_S = g_S - jb_S$. If $b_L = \pm\infty$, $-E_L/z_S = 0$ for all $g_L$; so all circular loci will pass through $A$. Evidently $-E_L/z_S$ will have its maximum magnitude when $b_L = -b_S$ and is then

$$-\frac{E_{Lmax}}{z_S} = -\frac{E_{L0}}{z_S^2}\cdot\frac{1}{g_S + g_L} \tag{36}$$

The center of the circle is then the extremity of the vector (from $A$),

$$-\frac{1}{2}\frac{E_{Lmax}}{z_S} = -\frac{E_{L0}}{z_S^2}\cdot\frac{1}{2(g_S + g_L)} \tag{37}$$

This vector evidently lags behind $-E_{L0}/z_S$ by the angle $\varphi_S$; so it lies along the line $AB$, on which therefore all centers lie, as drawn in figure 2*f*. For $g_L = \pm\infty$, the circles shrink to the point $A$. For $g_L = 0$, the circle is the zero-active-power circle $C_P$ since then

$$\frac{1}{2}\frac{E_{Lmax}}{z_S} = \frac{E_{L0}}{z_S^2\cdot 2g_S} = \frac{E_{L0}}{2r_S} \tag{38}$$

as found for the radius of $C_P$. Positive values of $g_L$ correspond to circles inside $C_P$, negative values to circles outside. For $g_L = -g_S$, the circle has an infinite radius and becomes the straight line $AC$.

If the *susceptance* $b_L$ is fixed and $g_L$ varies, the vector $1/z_L = g_L - jb_L$ will again have a straight-line locus (now horizontal). And $-E_L/z_S$, expressed by (35), will have a similar set of circular loci, all passing through $A$ (for $g_L = \pm\infty$). It will have its maximum magnitude when $g_L = -g_S$ and is then

$$-\frac{E_{Lmax}}{z_S} = \frac{E_{L0}}{z_S^2}\cdot\frac{1}{j(b_S + b_L)} \tag{39}$$

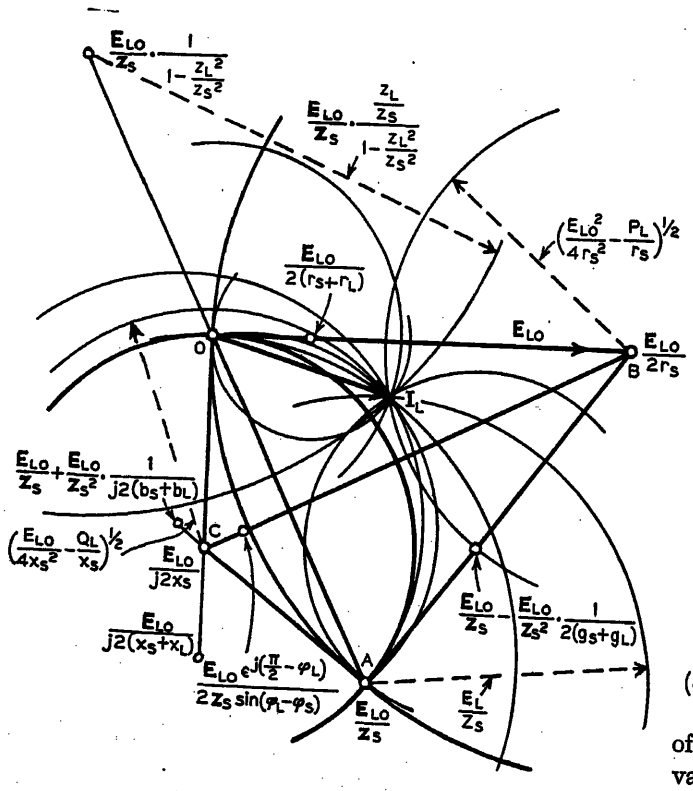
The center of the circle is then the extremity of the vector (from $A$),

$$-\frac{1}{2}\frac{E_{Lmax}}{z_S} = \frac{E_{L0}}{z_S^2}\cdot\frac{1}{j2(b_S + b_L)} \tag{40}$$

This vector is evidently in quadrature with the vector of equation 37; so it lies along the line $AC$ (perpendicular to $AB$), on which therefore all centers lie, as drawn in figure 2*f*. For $b_L = \pm\infty$, the circles shrink to the point $A$. For $b_L = 0$, the circle is the zero-reactive-power circle $C_Q$, since then

$$\frac{1}{2}\frac{E_{Lmax}}{z_S} = \frac{E_{L0}}{z_S^2\cdot 2b_S} = \frac{E_{L0}}{2x_S} \tag{41}$$

as found for the radius of $C_Q$. Positive (inductive) values of $b_L$ correspond to circles inside $C_Q$, negative (capacitive) values to circles outside. For $b_L = -b_S$, the circle has an infinite radius and becomes the straight line $AB$.



The 2 sets of circles in figure 2*f* are orthogonal, for the same reason as in figure 2*d* and *e*. The equation which applies in this case is found by differentiating equation 35:

$$d\left(-\frac{E_L}{z_S}\right) = \frac{E_{L0}}{z_S^2}\cdot\frac{1}{\left(\frac{1}{z_S} + \frac{1}{z_L}\right)^2}\,d\left(\frac{1}{z_L}\right) \tag{42}$$

for $d(1/z_L)$ will first be vertical and then horizontal when $1/z_L$ is varied first with $g_L$ fixed and then with $b_L$ fixed.

In figure 5*a* we have drawn (to double the scale of figure 2) for a particular current vector $I_L$ the 10 loci which pass through its extremity, values of the radii and locations of the centers being indicated, for convenience of reference. Figure 5*b* is derived from figure 5*a* by multiplying all vectors by the constant $K_M$ and adding the constant $I_{M0}$, to give $I_M$, in accordance with equation 1. This concludes our general problem.

Fig. 5

# A Suggested Rotor Flux Locus Concept of Single-Phase Induction-Motor Operation

By C. T. BUTTON
ASSOCIATE AIEE

THE cross field theory and the revolving field theory are the 2 commonly accepted bases for analytical treatment of the single phase squirrel cage induction motor. For the purpose of quantitative analysis as well as to explain why and how the motor runs, the first mentioned theory resolves fluxes, voltages, and currents into components in 2 axes fixed with reference to the stator; whereas the second theory resolves the flux into 2 rotating components—one rotating in a positive direction at synchronous speed, and the other rotating in a negative direction at synchronous speed.

An alternative concept is outlined below which is perhaps less involved than either of the above theories, although it does not lend itself to quantitative mathematical treatment. In a word, it considers the total flux traversing the air gap, and gives a complete picture of the variation in magnitude and direction of the total or resultant flux. The novelty of the treatment consists in referring the flux to axes fixed with reference to the rotor. Once the mind of the reader becomes accustomed to thinking of the rotor as a fixed basis of reference, the development becomes quite clear and rational. (The rotor may be regarded as stationary with the stator rotating about it, or if it assists in visualizing one can imagine he is hanging to the rotor and turning around with it.)

## Assumptions

Inasmuch as quantitative results are not attempted, stator resistance and leakage reactance will either not be involved, or will be considered zero. For purposes of simplifying the diagrams, a 2 pole motor will be considered (figure 1). Motor torque will be considered as clockwise. The flux crossing the air gap in the axis of the stator winding poles will be called primary flux. At synchronous speed the axis of the primary flux will accordingly be rotating with an angular velocity of $2\pi f$ in a counterclockwise sense, with respect to axes of reference fixed in relation to the rotor.

## Condition at Synchronous Speed

We may first plot the locus of the primary magnetomotive-force vector with reference to the rotor for the synchronous speed condition, as indicated in figure 2. This may also be considered as representing the locus of flux through the rotor if there were no rotor conductors; or as representing the primary flux as defined above. (If the rotor were at standstill, the flux locus would of course be a straight line, the instantaneous magnitude of the flux pulsating sinusoidally positive and negative with respect to time.) At synchronous speed, this primary magnetomotive-force or primary flux vector locus would be a circle as shown, never going below the horizontal (rotor) axis. The maximum primary flux is shown as $F_M$ in figure 2; and one-eighth of a cycle later the vector would be in the position shown dotted. The locus would be traversed (in a C.C.W. sense) by the vector twice per cycle, although its angular velocity is only $2\pi f$, as stated above.

The effect produced by the rotor conductors may be described as follows. The rotor is an inductive body circularly symmetrical, so to speak. It is evident that the effect of rotor inductance (not the leakage reactance) will be to resist any change in magnitude or direction of the total flux through it. In other words, due to change in magnitude and direction of the primary flux (figure 3) currents will flow in the rotor conductors producing a secondary flux at right angles to the primary flux; and this secondary flux will have a magnitude and direction tending to maintain the total resultant rotor flux constant at $OF$. At the instant when the primary flux is zero, the secondary flux will be a maximum, and perpendicular upward. This of course simply means that (to use ordinary terminology) the cross field is maximum when the main field is zero.

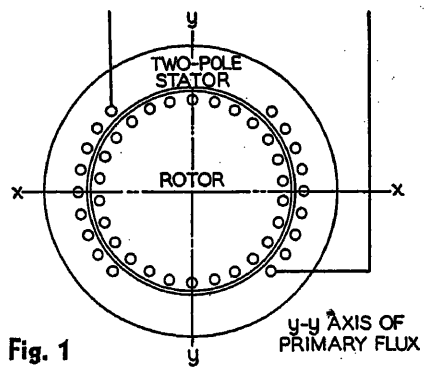


Fig. 1

The inductive effect of the rotor will not be 100 per cent in maintaining constant flux through the rotor at synchronous speed of course, due to the effect of rotor resistance and leakage reactance. The actual total rotor flux at synchronous speed in the practical motor will then be something like the locus indicated in figure 4.

The concept which this treatment attempts to visualize does not emphasize the components $OM$ and $MF$ of figure 3; but rather states simply that (to reiterate) the inductive effect of the rotor resists the amount of total flux change which would exist in an open-circuited rotor condition for the same rotor speed, constraining the total flux to the circular locus of small diameter shown in figure 4.

(It might be mentioned however, that in addition to the main and cross field components, we could also indi-

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted June 17, 1935; released for publication June 29, 1936.

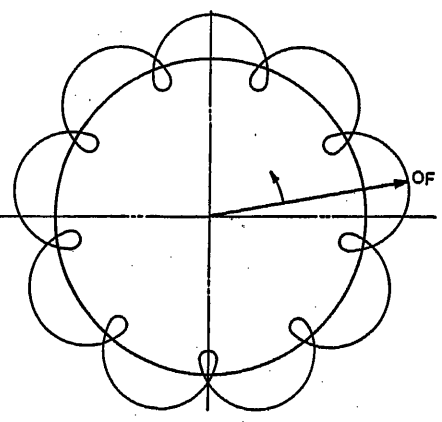

Fig. 7

cate on our diagram the forward and backward rotating flux components $OX$ and $XF$ as in figure 5. $OX$ is constant, and $XF$ is constant in magnitude and rotating with a velocity of $4\pi f$. Again, there is no motive for separation into components except possibly to tie in our diagrams with both of the theories mentioned at the outset.)

## Normal Motoring Condition

It is now but a step to the conception of the locus of total flux at any particular amount of slip. This is shown by figure 6, where the flux vector progresses around the rotor in a clockwise sense (taking 2 steps forward and one step backward, so to speak).

Torque is produced by change in direction of flux through the rotor. The instantaneous torque will be a function of flux magnitude and angular velocity (torque would not be directly proportional to angular velocity of course). Inspection of figure 4 will show that at synchronous speed there is a pulsating torque with a net or average counter clockwise value. In other words, it requires power input to drive the motor at synchronous speed even with losses neglected. Or in still other words, the no load point is at some speed slightly below synchronism.

With normal slip, inspection of the corresponding flux locus (figure 6) will reveal the existence and reason for the pulsating double frequency torque component, and also the average motor torque.

The magnitude of the main flux will be the radius of the outer envelope of the total flux locus; and the quadrature flux will be represented by the radius of the inner envelope.

## Conditions Above Synchronous Speed

In the same way, the total flux locus at a speed above synchronism may be drawn as shown by figure 7.

## Conclusion

It is not claimed that the concepts outlined may be of direct use in calculating performance of single phase motors. However, it is important to have clear mental pictures of just what is going on in any machine under consideration. Such concepts may serve to assist in interpreting results obtained from mathematical treatment, and they may also serve a purpose in connection with general educational work.

The rotor is conceived of briefly as an inductive "circularly symmetrical" rotating body which tends to maintain total flux constant in magnitude and direction with respect to itself. This inductive effect prevents total flux from disappearing at the instant the primary field is zero; and its resistance to change in direction of total flux through it produces torque. The reason for the pulsating and average motor torque components is thus clearly visualized, by reference to the diagrams showing the behavior of the "mutual reactance flux" through stator and rotor.

# Characteristic Constants of Single-Phase Induction Motors Part I: Air-Gap Reactances

By WAYNE J. MORRILL
MEMBER AIEE

## Synopsis

This paper is the first of 2 papers dealing with the development of equations for determining the characteristic constants of single-phase induction motors. It is intended to present in the complete paper a unified tabulation of formulas consistent in symbols with those used in the paper which I presented at the midwinter convention of the AIEE, New York, January 28–February 1, 1929.

This particular section of the paper deals with a rigorous development of the reactances of single-phase motors which result from fluxes crossing the air gap between the stator and rotor.

## Introduction

SINCE 1929 great strides have been made in the design and development of the capacitor motor. As evidence of this fact, the capacitor motor is now the accepted motor for use on domestic refrigeration machines and many other domestic appliances. During the last year over 1,000,000 such motors were built in the United States.

It is felt that at this time a further contribution to the art can be made by presenting in one paper a systematic development consistent within itself, covering the method of calculating the electrical characteristic constants of single-phase induction motors.

It is hoped that such a complete and consistent presentation of the matter will be useful in view of the fact that most of the previous information on the subject has been based upon polyphase formulas adapted to single-phase construction.

While the constants as developed in this paper are intended primarily for use in conjunction with the theory of the capacitor motor and the resistance split-phase motor, the point of view of the development is such as to furnish calculational methods which apply equally well to other types of single phase motors as, for example, the repulsion-start induction-run single-phase motor.

## Plan of Development

The plan of the development follows closely that employed by Chapman for polyphase induction motors and Alger for synchronous motors except, that the single-phase point of view is maintained throughout and the results apply especially to single-phase motors.

The development has as its basis the assumption that only flux of fundamental space distribution links mutually the rotor and stator. Harmonic fluxes are assumed to be self-inductive to the members producing them and their effect is treated as that of self-inductive leakage reactance.

It is shown that spiraling either member reduces the effectiveness of the fundamental flux of one member as regards the other member while having no effect upon the producing member. It follows that where relative spiraling exists between the stator and the rotor the mutual reactance is reduced and since the self-inductive reactance is unchanged there must be effective in each member a component of leakage reactance due to self produced flux of fundamental space distribution. Expressions for exact determination of these effects are derived.

## Results of Development

There results from the development an exact definition of 6 primary reactances and 5 secondary reactances. Only 3 of each are useful in actual calculation, the others being used in the development and for the sake of clarity. The constants and their derived formulas are listed in the tabulation below and their significance indicated by the accompanying equivalent circuits.

For the primary, the reactances defined are:

### Primary Air-Gap Reactances

$X_{T_1}$ = total primary self-inductive reactance due to air-gap flux
$X_{m_1 f}$ = total primary self-inductive reactance due to fundamental flux (both forward and backward)
$X_{m_1}$ = total primary self-inductive reactance due to either fundamental field
$X_{1 \delta f}$ = total primary self-inductive reactance due to harmonic flux
$X_{\alpha 1 f}$ = total primary self-inductive reactance due to spiral
$X_m$ = primary mutual reactance of either forward or backward field

### Secondary Air-Gap Reactances

$X_{T_2}$ = total secondary self-inductive reactance to a revolving field
$X_{m_2}$ = secondary self-inductive reactance due to fundamental flux
$X_{2\delta}$ = secondary self-inductive leakage reactance due to air-gap flux
$X_\alpha$ = secondary self-inductive leakage reactance due to spiral
$X_m$ = secondary mutual reactance (with primary) to either field

## Nomenclature

All of the nomenclature is defined in the course of the development. For convenience those symbols needed in interpreting the results are listed below.

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted March 21, 1936; released for publication December 14, 1936.

WAYNE J. MORRILL is engineer in charge of design in the fractional horsepower motor engineering division of the General Electric Company, Fort Wayne, Ind.

$f$ = line frequency, cycles per second
$f_T$ = function of primary turns. See remarks preceding (18)
$K$ = $2\pi f 10^{-8}$
$l$ = axial length of air gap section in inches
$m_2$ = total number of rotor slots
$\mathcal{P}$ = $A/\delta$
$A$ = effective air-gap area per square inch
$\delta$ = radial length of air gap in inches
$P$ = number of fundamental poles
$T_pW_k$ = primary effective turns per pole. See (11) and (12)
$\lambda$ = fundamental peripheral pole pitch in inches
$\lambda_\alpha$ = peripheral distance in inches by which one end of spiraled member is displaced from its other end. See (40)

## Appendix—Development of Expressions for Reactance

### General Assumptions in the Development of Equations for Air-Gap Reactances

The usual assumptions which are made in the exact analysis of induction motors and which are listed in the appendix of my 1929 paper are made in this paper and will not be repeated.

In determining the air-gap reactances of induction motors, however, there are certain assumptions in addition to those already mentioned which must be made for the sake of establishing a simple and exact method of attack. These assumptions are listed below.

(*a*) *Only air gap flux of fundamental sinusoidal space distribution links mutually the rotor and stator winding.* This is true because unless the number of slots in the rotor and stator are made multiples of each other, or the stator winding is carelessly proportioned, experience and theory both show that harmonic fluxes of one winding generate negligible fundamental voltages in the other winding. It is true that the harmonic fluxes of one winding may generate voltages of other than fundamental frequency in the other winding under certain conditions, but the phenomena involved may be treated independently of the fundamental theory of the motor, and therefore, are not touched upon in the present report.

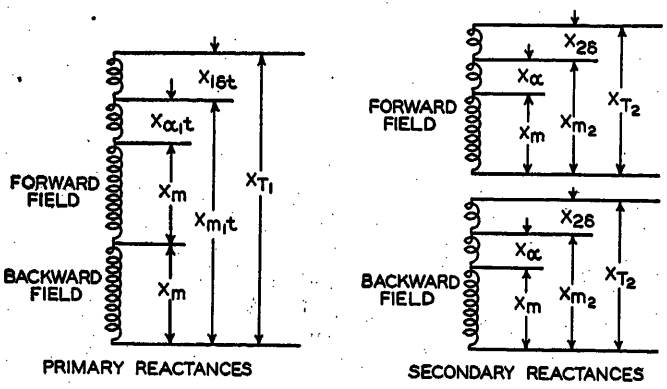

**Fig. 1. Summary of air-gap reactances**

$$X_{T_1} = K\mathcal{P}l\lambda f_T \quad (18)$$

$$X_{m_1 t} = \frac{8}{\pi^2} K\mathcal{P}l\lambda(T_pW_k)^2 \quad (13)$$

$$X_{m_1} = \frac{4}{\pi^2} K\mathcal{P}l\lambda(T_pW_k)^2 \quad (15)$$

$$X_{1\delta t} = X_{m_1}\left[\frac{\frac{\pi^2}{8} f_T}{(T_pW_k)^2} - 1\right] \quad (20)$$

$$X_{\alpha_1 t} = X_{m_1} 2\left[1 - \frac{2}{\pi}\frac{\lambda}{\lambda_\alpha}\sin\frac{\lambda_\alpha}{\lambda}\frac{\pi}{2}\right] \quad (48)$$

$$X_m = X_{m_1}\frac{2}{\pi}\frac{\lambda}{\lambda_\alpha}\sin\frac{\lambda_\alpha}{\lambda}\frac{\pi}{2} \quad (51)$$

$$X_{T_2} = X_{m_2} + X_{2\delta}$$

$$X_{m_2} = X_{m_1} \quad (39)$$

$$X_{2\delta} = X_m\left[\left(\frac{\frac{P}{m_2}\pi}{2\sin\frac{P\pi}{2m_2}}\right)^2 - 1\right] \quad (38)$$

$$X_\alpha = X_{m_1}\left[1 - \frac{2}{\pi}\frac{\lambda}{\lambda_\alpha}\sin\frac{\lambda_\alpha}{\lambda}\frac{\pi}{2}\right] \quad (47)$$

(*b*) *Only that portion of the stator fundamental flux which produces voltage in the rotor winding, and only that portion of the rotor fundamental flux which produces voltage in the stator winding, are considered as mutual fluxes.* The test for mutual flux is that it must generate the same voltage per turn in one member as in the other member, and if this condition is not fulfilled the effect of reduction in voltage in the second member is that of leakage flux and must be so treated.

(*c*) *Those fluxes which are produced by one member and which do not produce fundamental voltage in the other member are treated as leakage fluxes.* From this point of view the difference, between the total flux of any winding and that portion of the flux which generates fundamental voltage in the opposite winding is defined as leakage flux.

### I—Air-Gap Leakage Reactance of a Concentric Stator Winding

The primary windings of single-phase induction motors are invariably of the concentric type (coaxial coils of varying pitch) as shown in figure 2.

The total air-gap reactance of one pole of a concentric type winding can be obtained by taking the summation of the reactances corresponding to each stator tooth and the turns surrounding it. The general equation for the tooth reactance is

$$X_{tn} = K\mathcal{P}l\lambda_{tn}(\Sigma_n T)^2 \quad (1)$$

where

$l$ = axial length of air gap
$X_{tn}$ = reactance due to "$n$th" tooth flux
$K$ = constant to convert to ohms
$\lambda_{tn}$ = peripheral pitch of "$n$th" tooth section
$\Sigma_n T$ = sum of turns surrounding "$n$th" tooth section
$\mathcal{P}$ = permeance per square inch of air gap (see nomenclature)

By reference to figure 2 it is possible to write the expression for

the reactance corresponding to the innermost teeth whose total peripheral pitch is $\lambda_a$.

$$X_{ta} = K\mathcal{P}l\lambda_a(T_a + T_b + T_c + T_d + T_e)^2 \tag{2}$$

On each side of the $\lambda_a$ section there are 2 sections of total peripheral pitch $\lambda_b - \lambda_a$. The reactance due to these sections is:

$$X_{tb} = K\mathcal{P}l(\lambda_b - \lambda_a)(T_b + T_c + T_d + T_e)^2 \tag{3}$$

By the same method of reasoning the remaining reactances may be determined and the total reactance becomes:

$$X_{T_1} = K\mathcal{P}l\lambda \begin{bmatrix} \frac{\lambda_a}{\lambda}(T_a + T_b + T_c + T_d + T_e)^2 \\ \frac{\lambda_b - \lambda_a}{\lambda}(T_b + T_c + T_d + T_e)^2 \\ \frac{\lambda_c - \lambda_b}{\lambda}(T_c + T_d + T_e)^2 \\ \frac{\lambda_d - \lambda_e}{\lambda}(T_d + T_e)^2 \\ \frac{\lambda - \lambda_d}{\lambda}(T_e)^2 \end{bmatrix} \tag{4}$$

If only the air-gap magnetomotive-force distribution of the $n$th primary coil is considered, a diagram as shown in figure 3 is obtained.

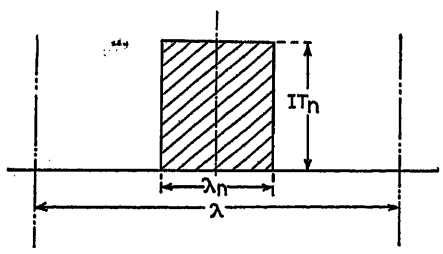

**Fig. 3. Air-gap magnetomotive force of nth primary coil**

By Fourier analysis it is possible to express the amplitude of the corresponding fundamental component of magnetomotive-force, $a_n$:

$$a_n = \frac{4}{\pi} IT_n \sin \frac{\pi}{2}\frac{\lambda_n}{\lambda} \tag{5}$$

By the use of (5) the amplitude of the fundamental component of magnetomotive-force due to all the coils on a pole may be written:

$$a = \Sigma a_n \tag{6}$$

$$a = \frac{4}{\pi} I \begin{bmatrix} T_a \sin \frac{\pi}{2}\frac{\lambda_a}{\lambda} \\ T_b \sin \frac{\pi}{2}\frac{\lambda_b}{\lambda} \\ T_c \sin \frac{\pi}{2}\frac{\lambda_c}{\lambda} \\ T_d \sin \frac{\pi}{2}\frac{\lambda_d}{\lambda} \\ T_e \sin \frac{\pi}{2}\frac{\lambda_e}{\lambda} \end{bmatrix}$$

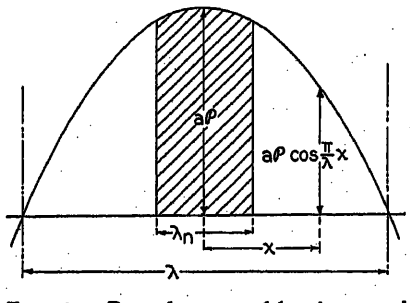

**Fig. 4. Distribution of fundamental flux**

The flux density at any point on the air gap periphery corresponding to a magnetomotive-force wave having a maximum amplitude of $a$ may be expressed:

$$B = a\mathcal{P}\cos\frac{\pi}{\lambda}x \tag{7}$$

where

$B$ = flux density at point $x$
$\mathcal{P}$ = permeance per square inch of air gap

The portion of fundamental flux which links the $n$th stator coil can be obtained by multiplying equation (7) by the axial length in inches $l$ and integrating between the limits of $-\frac{\lambda_n}{2}$ and $+\frac{\lambda_n}{2}$ as indicated in (8). This is the equivalent of finding the flux cross hatched in figure 4.

$$\Phi_{1n} = \int_{-\lambda_n/2}^{+\lambda_n/2} a\mathcal{P}l\cos\frac{\pi}{\lambda}x\,dx \tag{8}$$

$$\Phi_{1n} = a\mathcal{P}l\frac{\lambda}{\pi}\left[\sin\frac{\pi}{\lambda}x\right]_{-\lambda_n/2}^{+\lambda_n/2}$$

$$\Phi_{1n} = 2a\mathcal{P}l\frac{\lambda}{\pi}\sin\frac{\pi}{2}\frac{\lambda_n}{\lambda} \tag{9}$$

The reactance of the $n$th stator coil due to the fundamental flux which links it may be expressed by multiplying (9) by the number of turns in the coil, $T_n$, and by $K/I$ to convert to ohms.

$$X_{1n} = 2a\mathcal{P}l\frac{\lambda}{\pi}\frac{K}{I}T_n\sin\frac{\pi}{2}\frac{\lambda_n}{\lambda} \tag{10}$$

The total reactance of the stator winding due to the self-produced fundamental flux is obtained as the sum of $X_{1n}$ for all coils:

$$X_{m_1l} = 2a\mathcal{P}l\frac{\lambda}{\pi}\frac{K}{I}\begin{bmatrix} T_a \sin \frac{\pi}{2}\frac{\lambda_a}{\lambda} \\ T_b \sin \frac{\pi}{2}\frac{\lambda_b}{\lambda} \\ T_c \sin \frac{\pi}{2}\frac{\lambda_c}{\lambda} \\ T_d \sin \frac{\pi}{2}\frac{\lambda_d}{\lambda} \\ T_e \sin \frac{\pi}{2}\frac{\lambda_e}{\lambda} \end{bmatrix} \tag{11}$$

The bracketed member of (6) and (11) is termed the "effective turns" per pole of the primary winding and is symbolized by:

$$\text{Effective turns per pole} = T_P W_K \tag{12}$$

where

$T_P$ = total turns per pole
$W_K$ = winding constant to convert to "effective turns"

If (6) and (12) are substituted in (11) the following is obtained:

$$X_{m_1l} = \frac{8}{\pi^2}\mathcal{P}l\lambda K(T_P W_k)^2 \tag{13}$$

Equation (13) expresses the total reactance of the primary winding due to pulsating self produced flux of fundamental sinusoidal distribution.

It has long been known that a pulsating wave of sinusoidally distributed flux may be represented by 2 equal oppositely gliding waves of flux each having a constant amplitude equal to half the amplitude of the pulsating wave. In my 1929 paper I defined the magnetizing reactance of a single-phase motor as that value of reactance corresponding to either of the gliding fields of flux. In equation (19) of that paper its value was given as:

$$X_{m_1} = 2\pi f C_m^2 \frac{1}{16}\mathcal{P}l\lambda 10^{-8} \tag{14}$$

In the present case, since the reactance due to each gliding (or revolving) wave of flux has the same value, the primary reactance

due to either must be equal to half the total primary magnetizing reactance:

$$X_{m_1} = \frac{1}{2} X_{m_1 t} \tag{15}$$

$$X_{m_1} = \frac{4}{\pi^2} \mathcal{P} l \lambda K (T_p W_k)^2$$

If the following substitutions are made in (14) and (15) the 2 equations will be found to be identical.

$$C_m = \frac{8}{\pi} T_p W_k \tag{16}$$

$$K = 2\pi f 10^{-8} \tag{17}$$

It will be found convenient in the present paper to express as many air-gap reactances as possible in terms of per unit of $X_{m_1}$.

If the bracketed member of (4) be called $f_T$ (function of turns), the equation for $x_{T_1}$ is:

$$X_{T_1} = K \mathcal{P} l \lambda f_T \tag{18}$$

Equation (18) expresses the total reactance of the primary winding due both to the flux of fundamental sinusoidal distribution and the leakage flux which is of other than fundamental distribution. The reactance due to air-gap leakage flux may, therefore, be expressed as the difference between the total reactance and the total reactance due to the fundamental flux:

$$X_{1\delta t} = X_{T_1} - X_{m_1 t} \tag{19}$$

Expressed in terms of $X_{m_1}$ the total per-unit leakage reactance due to air gap flux is:

$$\text{Per unit } X_{1\delta t} = \frac{X_{T_1} - X_{m_1 t}}{X_{m_1}} \tag{20}$$

$$\text{Per unit } X_{1\delta t} = 2 \left[ \frac{\frac{\pi^2}{8} f_T}{(T_p W_k)^2} - 1 \right] \tag{21}$$

Equation (21) is a dimensionless formula and because of its dimensionless character gives a clear picture of the relationships involved. In order to obtain the actual total primary air-gap leakage reactance it is necessary to multiply (21) by $X_{m_1}$

## The Air-Gap Leakage Reactance of a Rotor With Uniformly Spaced Slots Wound One Phase per Slot

In the case of a motor of the repulsion-start induction-run type, the rotor winding employed during running operation is a winding having as many phases as there are slots in the rotor. If the rotor has an even number of slots or a number of slots corresponding to a multiple of the number of poles, certain of these phases may be repetitions of each other, but the analysis to be presented will be found to include such special cases.

If a rotor of the type described be acted upon by a revolving field of stator flux, the voltages generated in succeeding coils (phases) and the currents which result will have a peripheral distribution in the rotor slots as shown in figure 5. The upper diagram indicates the slot distribution of the ampere conductors of the left hand sides of the coils and the lower diagram indicates the ampere-conductor distribution of the right-hand coil sides. The sum of these 2 diagrams furnishes the total ampere-conductors distributed in each slot.

Proceeding from the distribution shown in figure 5, it is possible to develop 2 magnetomotive-force distribution diagrams as shown in figure 6. The sum of these 2 diagrams furnishes the resultant magnetomotive-force distribution produced by the rotor winding.

It is possible to express analytically the ampere-conductor distribution in the rotor slots due to the left coil sides shown in the upper diagram, figure 5.

$$I_{nL} C_c = I_{2n \max} C_c \cos \frac{P\lambda}{m_2} n \frac{\pi}{\lambda} \tag{22}$$

where

$C_c$ = conductors per coil side
$I_{nL}$ = amperes per conductor in left side of $n$th coil
$I_{2n \max}$ = maximum amperes per conductor in rotor coils
$n$ = integer indicating the number of the rotor phase under consideration, starting with a rotor phase carrying maximum current as the zero phase and counting in a forward direction
$P$ = number of fundamental poles
$\lambda$ = pole pitch in inches
$m_2$ = number of rotor phases (total)

The equation for the ampere-conductor distribution in the $n$th slot due to the right-hand coil side is very similar to that of the left-hand coil side except displaced by a difference corresponding to the coil pitch and reversed in sign. This distribution is given by equation 23.

$$I_{nR} C_c = - I_{2n \max} C_c \cos \frac{P\lambda}{m_2} (n - t_c) \frac{\pi}{\lambda}$$

$t_c$ = number of rotor teeth included by one rotor coil (23)

The sum of equation (22) and (23) gives the total ampere-conductor distribution in the $n$th rotor slot.

$$I_n C_c = (I_{nL} + I_{nR}) C_c =$$

$$I_{2n \max} C_c \left[ \cos \frac{P\lambda}{m_2} n \frac{\pi}{\lambda} - \cos \frac{P\lambda}{m_2} (n - t_c) \frac{\pi}{\lambda} \right] \tag{24}$$

The sum of the ampere-conductors in each of the slots from the "zero" slot to the $n$th slot is the number of ampere-conductors tending to produce flux across the air gap from the face of the $n$th tooth.

$$MMF_n = \sum_0^n I_{2n \max} C_c \left[ \cos \frac{P\pi}{m_2} n - \cos \frac{P\pi}{m_2} (n - t_c) \right] \tag{25}$$

$$MMF_n = I_{2n \max} C_c \left[ \frac{\cos \frac{P\pi}{2m_2} (2n + 1 - t_c) \sin \frac{P\pi}{2m_2} t_c}{\sin \frac{P\pi}{2m_2}} \right] \tag{26}$$

The flux in the $n$th tooth which will be produced by $MMF_n$ may

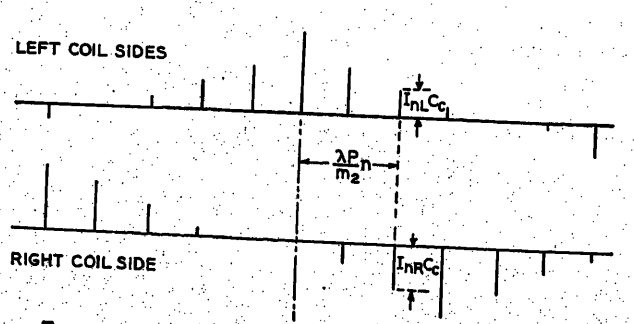

Fig. 5. Rotor slot ampere-conductor distribution

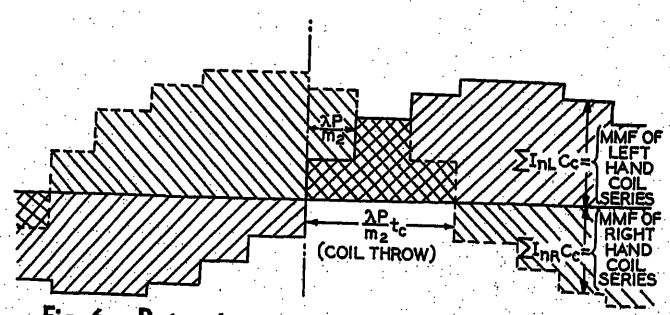

Fig. 6. Rotor-air-gap magnetomotive force distribution

be obtained by multiplying $MMF_n$ by the permeance per tooth. It can be expressed as in (27).

$$\Phi_n = MMF_n \frac{\lambda Pl}{m_2} \mathcal{P} =$$

$$I_{2n\,\max} C_c \frac{\lambda Pl}{n} \mathcal{P} \left[ \frac{\cos \frac{P\pi}{2m_2} (2n + 1 - t_c) \sin \frac{P\pi}{2m_2} t_c}{\sin \frac{P\pi}{2m_2}} \right] \quad (27)$$

The total flux per pole is the sum of the fluxes in each tooth across one pole face:

$$\Phi_{T_2} = \sum_{0}^{\frac{m_2}{P}-1} \Phi_n = I_{2n\,\max} C_c \frac{\lambda Pl}{m_2} \mathcal{P} \left[ \frac{\sin \frac{P\pi}{2m_2} t_c}{\sin \frac{P\pi}{2m_2}} \right] \quad (28)$$

$l$ = axial length of air gap
$\mathcal{P}$ = permeance per square inch of air gap

The amplitude of the fundamental component of the rotor flux can be obtained by Fourier analysis. In figure 7 is shown the flux of one rotor tooth. The amplitude of the fundamental sine component of this flux will be derived. (Due to the choice of axis the cosine component drops out in taking a summation of the sine and cosine components across one pole and the cosine component is, therefore, being omitted.)

The amplitude of the fundamental sine component of the flux shown in figure 7 is given by the expression of equation (29) which can be converted to (30) and (31).

$$a_{\Phi n} \int_0^{\lambda} \sin^2 \frac{\pi}{\lambda} x dx = \int_{\frac{\lambda\rho}{m_2} n}^{\frac{\lambda\rho}{m_2}(n+1)} MMF_n \mathcal{P} \sin \frac{\pi}{\lambda} x dx \quad (29)$$

$$a_{\Phi n} = -\frac{2}{\pi} MMF_n \mathcal{P} \left[ \cos \frac{\pi P}{m_2} (n + 1) - \cos \frac{\pi P}{m_2} n \right] \quad (30)$$

$$a_{\Phi n} = \frac{4\mathcal{P}}{\pi} I_{2n\,\max} C_c \left[ \frac{1}{2} \sin \frac{\pi P}{2m_2} (4n + 2 - t_c) + \frac{1}{2} \sin \frac{\pi P}{2m_2} t_c \right] \sin \frac{\pi P}{2m_2} t_c \quad (31)$$

The value of $a_{\Phi n}$ is the maximum density of the sine component of the flux of the $n$th rotor tooth. To obtain the amplitude of the total sine component the summation of $a_{\Phi n}$ across one pole pitch is taken:

$$a_\Phi = \sum_{0}^{\frac{m_2}{P}-1} a_{\Phi n} \quad (32)$$

$$a_\Phi = \frac{4\mathcal{P}}{\pi} I_{2n\,\max} C_c \frac{m_2}{P} \left[ \frac{1}{2} \sin^2 \frac{\pi P}{2m_2} t_c \right] \quad (33)$$

The quantity $a_\Phi$ is the maximum amplitude of the fundamental flux component produced by the rotor winding. In order to express the value of the flux it is necessary to integrate the wave corresponding to $a_\Phi$ over one pole pitch and for an axial length, $l$.

$$\Phi_{m_2} = \int_0^{\lambda} la \sin \frac{\pi}{\lambda} x dx = \frac{2}{\pi} \lambda a \quad (34)$$

$$\Phi_{m_2} = \frac{4}{\pi^2} l\lambda \mathcal{P} I_{2n\,\max} C_c \frac{m_2}{P} \sin^2 \frac{\pi P}{2m_2} t_c \quad (35)$$

Since all the currents which produce both $\Phi_{m_2}$ and $\Phi_{T_2}$ vary sinusoidally with respect to time, $\Phi_{m_2}$ and $\Phi_{T_2}$ vary sinusoidally with respect to time and their difference, $\Phi_{T_2} - \Phi_{m_2}$, varies in the same fashion. All of these fluxes completely link each rotor bar, and since all of them are of the same frequency with respect to the rotor they generate voltages of the same frequency which referred to the stator winding is the fundamental frequency of the motor.

Since, with a given value of current, the magnitude of reactance is proportional to generated voltage, the total rotor-air-gap reactance (referred to primary) $X_{T_2}$ and the fundamental rotor air gap reactance $X_{m_2}$ must be proportional respectively to the total rotor air gap flux $\Phi_{T_2}$ and the fundamental air gap flux $\Phi_{m_2}$.

$$\frac{X_{T_2}}{X_{m_2}} = \frac{\Phi_{T_2}}{\Phi_{m_2}} \quad (36)$$

In the same way that the per-unit air-gap leakage reactance of the primary was defined we may write

$$\text{Per unit } X_{2\delta} = \frac{X_{T_2} - X_{m_2}}{X_{m_2}} = \frac{\Phi_{T_2} - \Phi_{m_2}}{\Phi_{m_2}} \quad (37)$$

If the values for $\Phi_{T_2}$ and $\Phi_{m_2}$ be substituted from (28) and (35) respectively equation (38) is obtained.

$$\text{Per unit } X_{2\delta} = \frac{I_{2n\,\max} C_c \frac{\lambda Pl}{m_2} \mathcal{P} \left[ \frac{\sin \frac{P\pi}{2m_2} t_c}{\sin \frac{P\pi}{2m_2}} \right]^2}{I_{2n\,\max} C_c \lambda l \mathcal{P} \frac{m_2}{P} \sin^2 \frac{\pi P}{2m_2} t_c} \quad (38)$$

Equation (38) simplifies to:

$$\text{Per unit } X_{2\delta} = \left( \frac{P}{m_2} \right)^2 \frac{\pi}{4 \sin^2 \frac{P\pi}{2m_2}} - 1 \quad (39)$$

Equation (39) expresses the rotor-air-gap leakage reactance in per unit of $X_{m_2}$ but a valuable simplification can be made if it be recognized that:

$$X_{m_2} = X_{m_1} \quad (40)$$

This is true because the dimensions of the magnetic circuits of $X_{m_2}$ and $X_{m_1}$ are the same and $X_{m_2}$ is "referred to the primary," which means that the effective turns are the same.

## The Air-Gap Reactance Due to Spiral

Thus far in the discussion of the air-gap reactances of single-phase induction motors only fluxes of other than fundamental distribution have acted in the rôle of leakage fluxes. We come now to a reactance caused by flux of fundamental distribution.

If one of the members (stator or rotor) of an induction motor is spiraled, no change is produced in either the fundamental air-gap flux reactance or the total air-gap reactance as far as the spiraled member is concerned. There is, however, a change in the effectiveness of the spiraled flux in inducing voltage in the other member and since the proof of mutual flux is that it induce equal volts per turn at the same frequency in both members, it must be concluded that the reduced effectiveness of the primary flux is a leakage-reactance phenomenon.

The equation for the 3-dimension wave of flux when the producing member is spiraled is given by (41).

$$B = MMF_{\max} \mathcal{P} \cos \left[ \frac{\pi}{\lambda} \left( x - \frac{\lambda_\alpha}{l} z \right) - \omega t \right] \quad (41)$$

$\lambda_\alpha$ = peripheral amount by which one end of the spiraled member is displaced from the other end
$z$ = axial distance measured from one end of spiraled member toward the other end
$l$ = axial length of air gap

The voltage per conductor generated in the unspiraled member is equal to the integral of the rate of change of the flux as $z$ varies from zero to $l$.

$$E_{c\alpha} = \int_0^l K_c MMF_{\max} \mathcal{P} \frac{d}{dt} \cos \left[ \frac{\pi}{\lambda} \left( x - \frac{\lambda_\alpha}{l} z \right) - \omega t \right] dz \quad (42)$$

$$E_{c\alpha} = K_e MMF_{max}\, \rho\, \omega\, \frac{\lambda}{\pi}\, \frac{l}{\lambda_\alpha} \left\{ \begin{matrix} \cos\left[\frac{\pi}{\lambda}(x - \lambda_\alpha) - \omega t\right] \\ - \cos\left[\frac{\pi}{\lambda} x - \omega t\right] \end{matrix} \right\} \quad (43)$$

$$E_{c\alpha} = 2K_e MMF_{max}\, \rho\, \omega\, \frac{\lambda}{\pi}\, \frac{l}{\lambda_\alpha} \times \sin\left[\frac{\pi}{\lambda}\left(x - \frac{\lambda_\alpha}{2}\right) - \omega t\right] \sin \frac{\lambda_\alpha}{\lambda}\, \frac{\pi}{2} \quad (44)$$

Equation (44) indicates the voltage per conductor generated in the unspiraled member by the spiraled flux. The voltage which would be generated in the same conductor by the same fundamental flux if there were no spiral can be obtained from (44) by allowing $\lambda_\alpha$ to approach zero as a limit. This voltage is given by equation (45).

$$E_c = K_e MMF_{max}\, \rho \omega l \sin\left(\frac{\pi}{\lambda} x - \omega t\right) \quad (45)$$

The ratio of the mutual fundamental flux to the self-inductive fundamental flux must be equal to (44) divided by (45)

$$\frac{\Phi_m}{\Phi_{m_1}} = \frac{2}{\pi}\, \frac{\lambda}{\lambda_\alpha} \sin \frac{\lambda_\alpha}{\lambda}\, \frac{\pi}{2} \quad (46)$$

The ratio of the leakage flux of fundamental distribution to the fundamental flux must, therefore, be:

$$\frac{\Phi_{m_1} - \Phi_m}{\Phi_{m_1}} = \left[1 - \frac{\Phi_m}{\Phi_{m_1}}\right] = 1 - \frac{2}{\pi}\, \frac{\lambda}{\lambda_\alpha} \sin \frac{\lambda_\alpha}{\lambda}\, \frac{\pi}{2} \quad (47)$$

The ratio expressed in (47) is also the ratio of the leakage reactance to the primary fundamental air-gap reactance.

$$\text{Per unit } X_\alpha = \left[1 - \frac{2}{\pi}\, \frac{\lambda}{\lambda_\alpha} \sin \frac{\pi}{2}\, \frac{\lambda_\alpha}{\lambda}\right] \quad (48)$$

In order to obtain either the primary or secondary forward or backward field leakage reactance due to spiral it is necessary to multiply (48) by $X_{m_1}$. Since each stator phase produces a forward field of flux just equal to its backward field the total primary reactance due to spiral is equal to twice the spiral reactance of either field:

$$X_{\alpha t} = 2X_\alpha = 2X_{m_1}\left[1 - \frac{2}{\pi}\, \frac{\lambda}{\lambda_\alpha} \sin \frac{\pi}{2}\, \frac{\lambda_\alpha}{\lambda}\right] \quad (49)^*$$

The rotor forward-field flux is not equal to its backward-field flux and the value $X_{\alpha_2}$ must be introduced separately into the equivalent circuit for each field.

It is obvious from the development that it makes no difference which member is spiraled in so far as the resultant effect upon the mutual flux and the leakage-reactance fluxes are concerned.

## Mutual Magnetizing Reactance Due to Fundamental Flux

In connection with the reactance due to spiral, it should be further noticed that the reduction in fundamental flux effectiveness mentioned at the start of the spiral reactance discussion amounts to a reduction in $X_m$, the mutual flux reactance. The reduction is precisely the same as the leakage reactance due to spiral for that is the way the spiral reactance was defined. If there is no spiral:

$$X_m = X_{m_1} \text{ when there is no spiral} \quad (50)$$

When relative spiral exists the mutual reactance, $X_m$ is reduced.

$$X_m = X_{m_1}[1 - \text{Per unit } X_\alpha] \quad (51)$$

$$X_m = X_{m_1}\, \frac{2}{\pi}\, \frac{\lambda}{\lambda_\alpha} \sin\left(\frac{\lambda_\alpha}{\lambda}\, \frac{\pi}{2}\right) \quad (52)$$

It will be noticed that when the spiral is equal to twice the pole pitch the fundamental mutual magnetizing reactance becomes zero and all the fundamental air gap flux produced by the primary winding acts as leakage flux.

* It is important to notice that only when the primary phases are in quadrature, as is usual with capacitor motors and split-phase motors, can $X_{\alpha_1}$ be treated as a self-inductive reactance. Under other conditions $X_{\alpha_1}$ becomes mutual with other primary phases.

# Rectifier Circuit for Measurement of Small Power-Angle Oscillations

By T. A. ROGERS
ASSOCIATE AIEE

B. L. ROBERTSON
MEMBER AIEE

KNOWLEDGE of transient oscillations of synchronous machines is of considerable importance because of the application of such information to studies on system load changes which may lead to loss of synchronism, to voltage fluctuations, or to hunting. Although in many instances very large angular swings must be taken into account, for many investigations only relatively small angular swings are considered. In this latter class are problems of determining the effects of saturation on load angle, angular variations with attendant current pulsations for variable torque loads, and the prediction of stability under large load changes as determined from studies of loads causing small displacements.

Rotor swinging has been observed under stroboscopic illumination, and displacement angles have been recorded by a motion picture camera taking 30 frames per second used in conjunction with the stroboscope.[1] A mark on a moving field pole may be followed exactly in its oscillations, a plot of displacements shown on the films yielding the time-angle relation of the rotor. Rotor oscillations also have been determined by means of a pilot alternator direct connected to the shaft of the main machine.[2] In this case, 2 phases (single-phase line-to-line voltages), one from each machine, are tied together at one end, and the rotor and voltage of the pilot alternator so adjusted that the voltage difference between the other 2 phase terminals is zero at the reference angle, which may be for zero or any specified load. The voltage difference appearing under load is a direct measure of the corresponding displacement angle, and the voltage carried to an oscillograph results in a wave of line frequency with a varying amplitude if the rotor is swinging.

The first method, although by far the best, because it gives the displacement angle directly under all conditions of operation, involves apparatus not generally available. The second method has the disadvantages of requiring an auxiliary alternator and a replot of the test data. Oscillations about a reference axis introduce a change of phase which may be difficult to determine under some conditions. In addition, the difference voltage is not proportional to angle outside a region of 60 electrical degrees. This last disadvantage, however, is eliminated when studies are confined to small angular displacements, as many investigations are.

## The Circuit

It is probable that the second method is more readily adaptable to studies undertaken in most laboratories because of availability of equipment, in which case it then is of convenience to have the oscillograph plot the actual displacement curve directly rather than the wave of system frequency with varying amplitude. The full wave rectifier tube is well suited to this problem because of the practically linear relationship between the plate current and the applied voltage. The addition of a filter circuit to reduce the unidirectional pulsations at line frequency to an average value greatly simplifies the resulting oscillogram.

With a single rectifier and filter circuit driven by the voltage difference between the pilot alternator and the machine under investigation, there results a single trace on the oscillogram the amplitude of which is directly proportional to the difference voltage. The magnitude of

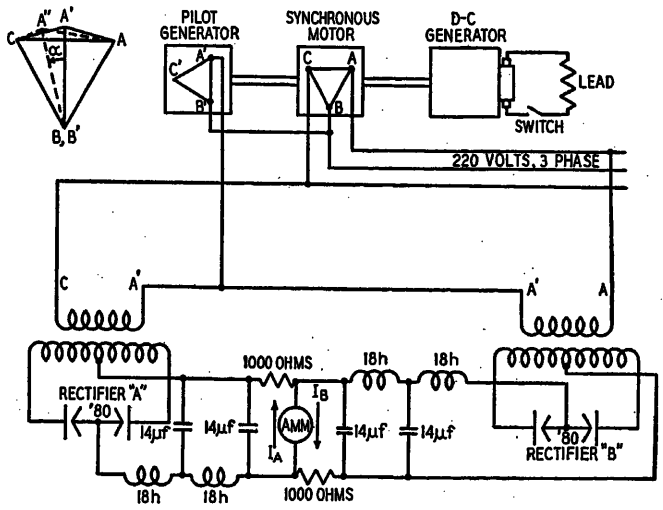

**Fig. 1. Rectifier circuit for determination of angular oscillations of a synchronous machine**

the difference voltage is proportional to sin $(\alpha/2)$ where $\alpha$ is the displacement angle between the machine terminal voltage and the pilot alternator voltage. As the sine of the angle is almost proportional to the angle itself for the range between 0 and 30 degrees, this circuit will give practically linear deflections up to torque-angles of 60 electrical degrees. All of the deflections, however, are above the zero axis, those for negative as well as for positive angles because of the characteristics of the rectifier. This difficulty may be overcome if 2 such circuits are used in opposition and are driven by 2 such difference voltages equal in magnitude at the reference angle. At the zero position the currents will balance out, the current through

*C*—Machine angle, load applied (20.5 electrical degrees maximum angle)
*D*—Machine angle, load dropped (8.5 electrical degrees initial angle)

the oscillograph element being zero for this rotor position. The circuit is shown in figure 1.

## Circuit Action

The line voltages of the motor under observation are represented by the sides of the triangle $ABC$. The single-phase voltage, $B'A'$, of the pilot alternator represents the rotor position of the motor. This voltage is made equal in magnitude to the line voltage of the motor, and is adjusted in phase so that it lies midway between the line voltages $BA$ and $BC$. The difference voltages, $CA'$ and $AA'$, are equal and produce equal rectifier currents, $I_A$ and $I_B$, which are in opposition, thus resulting in zero current through the instrument.

If a load is applied to the motor shaft there will be an angular displacement between the stator magnetomotive force and rotor poles which will be indicated by a shift in position of the pilot alternator voltage through the angle $\alpha$, i.e., from $B'A'$ to $B'A''$. The new rectifier voltages will be $CA''$ and $AA''$, resulting in an increased voltage on rectifier $B$ and a decreased voltage on rectifier $A$. $I_B$ will increase, $I_A$ will decrease, and the instrument or oscillograph will indicate a current equal to the new difference. In this discussion it is assumed that the machine under investigation is connected to an infinite bus. Practically, a drop of 5 per cent in line voltage will introduce about a 2 per cent error in the difference voltage.

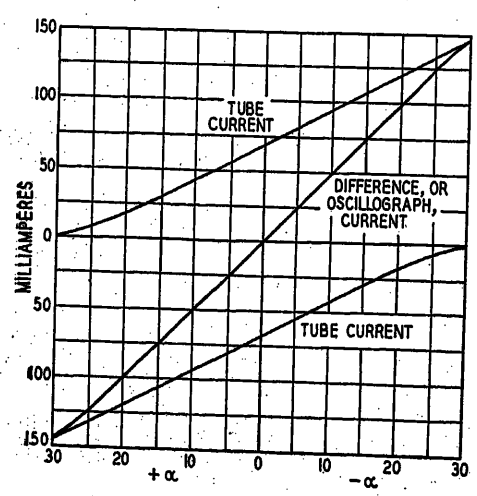

**Fig. 2. Characteristic curves for rectifier circuit showing tube currents and difference current as functions of angle $\alpha$**

The characteristic curves of each rectifier, and the resulting characteristic, are given in figure 2. It will be observed that if the displacement angle is greater than 30 electrical degrees both rectifier voltages will increase with angle, and the oscillograph current will remain constant, being the difference of 2 increasing currents. This circuit eliminates any question on change of phase. The filter circuit, with the constants as given in figure 1, may be relied upon with an error not over one per cent for oscillations of the rotor up to 4.5 cycles per second. This is a frequency of rotor swing much higher than normally would be found for either large or small machines.

The oscillograms of figure 3 illustrate the application of the device just described, and show the angular oscillations of a synchronous motor as load is thrown on and off. The pilot alternator had an adjustable stator, thus allowing ready phase adjustment between the 2 machines, although a phase shifting transformer or a wound rotor induction motor with rotor blocked may be employed. Angle calibration may be obtained with a stroboscope, from a vector diagram for the difference voltages, from a calibrated phase shifting device, or perhaps by calculation from the power-angle relation for the motor.

# Current and Voltage Loci in 3-Phase Circuits Part III: Δ-Y Connection

By A. C. SELETZKY MEMBER AIEE K. F. SIBILA ENROLLED STUDENT AIEE

## Introduction

IT HAS been shown that the method of circular loci may be conveniently applied to obtain the variation of currents and voltages when self-impedances are changed in various types of circuits operated at constant frequency. Part I[1] dealt with this problem in a Y-Y connection and part II[2] in a Δ-Δ connection. In both of these papers current equations were given involving all the impedances and voltages of the most general types of Y-Y and Δ-Δ circuits and required only the substitution of numerical values to obtain the locus of any current or voltage existing in the system. The same treatment will now be applied to the Δ-Y connection.

## The Δ-Y Circuit

In figure 1 is shown the general Δ-Y circuit. Internal voltages of like frequency are assumed to exist in both source and load phases and to have any magnitude and phase angle. Self impedances are considered in the interconnecting lines as well as in the source and in the load. For the sake of generality mutual impedances are assumed in the source and load and also between the lines. There are no restrictions on the values of any of the self- and mutual-impedance elements other than they be linear and bilateral.

Equations will be set up for the 6 phase currents which in this case also include the 3 line currents. The voltages in the system will be obtained by adding internal voltages to appropriate impedance drops.

Adding the potential differences about meshes $a102ba$, $b203cb$, and $c301ac$, and summing up the currents about junctions, $o$, $a$, and $b$, the requisite equations are:

$$I_1A_1 + I_2A_2 + I_3A_3 + I_aZ_{aa} + I_bZ_{ab} + I_cZ_{ac} = K_1 \quad (1)$$
$$I_1B_1 + I_2B_2 + I_3B_3 + I_aZ_{ba} + I_bZ_{bb} + I_cZ_{bc} = K_2 \quad (2)$$
$$I_1C_1 + I_2C_2 + I_3C_3 + I_aZ_{ca} + I_bZ_{cb} + I_cZ_{cc} = K_3 \quad (3)$$
$$I_1 + I_2 + I_3 = 0 \quad (4)$$
$$I_1 + I_a - I_c = 0 \quad (5)$$
$$I_2 - I_a + I_b = 0 \quad (6)$$

in which

$$\left.\begin{aligned} A_1 &= Z_{r3} - Z_{rr} + Z_{12} - Z_{11} \\ B_2 &= Z_{s1} - Z_{ss} + Z_{23} - Z_{22} \\ C_3 &= Z_{tr} - Z_{tt} + Z_{31} - Z_{33} \\ A_2 &= Z_{s3} - Z_{sr} + Z_{22} - Z_{21} \\ B_3 &= Z_{t1} - Z_{ts} + Z_{33} - Z_{32} \\ C_1 &= Z_{rr} - Z_{rt} + Z_{11} - Z_{13} \\ A_3 &= Z_{t3} - Z_{tr} + Z_{32} - Z_{31} \\ B_1 &= Z_{r1} - Z_{rs} + Z_{13} - Z_{12} \\ C_2 &= Z_{sr} - Z_{st} + Z_{21} - Z_{23} \\ K_1 &= E_{01} - E_{02} + E_{ab} \\ K_2 &= E_{02} - E_{03} + E_{bc} \\ K_3 &= E_{03} - E_{01} + E_{ac} \end{aligned}\right\} \quad (7)$$

By Cramers' rule the currents may be expressed as

$$\left.\begin{aligned} I_a &= \frac{\Delta I_a}{\Delta} & I_1 &= \frac{\Delta I_1}{\Delta} \\ I_b &= \frac{\Delta I_b}{\Delta} & I_2 &= \frac{\Delta I_2}{\Delta} \\ I_c &= \frac{\Delta I_c}{\Delta} & I_3 &= \frac{\Delta I_3}{\Delta} \end{aligned}\right\} \quad (8)$$

Here Δ is the general determinant or the common denominator and $\Delta I_a$, $\Delta I_b$, etc., are the specific determinants obtained from the general determinant by replacing the coefficients of the current desired by the column of $K$'s.

The expansions of the common denominator and the numerators follow below. It should be noted that although the mutual elements are bilateral, i.e., $Z_{23} = Z_{32}$, both sequences of subscripts are used in order to display the cyclicity of terms.

$$\begin{aligned} \Delta = {} & (Z_{aa} + Z_{ab} + Z_{ac})\{-(B_3C_3 - B_3C_2) + (B_1C_3 - B_3C_1) - (B_1C_2 - B_2C_1)\} + \\ & (Z_{bb} + Z_{bc} + Z_{ba})\{(A_2C_3 - A_3C_2) - (A_1C_3 - A_3C_1) + (A_1C_2 - A_2C_1)\} + \\ & (Z_{cc} + Z_{ca} + Z_{cb})\{-(A_2B_3 - A_3B_2) + (A_1B_3 - A_3B_1) - (A_1B_2 - A_2B_1)\} + \\ & (Z_{aa}Z_{bb} - Z_{ab}^2)(C_3 - C_1) + \\ & (Z_{bb}Z_{cc} - Z_{bc}^2)(A_1 - A_2 - Z_{aa}) + \\ & (Z_{cc}Z_{aa} - Z_{ca}^2)(B_2 - B_3) + \\ & (Z_{ab}Z_{bc} - Z_{bb}Z_{ca})(A_3 - A_1 + C_1 - C_2 - Z_{ac}) + \\ & (Z_{bc}Z_{ca} - Z_{cc}Z_{ab})(A_2 - A_3 + B_1 - B_2 - Z_{ab}) + \\ & (Z_{ca}Z_{ab} - Z_{aa}Z_{bc})(B_3 - B_1 + C_2 - C_3) \end{aligned} \quad (9)$$

$$\Delta I_b = K_1\{-(Z_{ca}Z_{bc} - Z_{cc}Z_{ab}) + Z_{cc}(B_2 - B_1) + Z_{ba}(C_1 - C_3) + Z_{ca}(B_3 - B_1) + Z_{bc}(C_1 - C_2) - (B_2C_3 - B_3C_2) + (B_1C_3 - B_3C_1) - (B_1C_2 - B_2C_1)\} + K_2\{-(Z_{aa}Z_{cc} - Z_{ac}^2) + Z_{aa}(C_3 - C_1) + Z_{ca}(A_1 - A_3 + C_2 - C_1) + Z_{cc}(A_1 - A_2) + (A_2C_3 - A_3C_2) - (A_1C_3 - A_3C_1) + (A_1C_2 - A_2C_1)\} + K_3\{-(Z_{ba}Z_{ac} - Z_{aa}Z_{bc}) + Z_{aa}(B_1 - B_3) + Z_{ba}(A_3 - A_1) + Z_{ac}(B_1 - B_2) + Z_{bc}(A_2 - A_1) - (A_2B_3 - A_3B_2) + (A_1B_3 - A_3B_1) - (A_1B_2 - A_2B_1)\} \quad (14)$$

$$\Delta I_c = K_1\{-(Z_{ba}Z_{cb} - Z_{bb}Z_{ca}) + Z(_{bb}C_2 - C_1) + Z_{ba}(C_2 - C_3) + Z_{ca}(B_3 - B_2) + Z_{cb}(B_1 - B_2) - (B_2C_3 - B_3C_2) + (B_1C_3 - B_3C_1) - (B_1C_2 - B_2C_1)\} + K_2\{-(Z_{ca}Z_{ab} - Z_{aa}Z_{cb}) + Z_{aa}(C_3 - C_2) + Z_{ca}(A_2 - A_3) + Z_{ab}(C_1 - C_2) + Z_{cb}(A_2 - A_1) + (A_2C_3 - A_3C_2) - (A_1C_3 - A_3C_1) + (A_1C_2 - A_2C_1)\} + K_3\{-(Z_{aa}Z_{bb} - Z_{ab}^2) + Z_{aa}(B_2 - B_3) + Z_{ba}(A_3 - A_2 + B_2 - B_1) + Z_{bb}(A_1 - A_2) - (A_2B_3 - A_3B_2) + (A_1B_3 - A_3B_1) - (A_1B_2 - A_2B_1)\} \quad (15)$$

The Δ-Y connection contains passive impedance elements and sinusoidal electromotive forces of the same frequency only. This means that if any one self-impedance be varied all voltages and currents will follow circular loci according to the following theorem:[3]

In a network consisting of any number of linear and bilateral self- and mutual-impedance elements connected in any manner with constant sinusoidal electromotive forces of like frequency connected in any arms, all currents and voltages existing in the system follow circular loci when any one self-impedance is varied along a straight line in the complex plane.

If any numerator and the denominator of the phase currents be expanded term by term it will be seen that self-impedances occur only to the first power. Then if any self-impedance be chosen as the variable, the terms of the denominator Δ, may be collected into 2 parts $\gamma$ the summation of the terms free of the variable, and $\delta$, the summation of the terms containing the variable as a factor. The denominator may then be written as

$$\Delta = \gamma + \delta\rho$$

in which $\rho$ is the scalar variable ranging from zero to infinity as the variable self-impedance varies from short circuit to open circuit.

In the same way, the numerator of any current, such as $\Delta I_a$ may be divided into 2 sets of terms, the first $\alpha$ being the summation of terms free of the variable and the second, $\beta$, being the summation of terms multiplied by the variable. The numerator may then be expressed as

$$\Delta I_a = \alpha + \beta\rho$$

The current $I_a$ then becomes

$$I_a = \frac{\alpha + \beta\rho}{\gamma + \delta\rho}$$

which is the canonical form of a circular locus expressed as a linear fractional transformation. That is, the vector $I_a$ describes a circle as $\rho$ varies from minus to plus infinity.

The theorem also states that all voltages follow circular loci when any one self-impedance is varied. That this is true may be readily shown by mere inspection of any current equation. The numerator of any current equation is free of all impedance elements through which the current flows. Therefore the product of any current and impedance to obtain a potential difference between 2 points will remain linear with respect to all self-impedances.

To illustrate this condition, the voltage $V_{01}$ across phase 1 of the load will be considered. This voltage is

$$V_{01} = E_{01} + I_1Z_{11} + I_2Z_{12} + I_3Z_{13}$$

$$= \frac{\Delta \times E_{01} + \Delta I_1Z_{11} + \Delta I_2Z_{12} + \Delta I_3Z_{13}}{\Delta}$$

The numerator may be separated into a constant portion $\alpha'$, which is free of the variable and a group of remaining terms $\beta'$, having $\rho$ as a factor.
Then

$$V_{01} = \frac{\alpha' + \beta'\rho}{\gamma + \delta\rho}$$

Thus the voltage $V_{01}$ follows a circular locus.

The equations are not linear with respect to mutual impedances and on this account the variation of self-impedances must not change any of the mutual elements in the circuit. The 3-point method is used to determine the loci, that is, evaluation of the desired quantity at the 2 invariant points, $\rho = 0$ and $\rho = \infty$, and some third convenient value of $\rho$. Only the current equations are used in analyti-

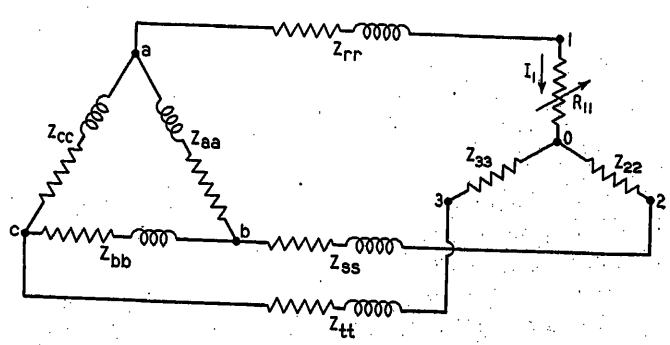

**Fig. 2. Circuit for example**

cal form and once these are reduced to numerical form as linear fractional transformations, all voltage loci may be computed directly therefrom by operating on the currents with impedances. Inasmuch as the denominator of all current and voltage expressions is common, it follows that all summations of currents and voltages remain in the form of linear fractional transformations. Hence the loci of all symmetrical components are also circular.

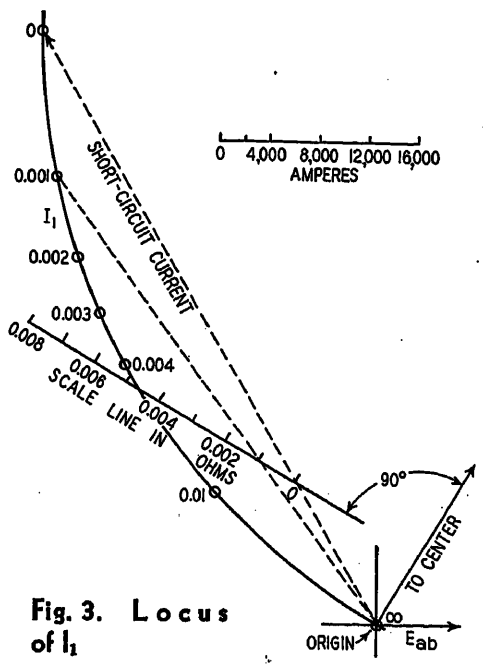

**Fig. 3. Locus of $I_1$**

It is not anticipated that a practical problem will involve as many unbalanced elements as have been treated in this circuit. However problems arise in which any one section of the circuit may be heavily unbalanced, as for example, single-phase loads. Substitution of such conditions into the equations simplifies them considerably, especially when mutual elements are absent.

## Numerical Example

The circuit drawn in figure 2 will show the application of this method to an actual problem. The source phases are assumed to be balanced with respect to both internal voltages and impedances. No mutual impedances are present in the source phases. The connecting lines have equal resistances but unequal reactances. The load is entirely resistive, 2 arms being equal and the third will be considered as the variable self-impedance. The loci of the current in the variable load phase $Z_{11}$ and the voltage across it will be determined as the variable $R_{11}$ varies from short circuit to open circuit. The constants of the circuit are as follows:

$Z_{aa} = Z_{bb} = Z_{cc} = (0.404 + j2.02)10^{-3}$ ohms
$Z_{rr} = (0.08 + j1.131)10^{-3}$ ohms
$Z_{ss} = (0.08 + j0.98)10^{-3}$ ohms $\quad Z_{ss} = (5.88)10^{-3}$ ohms
$Z_{tt} = (0.08 + j0.754)10^{-3}$ ohms $\quad Z_{ab} = Z_{bc} = Z_{ca} = 0$
$Z_{rs} = (j0.452)10^{-3}$ ohms $\quad Z_{12} = Z_{22} = Z_{21} = 0$ ohms
$Z_{st} = (j0.415)10^{-3}$ ohms $\quad E_{21} = E_{32} = E_{13} = 0$ volts
$Z_{tr} = (j0.528)10^{-3}$ ohms $\quad E_{ab} = 230\angle 0°$ volts
$Z_{11} = R_{11} + j0$ ohms $\quad E_{bc} = 230\angle -120°$ volts
$Z_{22} = (5.88)10^{-3}$ ohms $\quad E_{ca} = 230\angle 120°$ volts

Substituting in equations (7) the group constants are:

$A_1 = (-0.08 - j0.679)10^{-3} - R_{11} \quad A_2 = (0 - j0.113)10^{-3}$

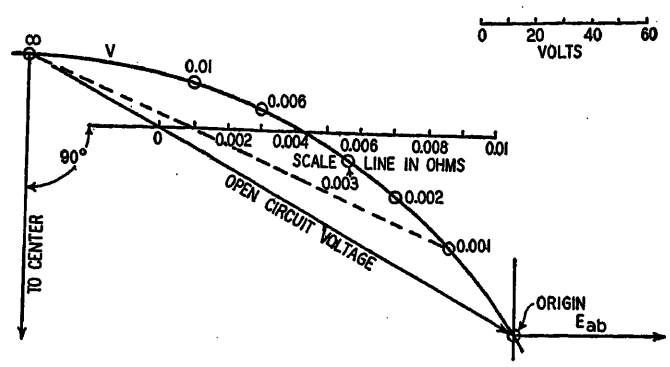

**Fig. 4. Locus of $V_{01}$**

$B_2 = (-5.96 - j0.565)10^{-3} \quad B_1 = (0 + j0.076)10^{-3}$
$C_2 = (-5.96 - j0.226)10^{-3} \quad C_2 = (0 + j0.037)10^{-3}$
$A_2 = (5.96 + j0.528)10^{-3} \quad K_1 = 230 + j0$
$B_2 = (5.96 + j0.339)10^{-3} \quad K_2 = -115 - j199.2$
$C_1 = (0.08 + j0.603)10^{-3} \quad K_3 = -115 + j199.2$

From equation (9) the denominator becomes

$$\Delta = (0.134 - j0.252)10^{-6} + R_{11}(-1.14 - j76.6)10^{-6}$$

From equation (10) the numerator of $I_1$ is

$$\Delta I_1 = (8000 + j13300)10^{-6}$$

The current $I_1$ written as a linear fractional transformation is then

$$I_1 = \frac{8000 + j13300}{(0.134 - j0.252) + R_{11}(-1.14 - j76.6)}$$

Determining the invariant points and using $R_{11} = 0.001$ ohm for the third point the corresponding currents are:

| $R_{11}$ ohms | $I_1$ amperes |
|---|---|
| 0 | 54400 ∠121.0° |
| 0.001 | 44800 ∠126.9° |
| ∞ | 0 |

These 3 points determine the locus of $I_1$ which is drawn in figure 3.

The voltage $V_{01}$ across phase 1 of the load is

$$V_{01} = I_1 Z_{11} = \frac{R_{11}(8000 + j13300)}{(0.134 - j0.252) + R_{11}(-1.14 - j76.6)}$$

Evaluating $V_{01}$ at the same 3 points gives:

| $R_{11}$ ohms | $V_{01}$ volts |
|---|---|
| 0 | 0 |
| 0.001 | 44.8 ∠126.9° |
| ∞ | 205 ∠149.8° |

These points determine the locus of $V_{01}$ which is plotted in figure 4.

# Intersheet Eddy-Current Loss in Laminated Cores

By L. V. BEWLEY
ASSOCIATE AIEE

HILLEL PORITSKY
Member Am. Math. Soc.

CORE LOSS in laminated structures subjected to an alternating magnetomotive force is made up of a hysteresis loss and an eddy-current loss. In modern power transformers the eddy-current loss is approximately $^1/_4$ to $^1/_3$ of the total loss.

In the calculation of the eddy-current loss it is usually tacitly assumed that the parasitic currents are confined to the individual laminations, and that there is no appreciable cross flow from sheet to sheet. Further, it is assumed for the purposes of calculation that the current flow in the individual laminations is everywhere parallel to the width of the laminations, and the end effects are ignored; and usually, also, the demagnetizing effect is not taken into account.

While those assumptions have always appeared to be fully justified for engineering purposes; nevertheless, the validity of the assumption that the intersheet eddy-current losses are negligible is often questioned. For it is evident that as the width of the laminations is increased, the resistance across the packet decreases, whereas the flux increases; and it may very well be, therefore, that the intersheet loss is appreciable for large cores; particularly in those cases where the clamping pressure is very high, because the resistance rapidly decreases with the pressure.

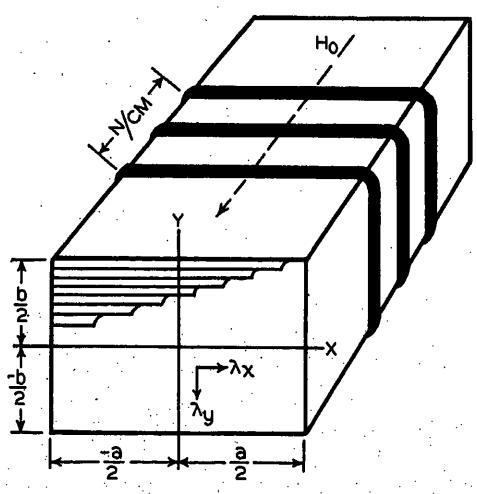

Fig. 1. Cross section of rectangular core

The investigation described herein was undertaken to determine the magnitude of the intersheet eddy-current loss, and incidentally to obtain a more rigorous formula for the eddy currents in rectangular sections that gives the actual distribution. While such refinements are found to be quite unnecessary as far as transformers are concerned, yet they may prove useful in other applications, particularly in cases where the punchings are not enamel insulated and immersed in insulating oil. Moreover, the results for the case where the ratio of conductivities is equal to unity apply exactly to a solid rectangular block, and also indicate the true end-effect correction in laminations even in the case of perfectly insulated punchings of finite thickness.

The cross section of a rectangular core is shown in figure 1. Uniform conductivities $\lambda_x$ and $\lambda_y$ along and across the sheets are assumed. For definiteness, the core is considered as placed inside a long solenoid with $N\,I$ ampere-turns per centimeter length, so that the field perpendicular to the core section is given by

$$H_0 = 0.4\pi\, N\, I \tag{1}$$

For the purposes of analysis, co-ordinates $(x, y)$ are chosen with origin at the center of the core. The mathematical derivations are given in the appendix, and are briefly as follows:

*a.* From Maxwell's equations there are obtained the differential equations for the field intensity $H$, and the relationship between $H$ and the electric intensity $E$.

*b.* The solution of the differential equation, subject to the boundary condition $H = H_0$ around the periphery of the core is obtained. The process of solution is the conventional method of product solutions and sums of these that satisfy the boundary conditions (see, for example, chapter IV of Byerly's "Fourier Series and Spherical Harmonics").

*c.* The flux $\phi$ is readily found by integrating $H$. Using the usual representation of sinusoidal quantities by complex numbers, the flux $\phi$ is given by either of the formulas:

$$\frac{\phi}{\phi_0} = \frac{\tanh\left[(\alpha a)/(2\sqrt{r})\right]}{(\alpha a)/(2\sqrt{r})} + \frac{8}{\pi^2}\sum_{1,3,\ldots}^{\infty} \frac{1}{n^2}\left(\frac{\alpha}{\beta_n}\right)^2 \frac{\tanh(\beta_n b/2)}{(\beta_n b/2)} \tag{2}$$

$$\frac{\phi}{\phi_0} = \frac{8}{\pi^2}\sum_{1,3,\ldots}^{\infty} \frac{1}{n^2}\left\{\frac{\tanh(\alpha_n a/2)}{(\alpha_n a/2)} + \frac{\tanh(\beta_n b/2)}{(\beta_n b/2)}\right\} \tag{3}$$

where

$\phi_0$ = flux corresponding to the maximum (crest value) of $H_0$ or the applied current $I$

$$\alpha_n^2 = \left(\alpha^2 + \frac{n^2\pi^2}{b^2}\right)\frac{1}{r} \qquad \beta_n^2 = \left(\alpha^2 + r\,\frac{n^2\pi^2}{a^2}\right)$$

$\alpha^2 = j\omega 4\pi\lambda_x\mu 10^{-9}$
$\omega = 2\pi f$
$\lambda_x$ = conductivity along laminations
$\lambda_y$ = conductivity across laminations
$r = \lambda_x/\lambda_y$ = ratio of conductivities
$\mu$ = permeability of the iron (assumed constant)
$a, b$ = core dimensions

*d.* The induced electromotive force in the winding is given by

$$E = -j\omega N\phi 10^{-8} \tag{4}$$

where $N$ is the number of terms.

The loss $W$ may be found from the real part of $E$, which

A paper recommended for publication by the AIEE committee on electrical machinery. Manuscript submitted September 24, 1936; released for publication December 15, 1936.

L. V. BEWLEY is in the power transformer department of the General Electric Company, Pittsfield, Mass. H. PORITSKY is in the engineering general department of the same company at Schenectady, N. Y.

is in phase with the exciting current, and turns out to be given by

$$W = \frac{\omega \phi_0 H_0}{8 \times 10^7} [- \mathfrak{I} (\phi/\phi_0)] \text{ watts per centimeter} \tag{5}$$

in which

$I$ = the maximum (crest value) of the current and $\mathfrak{I}(x + jy) = y$ = imaginary part of the complex number $(x + jy)$

For large values of $r$ ($> 1{,}000$) the formula (2) may be replaced by its first term:

$$\frac{\phi}{\phi_0} \cong \frac{\tanh [(\alpha a)/(2\sqrt{r})]}{(\alpha a)/(2\sqrt{r})} \tag{6}$$

This identical result is obtained if the currents are assumed to flow straight across the laminations and the end effects are neglected.

For small values of $[(\alpha a)/(2\sqrt{r})]$, (5) may be replaced by

$$W = \frac{\lambda y}{24} \left(\frac{\omega \phi_0}{10^8}\right)^2 \frac{a}{b} \text{ watts per centimeter} \tag{7}$$

This latter expression is also obtained if the currents are assumed to flow across the laminations and their demagnetizing effect be neglected.

The calculation of the losses by (5) or (6) is seen to hinge on the evaluation of complex functions of the form

$$\frac{\tanh (p + jq)}{(p + jq)} = U + jV$$

On account of the great differences between the conductivities $\lambda_x$ and $\lambda_y$ (their ratio may be as great as $10^7$:1), great care must be taken in evaluating these functions in order to secure sufficient accuracy. Methods are given in the appendix.

Direct calculations of the losses by integration throughout the core section is possible, but proves to be quite involved. The application of Poynting's vector, however, leads to the same result for the losses with only slightly more labor than the total flux method.

## Appendix

Maxwell's equations in centimeter-gram-second practical units are

$$\nabla \times H = 0.4\pi i \tag{8}$$

$$\nabla \times E = -10^{-8} \frac{\partial B}{\partial t} \tag{9}$$

where $H$ is the magnetic field, $E$ the dielectric field (volts per centimeter), $i$ the current density vector, and $B$ the flux density. Replace $B$ by $\mu H$, and assume the time $t$ to enter as a factor $e^{j\omega t}$ (but omit this factor in subsequent equations). Then supposing the only nonvanishing component of the magnetic field to be $H_z$ the component along the solenoid axis, while the induced field and current components are perpendicular to the $z$ axis; and finally that the field aspect is independent of $z$, there follows from (8) and (9)

$$\frac{\partial H}{\partial y} = 0.4\pi i_x, \quad \frac{\partial H}{\partial x} = -0.4\pi i_y \tag{10}$$

$$\frac{\partial E_y}{\partial x} - \frac{\partial E_x}{\partial y} = -j\omega\mu 10^{-8} H \tag{11}$$

the subscript in $H_z$ having been omitted since this is the only component present and there can be no confusion. Since the conductivities $\lambda_x$ and $\lambda_y$ are different in the 2 orthogonal directions, there is (neglecting the displacement currents)

$$i_x = \lambda_x E_x, \qquad i_y = \lambda_y E_y \tag{12}$$

Eliminating $i_x$, $i_y$, $E_x$, $E_y$ there is by (10), (11), and (12)

$$\frac{\lambda_x}{\lambda_y} \frac{\partial^2 H}{\partial x^2} + \frac{\partial^2 H}{\partial y^2} = j\omega 4\pi \lambda_x \mu 10^{-9} H \tag{13}$$

or putting $r = \lambda_x/\lambda_y$ and $\alpha^2 = j\omega 4\pi\lambda_x\mu 10^{-9}$

$$r \frac{\partial^2 H}{\partial x^2} + \frac{\partial^2 H}{\partial y^2} = \alpha^2 H \tag{13a}$$

It is of interest to point out that the relations of the form (12) exist in crystalline media which are homogeneous but not isotropic, though in the general case the 3 current components are expressible linearly in each of the field components by means of 9 conductivity constants, and similarly for the relation between the magnetic field and flux components.

Returning to the differential equation 13$a$, which is the differential equation of the problem, a solution $H$ is sought which takes on the boundary conditions

$$H = H_0 \text{ along } x = \pm a/2 \text{ and } y = \pm b/2 \tag{14}$$

where $H_0$ is given by (1).

To satisfy the boundary conditions (14) we may try to satisfy them first along 2 opposite sides of the rectangular boundary. A solution of (13$a$) independent of $y$ and which satisfies the boundary condition (14) along $x = \pm a/2$ is

$$H_1 = H_0 \frac{\cosh \alpha' x}{\cosh \alpha' a/2}, \quad \alpha' = \frac{\alpha}{\sqrt{r}} \tag{15}$$

Writing the complete solution

$$H = H_1 + H_2 \tag{16}$$

it remains to find $H_2$ such that

$$H_2 = 0 \text{ along } x = \pm a/2 \tag{17}$$

$$H_2 + H_1 = H_0 \text{ along } y = \pm b/2 \tag{18}$$

Product solutions of (13$a$) of the form

$$\cos \frac{n\pi x}{a} \cosh \beta_n y, \qquad \beta_n^2 = \alpha^2 + \frac{rn^2\pi^2}{a^2}$$

for $n = 1, 3, \ldots$ satisfy (17). To satisfy (18), or more explicitly

$$H_2 = H_0 \left(1 - \frac{\cosh \alpha' x}{\cosh \alpha' a/2}\right) \text{ along } y = \pm \frac{b}{2} \tag{18a}$$

an infinite series of the product solutions will be used:

$$H_2 = H_0 \sum_{1,3,\ldots}^{n} C_n \cos \frac{n\pi x}{a} \cosh \beta_n y \tag{19}$$

To satisfy (18$a$) the constants $C_n$ must be chosen so that

$$\sum C_n \cosh \frac{\beta_n b}{2} \cos \frac{n\pi x}{a} = 1 - \frac{\cosh \alpha' x}{\cosh \alpha' a/2} = f(x) \tag{20}$$

By Fourier's theorem, an arbitrary even function $f(x)$ in the interval $(-a/2, a/2)$ can be expanded in a series

$$\sum_{1,3,\ldots}^{n} A_n \cos \frac{n\pi x}{a}$$

and the series converges to $f(x)$ at $x = \pm a/2$ only if $f(x)$ vanishes there—this is the case at present. Applying the familiar rule for the Fourier coefficients to (20), there follows:

$$C_n \cosh \frac{\beta_n b}{2} = \frac{2}{a} \int_{-a/2}^{a/2} \left(1 - \frac{\cosh \alpha' x}{\cosh \alpha' a/2}\right) \cos \frac{n\pi x}{a} dx \tag{21}$$

To evaluate this integral, write it in the from

$$\int fg''dx$$

where primes denote differentiations, and integrate by parts twice, obtaining

$$\int fg''dx = \int f''gdx + [fg' - f'g] = \int f''gdx$$

since at the end points both

$$f = \left(1 - \frac{\cosh \alpha' x}{\cosh \alpha' a/2}\right) \text{ and } g = \frac{-a^2}{n^2\pi^2} \cos \frac{n\pi x}{a}$$

vanish in the present case. Also $f'' = (\alpha')^2(f - 1)$ while $g = -(a^2/n^2\pi^2)\, g''$, hence

$$\int fg''dx = -\frac{\alpha'^2 a^2}{n^2\pi^2} \int fg''dx - \alpha'^2 \int gdx$$

or

$$\int fg''dx = \frac{-\alpha'^2}{1 + \alpha'^2 a^2/n^2\pi^2} \int gdx$$

Carrying out the latter integration, solving for $C_n$ and substituting in (19), (16) there follows:

$$\frac{H}{H_0} = \frac{\cosh \alpha' x}{\cosh \alpha' a/2} + \frac{4}{\pi} \sum_{1,3,\ldots}^{n} \frac{\sin n\pi/2}{n} \left(\frac{\alpha}{\beta_n}\right)^2 \frac{\cosh \beta_n y}{\cosh \beta_n b/2} \cos \frac{n\pi x}{a} \quad (22)$$

From this, (2) is derived by integration.

Another form for $H$ is offered by

$$\frac{H}{H_0} \frac{4}{\pi} \sum_{1,3,\ldots}^{n} \frac{\sin n\pi/2}{n} \left\{ \frac{\cosh \alpha_n x}{\cosh \alpha_n a/2} \cos \frac{n\pi y}{b} + \frac{\cosh \beta_n y}{\cosh \beta_n b/2} \cos \frac{n\pi x}{a} \right\} \quad (23)$$

where

$$\alpha_n^2 = \left(\alpha^2 + \frac{n^2\pi^2}{b^2}\right) \frac{1}{r}$$

This is obtained by breaking up $H$ into 2 parts, of which one satisfies the boundary conditions (14) along $x = \pm a/2$ and vanishes along $y = \pm b/2$, while the other one satisfies (14) along $y = \pm b/2$ and vanishes along $x = \pm a/2$, and then solving for each one by means of an infinite series of product solutions and Fourier's theorem. From (23) the flux (3) follows by integration.

As compared with (22), the form (23), while more symmetric, involves 2 infinite series and has poorer convergence. This is due to the fact that the former Fourier expansion was for a function that vanished at the end points, while such is not the case for the expansions in (23).

From (2), (3), (5) it is seen that the calculation of the losses hinges on the functions of the form

$$U + jV = \frac{\tanh (p + jq)}{(p + jq)} \quad (24)$$

But it is only the imaginary component, $V$, of this function which contributes to the loss. In the laminated core problem, it so happens, on account of the great differences in conductivity along and perpendicular to the laminations, that either $p$ is very large, or else $p$ and $q$ are small and very nearly alike. For these 2 cases we have:

CASE I

Suppose $p$ is very large (say of the order of 100). Then

$$U + jV = \frac{\tanh (p + jq)}{(p + jq)} = \frac{\tanh p + j \tan q}{1 + j \tanh p \tan q} \frac{1}{p + jq}$$

$$\cong \frac{1}{p + jq} = \frac{p}{p^2 + q^2} - j \frac{q}{p^2 + q^2} \cong \frac{1}{p} - j \frac{q}{p^2} \quad (25)$$

CASE II

Suppose both $p$ and $q$ small compared to unity. Then

$$U + jV = \frac{\tanh (p + jq)}{p + jq} = 1 - \frac{1}{3}(p + jq)^2 + \frac{2}{15}(p + jq)^4 + \ldots \cong \left(1 - \frac{p^2 - q^2}{3}\right) - j\frac{2}{3} pq \quad (26)$$

APPROXIMATIONS

In the differential equation (13$a$) the ratio $\lambda_x/\lambda_y$ may be of the order of $10^7$ and the term $\partial^2 H/\partial y^2$ may then be dropped, so that (13$a$) becomes

$$\frac{\partial^2 H}{\partial x^2} = \frac{\alpha^2}{r} H = \alpha'^2 H \quad (27)$$

subject to the boundary condition $H = H_0$ at $x = \pm a/2$. The solution therefore is

$$H = H_0 \frac{\cosh \alpha' x}{\cosh \alpha' a/2} \quad (28)$$

which is the first term of (22). The flux becomes

$$\frac{\phi}{\phi_0} = \frac{\tanh \alpha' a/2}{\alpha' a/2} \quad (29)$$

which will be recognized as (6). As pointed out above, this is also obtained from (2) due to the smallness of the series. The losses are given by

$$W = \frac{1}{2}\left[\frac{\omega \phi H_0}{8\pi 10^8} \frac{\tanh \alpha' a/2}{\alpha' a/2}\right] \quad (30)$$

If the demagnetizing effect of the eddy currents is negligible, on the right-hand side of (27) put

$$\frac{\partial^2 H}{\partial x^2} = \alpha'^2 H_0 \quad (31)$$

the solution to which is

$$\frac{H}{H_0} = \left[1 - j \frac{4\pi\mu\omega\lambda_y}{10^9} \left(\frac{a^2}{8} - \frac{x^2}{2}\right)\right] \quad (32)$$

The flux is

$$\frac{\phi}{\phi_0} = \left(1 - j \frac{\pi\mu\omega\lambda_y a^2}{3 \times 10^9}\right) \quad (33)$$

and the losses become

$$W = \frac{\lambda_y}{24} \left(\frac{\omega\phi_0}{10^8}\right)^2 \frac{a}{b} \quad (34)$$

This approximation is the exact equivalent of assuming the eddy current to flow straight across the laminations parallel to the $Y$ axis, and neglecting the demagnetizing effect. Thus on these assumptions, the flux included between $-x$ and $+x$ is

$$\phi = 2b\mu H_0 x \quad (35)$$

which induces the voltage

$$e = -j \frac{2\omega}{10^8} \mu H_0 bx \quad (36)$$

The resistance of the elementary path is

$$\frac{2b}{\lambda_y dx} \quad (37)$$

and the losses therefore are ($e_{\text{rms}} = e/\sqrt{2}$)

$$W = \frac{\lambda_y}{2b} \int_0^{a/2} e^2 dx = \frac{\lambda_y}{24} \left(\frac{\omega ab\mu H_0}{10^8}\right)^2 \frac{a}{b} = \frac{\lambda_y}{24} \left(\frac{\omega \phi_0}{10^8}\right)^2 \frac{a}{b} \quad (38)$$

# Some Series Formulas for Mutual Inductance of Solenoids

By H. B. DWIGHT
FELLOW AIEE

F. W. GROVER
MEMBER AIEE

ABSOLUTE formulas for the mutual inductance of coaxial solenoids have been derived by Nagaoka, Terezawa, and Olshausen. These all give the mutual inductance as a combination of 4 integrals—2 positive and 2 negative—each of which is a function of one of the 4 distances measured between an end of one solenoid and an end of the other. The expressions for these terms involve elliptic integrals of all 3 kinds, and numerical computations of their values are exacting.

Fortunately, it is possible to use in place of the absolute formulas series expansions of them involving ratios of the dimensions of the coils. However, on account of the number of parameters involved, no single series expansion will suffice for all possible pairs of coils.

The present paper has for its object the derivation of new series formulas suitable for cases not previously covered. A survey is also made of the whole field.

The new formulas here developed are derived from certain basic formulas included in the Bureau of Standards collection of inductance formulas.[2] For the convenience of the reader, there have been here reproduced from that collection, in an appendix, those expressions to which reference will be made. The formula numbers in the original are retained in the appendix with the letter $A$ added, in order to avoid confusion with the formula numbers of the present paper.

Formulas for the mutual inductance of solenoids are usually obtained by integrating expressions for the mutual inductance of circles. For circles comparatively near together, a very useful formula (16)$A$ has been given by T. H. Havelock,[1] which has been extended by E. B. Rosa and F. W. Grover.[2] As the latter authors say in comparing it with their equation (14)$A$, which is an extension of a formula given by Clerk Maxwell, equation (16)$A$ requires only half as many terms to be calculated for a given degree of convergence. Another fundamental formula (56)$A$ for mutual inductance of a solenoid and a coaxial circle was given by Rosa, Scientific Paper 169, page 101.

In this paper, the formulas (16)$A$ and (56)$A$, mentioned above, will be used to derive some formulas for solenoids, and their ranges of application will be investigated by means of numerical examples.

The mutual inductance of 2 coaxial but unequal solenoids which are not far apart, can be obtained by twice integrating the equation (16)$A$, first over the length of one solenoid and second over the length of the other. See figure 1. The result is as follows:

$$\frac{M}{n_1 n_2} = F_{(x1)} - F_{(x2)} - F_{(x3)} + F_{(x4)} \text{ abhenries} \tag{1}$$

where $n_1$ and $n_2$ are the turns per centimeter of the coils, respectively, and where

$$x_1 = s + m_1 + m_2 \tag{2}$$

$$x_2 = s + m_1 - m_2 \tag{3}$$

$$x_3 = s - m_1 + m_2 \tag{4}$$

$$x_4 = s - m_1 - m_2 \tag{5}$$

$$\begin{aligned} F_{(x)} = \frac{\pi d^2\sqrt{Dd}}{2}\Bigg[ & \left\{ \operatorname{logn} \frac{x^2+c^2}{c^2} \right\} \times \\ & \left\{ \frac{c^2}{d^2}\left(1 + \frac{3}{8}\frac{c^2}{Dd} - \frac{5}{64}\frac{c^4}{D^2d^2} + \frac{35}{1024}\frac{c^6}{D^3d^3}\right)\right\} + \\ & \left\{ \operatorname{logn} \frac{16Dd}{x^2+c^2}\right\}\left\{ \frac{x^2}{d^2}\left(1 + \frac{3}{4}\frac{c^2}{Dd} - \frac{15}{64}\frac{c^4}{D^2d^2} + \frac{35}{256}\frac{c^6}{D^3d^3}\right) + \right. \\ & \frac{x^4}{8Dd^3}\left(1 - \frac{5}{8}\frac{c^2}{Dd} + \frac{35}{64}\frac{c^4}{D^2d^2}\right) - \\ & \left. \frac{x^6}{64D^2d^4}\left(1 - \frac{7}{4}\frac{c^2}{Dd}\right) + \frac{5}{1024}\frac{x^8}{D^3d^5} \cdots \right\} - \\ & \frac{4cx}{d^2}\left\{ \tan^{-1}\frac{x}{c}\right\}\left\{ 1 + \frac{c^2}{2Dd} - \frac{c^4}{8D^2d^2} + \frac{c^6}{16D^3d^3}\right\} - \\ & \frac{x^2}{d^2}\left(1 - \frac{9}{8}\frac{c^2}{Dd} - \frac{1}{16}\frac{c^4}{D^2d^2} + \frac{325}{3072}\frac{c^6}{D^3d^3}\right) + \\ & \frac{x^4}{16Dd^3}\left(1 + \frac{3}{2}\frac{c^2}{Dd} - \frac{695}{384}\frac{c^4}{D^2d^2}\right) + \\ & \left. \frac{x^6}{48D^2d^4}\left(1 - \frac{149}{64}\frac{c^2}{Dd}\right) - \frac{109}{12288}\frac{x^8}{D^3d^5}\cdots\right] \end{aligned} \tag{6}$$

where logn denotes natural logarithm.

If $x$ is large, say greater than the radius $a$, or if $c$ is comparatively large, say greater than $a/2$, the following expression for $F_{(x)}$, obtained by integrating equations (56)$A$, may be used:

$$\begin{aligned} F_{(x)} = 2\pi^2a^2A\Bigg[ & \frac{r}{A} - \frac{a^2A}{8r^3} + \frac{a^4A}{16r^5} - \frac{5}{64}\frac{a^4A^3}{r^7} - \\ & \frac{5}{128}\frac{a^6A}{r^7} + \frac{35}{256}\frac{a^6A^3}{r^9} + \frac{7}{256}\frac{a^8A}{r^9} - \frac{105}{1024}\frac{a^8A^5}{r^{11}} - \\ & \frac{189}{1024}\frac{a^8A^3}{r^{11}} - \frac{21}{1024}\frac{a^{10}A}{r^{11}} + \frac{693}{2048}\frac{a^8A^5}{r^{13}} + \frac{231}{1024}\frac{a^{10}A^3}{r^{13}} + \\ & \frac{33}{2048}\frac{a^{12}A}{r^{13}} - \cdots + \left(-1 + \frac{a^2}{8A^2} + \frac{a^4}{64A^4} + \frac{5}{1024}\frac{a^6}{A^6} + \right. \\ & \left. \frac{35}{16384}\frac{a^8}{A^8} + \frac{147}{128\times 1024}\frac{a^{10}}{A^{10}} + \cdots\right)\Bigg] \end{aligned} \tag{7}$$

where

$$r^2 = x^2 + A^2 \tag{8}$$

---

A paper recommended for publication by the AIEE committee on electrophysics. Manuscript submitted December 17, 1935; released for publication March 2, 1936.

H. B. DWIGHT is professor of electrical machinery at Massachusetts Institute of Technology, Cambridge, Mass. F. W. GROVER is professor of electrical engineering at Union College, Schenectady, N. Y.

1. *Phil. Mag.*, volume 15, 1908, page 332.

2. FORMULAS AND TABLES FOR THE CALCULATION OF MUTUAL AND SELF-INDUCTANCE, E. B. Rosa and F. W. Grover. Scientific Paper 169 of the Bureau of Standards, Washington, D. C. Scientific Paper 169 was published also as part number 1 of volume 8 of the *Bulletin* of the Bureau of Standards.

By grouping together terms of (7) of the same power of $a$, the following alternative form is obtained:

$$F_{(x)} = 2\pi^2 aA^2\left[ C_0 + \frac{a^3}{8r^3} C_2 + \frac{a^5}{64r^5} C_4 + \frac{5}{1024}\frac{a^7}{r^7} C_6 + \frac{35}{16384}\frac{a^9}{r^9} C_8 + \frac{147}{128 \times 1024}\frac{a^{11}}{r^{11}} C_{10} + \ldots + \frac{a}{A}\left(-1 + \frac{a^2}{8A^2} + \frac{a^4}{64A^4} + \frac{5}{1024}\frac{a^6}{A^6} + \frac{35}{16384}\frac{a^8}{A^8} + \frac{147}{128 \times 1024}\frac{a^{10}}{A^{10}} + \ldots\right)\right] \quad (9)$$

where

$$C_0 = \frac{ar}{A^2} = \frac{a\sqrt{(x^2 + A^2)}}{A^2}$$

$$C_2 = -1$$

$$C_4 = 2\left(2 - \frac{5}{2}\frac{A^2}{r^2}\right)$$

$$C_6 = 7\left(-\frac{8}{7} + 4\frac{A^2}{r^2} - 3\frac{A^4}{r^4}\right)$$

$$C_8 = \frac{9}{5}\left(\frac{64}{9} - 48\frac{A^2}{r^2} + 88\frac{A^4}{r^4} - \frac{143}{3}\frac{A^6}{r^6}\right)$$

$$C_{10} = \frac{11}{7}\left(-\frac{128}{11} + 128\frac{A^2}{r^2} - 416\frac{A^4}{r^4} + 520\frac{A^6}{r^6} - 221\frac{A^8}{r^8}\right)$$

Equations (7) and (9) are equivalent to (6) in all respects and they give the same numerical result as (6) for any case to which both the formulas can be properly applied. The criterion as to whether a series is applicable is that the last terms used shall be negligibly small. In other words, the series shall be practically convergent in the number of terms which are used.

Equation (6) is given in terms of diameters and (7) and (9) in terms of radii so that the numerical coefficients in each series will be as small as possible.

It is to be noted that the 4 values of $F_{(x)}$ in (1) need not necessarily be computed all by (6) or all by (7) or by (9), but some can be computed by one expression and some by another. This may be necessary in some cases, for $x_1$ may be so large that (6) cannot be used, and for the same pair of coils $x_4$ may be so small that only (6) can be employed.

There is an advantage in using (7) or (9) for all 4 cases of (1), namely, that then the round bracket of (7) or (9) need not be computed, for it is like a constant of integration and would cancel out when the 2 positive and 2 negative values were added.

The round bracket of (7) and (9) was put in for the purpose of making (7) and (9) equivalent to (6). All these expressions have the same physical interpretation—they are $^1/_2$ the mutual inductance of 2 equal and concentric coils of length $x$ and with one turn per centimeter. See equation (11). Thus, (9) is the same, term for term, as the well known mutual-inductance formula (36)$A$, (Scientific Paper 169, page 53), multiplied by $^1/_2$. A considerable number of additional terms of (7) and (9) can be written down by inspection, from this corresponding formula (36)$A$. The terms of (7), (9), and (21) are the same as those in the paper "Mechanical Forces in Transformers," by J. E. Clem, AIEE TRANSACTIONS, volume 46, 1927, page 577. The general term of the round bracket of (7) and (9) is given in the paper by T. H. Havelock, reference 1, and on page 56 of Scientific Paper 169. (See appendix also.)

Where $a$ is considerably smaller than $A$, the grouping in (9) according to powers of $a$ is convenient, but if $x$ and therefore $r$ are relatively large, the grouping according powers of $r$, as in (7) and (22), is convenient. That is, in general, (7) is for long coils and (9) for short coils, though not as short as those for which (6) is used. However, there is very little difference between (7) and (9) for they contain the same terms and the terms which are not negligible must be computed while those that are negligible will be omitted.

When the 2 coils are concentric as well as coaxial, $s = 0$. It is to be noted that only even powers of $x$ are involved in (6), (7), and (9), and so

$$F_{(x)} = F_{(-x)}$$

Therefore, for concentric coils of unequal length,

$$\frac{M}{n_1 n_2} = 2F_{(m_1+m_2)} - 2F_{(m_1-m_2)} \quad (10)$$

Equation (10), using (6), (7), or (9) as convenient, is thus equivalent to Ròiti's formula, equation (39)$A$, or Searle and Airey's formula extended, equation (43)$A$.

A further simplification results when the 2 concentric coils are of equal length, in which case only one expression is required.

$$\frac{M}{n_1 n_2} = 2F_{(2m_1)} \quad (11)$$

For (6), (7), and (9),

$$F_{(0)} = 0 \quad (12)$$

The round bracket of (7) and (9) was inserted to make this so. As previously mentioned, equation (11), using (7) or (9) is the same as equation (36)$A$. It is equivalent to equation (38) of Scientific Paper 169 or other formulas which are given for this type of problem.

Each dimension of the cross section of a coil should be taken to be the number of wires in a row along that dimension, multiplied by the center-to-center distance between adjacent wires.

If the 2 concentric coils of equal length are shorter than approximately the radius of the inner one, and if $c$ is less than $^1/_2$ the radius, equation (6) used with (11) is appropriate to use. It is a mutual-inductance formula which it is believed has not previously been published. It is very similar to equation (1) of the paper "Mutual Inductance of Short Concentric Solenoids," by H. B. Dwight and P. W. Sayles, *Journal of Mathematics and Physics*, volume 9, 1930, page 162. It is several terms shorter, for the same rapidity of convergence. Equation (6) of this paper contains only even powers of $c$ in the series but equation (1) of the paper referred to contains both odd and even powers of $c$, which increases the number of terms in the formula without any advantage.

A similar shortening of a formula by using (16)$A$ in-

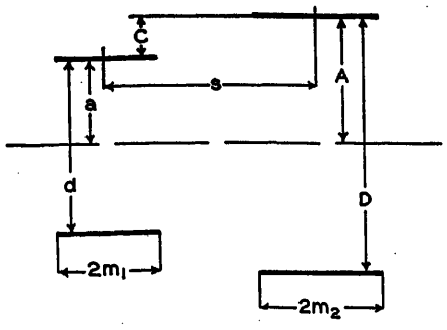

**Fig. 1. Two coaxial solenoids**

stead of (14)$A$, may be made in the case of equation (15)$A$, for the mutual inductance of 2 circles in the same plane. By putting $x = 0$ in (16)$A$, there results

$$M = 4\pi\sqrt{Aa}\left[\left\{\log_n \frac{8\sqrt{Aa}}{c}\right\}\left\{1 + \frac{3}{16}\frac{c^2}{Aa} - \frac{15}{1024}\frac{c^4}{A^2a^2} + \frac{35}{128^2}\frac{c^6}{A^3a^3} - \frac{1575}{2\times 128^3}\frac{c^8}{A^4a^4}\cdots\right\} - 2 - \frac{c^2}{16Aa} + \frac{31}{2048}\frac{c^4}{A^2a^2} - \frac{247}{6\times 128^2}\frac{c^6}{A^3a^3} + \frac{7795}{8\times 128^3}\frac{c^8}{A^4a^4}\cdots\right] \quad (13)$$

This contains only even powers of $c$ in the series, and so can be said to have $^1/_2$ as many terms as equation (15)$A$.

Another simplification of the problem of mutual inductance occurs when the 2 coils are not concentric but have equal radii. This means that $c = 0$ and $A = a$. Formula (6) then becomes $^1/_2$ times a self-inductance formula, namely, (71)$A$ (page 117, Scientific Paper 169). Formulas (7) and (9) similarly become $^1/_2$ times the self-inductance formula (11) published in the AIEE TRANSACTIONS, volume 38, 1919, page 1688. Equation (1) of this paper becomes the same as equation (51)$A$. When 2 coils have equal radii, their mutual inductance can be calculated by the above-mentioned equation (51)$A$, using well-known self-inductance formulas, and corrections can be added for the thickness of the winding and for the shape and spacing of the conductors. See Scientific Paper 169, pages 140–41.

Equation (51)$A$ can be used also for 2 concentric coils of equal length and of appreciable thickness of winding.

It is seen from equations (1) to (5) that if in the dimensions of the lengths, $2m_1$ and $2m_2$ are interchanged, the mutual inductance and also the force (see equation 20), are not changed. This can be called the *principle of interchange of lengths*. It has been pointed out previously for the mutual inductance of concentric solenoids. (See Scientific Paper 169, page 68,) Since it applies to each thin cylindrical element of thick solenoids or coils, it applies to the entire coils.

An inspection of the formulas[3] shows that the principle of interchange of lengths applies also to mutual inductance and force of unequal coils with parallel axes.

This principle applies, of course, to the case of a solenoid and coaxial circle also. That is, the mutual inductance of a solenoid, of length $2m$ and a radius $A$, and a circle of radius $a$ in its end plane, is the same as the mutual inductance of a solenoid of the same length $2m$ but of radius $a$, and a coaxial circle of radius $A$ in its end plane.

Equation (51)$A$ is derived from the knowledge of the properties of mutual and self inductance of coils. A corresponding relationship of mutual inductances for equation (1) of this paper is of interest since it makes clear the physical meaning of the formula. It requires the use of the principle of interchange of lengths, which is dependent on (1), and so it is not to be taken as a proof of (1).

Suppose that in addition to the 2 thin solenoids of figure 1, there are 4 others as in figure 2, the turns per centimeter being the same for all coils of a given radius. Since these touch each other end to end, they form longer solenoids. For instance, the 3 solenoids $P$, $Q$, and $R$ form one long solenoid which can be called $P + Q + R$.

$$M_{(P+Q+R)(p+q+r)} = M_{Pp} + M_{Pq} + M_{Pr} + M_{Qp} + M_{Qq} + M_{Qr} + M_{Rp} + M_{Rq} + M_{Rr}$$

Using the principle of interchange of lengths, by which $M_{Qp} = M_{Pq}$ etc., this becomes

$$M_{Pp} + M_{Qq} + M_{Rr} + 2M_{Pq} + 2M_{Qr} + 2M_{Rp}$$

Similarly,

$$M_{(P+Q)(p+q)} = M_{Pp} + M_{Qq} + 2M_{Pq}$$

and

$$M_{(Q+R)(q+r)} = M_{Qq} + M_{Rr} + 2M_{Qr}$$

Solving these equations simultaneously in such a way as to leave only pairs of coils which are concentric and of equal length on the right-hand side of the equation,

$$2M_{Rp} = M_{(P+Q+R)(p+q+r)} - M_{(P+Q)(p+q)} - M_{(Q+R)(q+r)} + M_{Qq} \quad (14)$$

The lengths of the concentric coils are evidently $x_1$, $x_2$, $x_3$, and $x_4$.

In a similar way, equation (10) can be treated.

In the general formula (10) for concentric solenoids the mutual inductance is given by the difference of 2 series. In the formula of Searle and Airey (formula (43)$A$) a *single* series of terms suffices for its calculation. Searle and Airey's formula may be derived from (10) and (7) by expanding the 2 values of $r$ in powers of the ratios of the solenoid lengths to the diagonal drawn from the center to the end of the longer solenoid and combining terms.

This formula does not converge well when the solenoids are of nearly equal radii and their lengths are small, compared with their radii. In such cases formula (6) must be used in connection with (10).

On the other hand, when the lengths of the coils are large, compared with their radii, the coefficients $X_{2n}$ and $L_{2n}$ may become very large, rendering the use of this

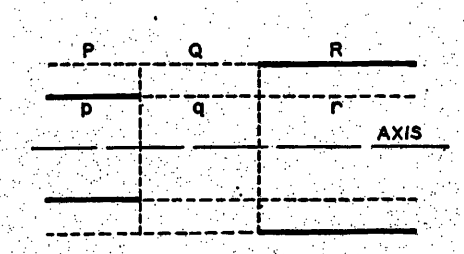

**Fig. 2. Coaxial solenoids**

[3] "The Force Between Unequal Reactance Coils Having Parallel Axes," by H. B. Dwight and R. W. Pursell, *General Electric Review*, volume 33, July 1930, page 401, formulas (1), (2), and (3).

formula uncertain and unsatisfactory (see pages 63 and 222 of Scientific Paper 169).

The following formula (17) is presented as an alternative to (43)$A$. Its coefficients $\lambda_n$ and $\xi_n$ are always less than unity and so it is possible to tell by inspection from the value of $\delta/\rho$ how rapid is the convergence of the series (17), which is a power series in $\delta/\rho$. The change lowers the powers of some of the letters making up the terms. By putting

$$\delta^2 = a^2 + m_1^2 \tag{15}$$

and

$$\rho^2 = A^2 + m_2^2 \tag{16}$$

we can replace

$m_1^2$ by $\delta^2 - a^2$ and $m_2^2$ by $\rho^2 - A^2$ in (43)$A$

giving for the concentric coils,

$$M = \frac{2\pi^2 a^2 N_1 N_2}{\rho}\left[1 - \frac{A^2\delta^2}{2\rho^4}\left\{\lambda_2 + \frac{\delta^2}{\rho^2}\lambda_4\xi_2 + \frac{\delta^4}{\rho^4}\lambda_6\xi_4 + \frac{\delta^6}{\rho^6}\lambda_8\xi_6 + \ldots\right\}\right] \tag{17}$$

where $N_1$ and $N_2$ are the turns per coil of the 2 coils, respectively, and where

$$\lambda_2 = 1 - \frac{7}{4}\frac{a^2}{\delta^2} \qquad \xi_2 = 1 - \frac{7}{4}\frac{A^2}{\rho^2}$$

$$\lambda_4 = 1 - \frac{9}{2}\frac{a^2}{\delta^2} + \frac{33}{8}\frac{a^4}{\delta^4} \qquad \xi_4 = 1 - \frac{9}{2}\frac{A^2}{\rho^2} + \frac{33}{8}\frac{A^4}{\rho^4}$$

$$\lambda_6 = 1 - \frac{33}{4}\frac{a^2}{\delta^2} + \frac{143}{8}\frac{a^4}{\delta^4} - \frac{715}{64}\frac{a^6}{\delta^6}$$

$$\lambda_8 = 1 - 13\frac{a^2}{\delta^2} + \frac{195}{4}\frac{a^4}{\delta^4} - \frac{1105}{16}\frac{a^6}{\delta^6} + \frac{4199}{128}\frac{a^8}{\delta^8}$$

$$\lambda_{10} = 1 - \frac{75}{4}\frac{a^2}{\delta^2} + \frac{425}{4}\frac{a^4}{\delta^4} - \frac{8075}{32}\frac{a^6}{\delta^6} + \frac{33915}{128}\frac{a^8}{\delta^8} - \frac{52003}{512}\frac{a^{10}}{\delta^{10}}$$

The coefficients $\xi_6$, $\xi_8$, etc., are functions of $A^2/\rho^2$ and can be written down by inspection from the similar expressions for $\lambda_6$, $\lambda_8$, etc.

While formulas (17) and (43)$A$ are given for the case of the mutual inductance of a short solenoid and a longer one outside, these formulas can be used for the case when the shorter solenoid is outside, by first applying the principle of interchange of lengths.

Gray's[4] formula (40)$A$ expresses the mutual inductance of 2 coaxial solenoids, not concentric, as the difference of 2 series of terms. It may be derived from the general formula (1) and (7) by expressing the 4 distances $r$ in terms of the distances measured from the center of the coil of smaller radius to the ends of the winding of the other coil. In spite of its smaller number of terms, however, the convergence of Gray's formula is not so good as that of (7), except for coils far apart.

Since Gray's formula contains the same coefficient as (43)$A$, it is subject to the same disadvantage that, for certain proportions of coils, the coefficients become large and it cannot be told by inspection how satisfactory is the convergence of the series. By making the same type of substitution as was used for obtaining (17), the following alternative form of Gray's formula for 2 coils as in figure 1, is obtained:

$$M = \frac{4\pi^2 a^2 n_1 n_2 m_1 q_2}{d_2}\left[1 - \frac{A^2\delta^2}{2d_2^4}\left\{\lambda_2 + \left(\frac{\delta}{d_2}\right)^2\lambda_4\xi_2'' + \left(\frac{\delta}{d_2}\right)^4\lambda_6\xi_4'' + \ldots\right\}\right] - \frac{4\pi^2 a^2 n_1 n_2 m_1 q_1}{d_1}\left[1 - \frac{A^2\delta^2}{2d_1^4}\left\{\lambda_2 + \left(\frac{\delta}{d_1}\right)^2\lambda_4\xi_2' + \left(\frac{\delta}{\delta_1}\right)^4\lambda_6\xi_4' + \ldots\right\}\right] \tag{18}$$

where

$$q_1 = s - m_2$$
$$q_2 = s + m_2$$
$$d_1^2 = A^2 + q_1^2$$
$$d_2^2 = A^2 + q_2^2$$
$$\delta^2 = a^2 + m_1^2$$

where $\lambda_2$, $\lambda_4$, etc., are the same as for (17), where $\xi_n'$ is the same function of $A/d_1$ that $\lambda_n$ is of $a/\delta$ and where $\xi_n''$ is the same function of $A/d_2$ that $\lambda_n$ is of $a/\delta$. The quantities $n_1$ and $n_2$ are the numbers of turns per centimeter of the 2 coils, respectively.

Since the coefficients in (18) are less than unity, the rapidity of convergence of the series is evident at once from the values of $\delta/d_1$ and $\delta/d_2$. The formula also has been simplified to some extent.

If the 2 coils of figure 1 are concentric, $s = 0$, $d_1 = d_2$ and (18) becomes the same as (17).

The convergence of (18) may be improved by employing the principle of interchange of lengths if, by so doing, a smaller value of $\delta$ results.

The convergence of Gray's formula and the alternative form (18), like that of (7) and (9), improves as the distance between the 2 solenoids is increased, but for loosely coupled coils this advantage is offset by the difficulty that the mutual inductance is obtained as the small difference of much larger terms. Thus each series has to be calculated to a much higher accuracy than that required in the value of the mutual inductance.

This difficulty may be avoided by the use of a new formula derived from (18).
Writing

$$d_1 = q_1\sqrt{1 + \frac{A^2}{q_1^2}} \quad \text{and} \quad d_2 = q_2\sqrt{1 + \frac{A^2}{q_2^2}}$$

and expanding powers of $d_1$ and $d_2$ in (18) by the binomial theorem, there results the expression

$$M = \frac{2\pi^2 a^2 A^2 N_1 N_2 s}{q_1^2 q_2^2}\left[1 + \frac{2\delta^2}{q_1^2}\left(\lambda_2 - \frac{3}{4}\frac{A^2}{\delta^2}\right)\left(1 + \frac{m_2^2}{s^2}\right)\frac{s^2}{q_2^2} + \frac{3\delta^4}{q_1^4}\left(\lambda_4 - \frac{5}{2}\frac{A^2}{\delta^2}\lambda_2 + \frac{5}{8}\frac{A^4}{\delta^4}\right)\left(1 + \frac{10}{3}\frac{m_2^2}{s^2} + \frac{m_2^4}{s^4}\right)\frac{s^4}{q_2^4} + \frac{4\delta^6}{q_1^6}\left(\lambda_6 - \frac{21}{4}\lambda_4\frac{A^2}{\delta^2} + \frac{35}{8}\frac{A^4}{\delta^4}\lambda_2 - \frac{35}{64}\frac{A^6}{\delta^6}\right)\times \left(1 + 7\frac{m_2^2}{s^2} + 7\frac{m_2^4}{s^4} + \frac{m_2^6}{s^6}\right)\frac{s^6}{q_2^6} + \ldots\right] \tag{19}$$

[4] "Absolute Measurements in Electricity and Magnetism," by Andrew Gray, edition of 1893, volume 2, part 1, page 274, equation 53, and Scientific Paper 169 of the Bureau of Standards, by E. B. Rosa and F. W. Grover, page 59, equation 40 and 40$a$.

in which $N_1$ and $N_2$ are the total numbers of turns on the coils.

This formula is simpler and more accurate the looser the coupling of the coils, that is, in just those cases where formulas (1) and (7) require the greatest care. The coefficients of $\delta^n/q_1^n$ are less than unity.

Here also the principle of interchange of lengths should be employed so that $\delta$ may have the smaller of the 2 lengths which are possible.

When the 2 coils are not concentric, a mechanical force is exerted by one on the other in the direction of the axis. By a well-known proposition, this force is equal to

$$i_1 i_2 \frac{\partial M}{\partial s} \text{ dynes}$$

where $i_1$ and $i_2$ are in abamperes. This can be written

$$i_1 i_2 n_1 n_2 [Q_{(x_1)} - Q_{(x_2)} - Q_{(x_3)} + Q_{(x_4)}] \text{ dynes} \qquad (20)$$

where $x_1$ to $x_4$ are given by (2) to (5) and where

$$Q_{(x)} = \frac{\partial F_{(x)}}{\partial x}$$

since

$$\partial s = \partial x$$

For small values of $x$, the derivative of (6) may be taken from the first step of the integration by which (6) was obtained. This gives

$$Q_{(x)} = \pi x \sqrt{Dd} \left[ \left\{ \log_n \frac{16Dd}{x^2 + c^2} \right\} \left\{ 1 + \frac{3}{4}\frac{c^2}{Dd} - \frac{15}{64}\frac{c^4}{D^2d^2} + \frac{35}{256}\frac{c^6}{D^3d^3} + \frac{x^2}{4Dd}\left(1 - \frac{5}{8}\frac{c^2}{Dd} + \frac{35}{64}\frac{c^4}{D^2d^2}\right) - \frac{3}{64}\frac{x^4}{D^2d^2} \times \left(1 - \frac{7}{4}\frac{c^2}{Dd}\right) + \frac{5}{256}\frac{x^6}{D^3d^3} \cdots \right\} - \left\{ \frac{2c}{x} \tan^{-1}\frac{x}{c} \right\} \times \left\{ 1 + \frac{c^2}{2Dd} - \frac{c^4}{8D^2d^2} + \frac{c^6}{16D^3d^3} \right\} + \left( -2 + \frac{c^2}{2Dd} + \frac{15}{64}\frac{c^4}{D^2d^2} - \frac{151}{768}\frac{c^6}{D^3d^3} \right) + \frac{x^2}{Dd}\left(\frac{c^2}{4Dd} - \frac{209}{768}\frac{c^4}{D^2d^2}\right) + \frac{x^4}{D^2d^2}\left(\frac{5}{64} - \frac{43}{256}\frac{c^2}{Dd}\right) - \frac{31}{768}\frac{x^6}{D^3d^3} \cdots \right] \qquad (21)$$

For larger values of $x$ the following expression for $Q_{(x)}$ may be obtained by differentiating (7) with respect to $x$:

$$Q_{(x)}'' = \frac{2\pi^2 a^2 x}{r}\left[ 1 + \frac{3}{8}\frac{a^2A^2}{r^4} - \frac{5}{16}\frac{a^4A^2}{r^6} + \frac{35}{64}\frac{a^4A^4}{r^8} + \frac{35}{128}\frac{a^6A^2}{r^8} - \frac{315}{256}\frac{a^6A^4}{r^{10}} - \frac{63}{256}\frac{a^8A^2}{r^{10}} + \frac{1155}{1024}\frac{a^6A^6}{r^{12}} + \frac{2079}{1024}\frac{a^8A^4}{r^{12}} + \frac{231}{1024}\frac{a^{10}A^2}{r^{12}} - \frac{9009}{2048}\frac{a^8A^6}{r^{14}} - \frac{3003}{1024}\frac{a^{10}A^4}{r^{14}} - \frac{429}{2048}\frac{a^{12}A^2}{r^{14}} + \cdots \right] \qquad (22)$$

where

$$r^2 = x^2 + A^2$$

It is easy to show that the mutual inductance $m(x)$ of a solenoid of radius $A$, winding density $n_1$, length $x$, and a coaxial circle of radius $a$ in its end plane is connected with the function $Q(x)$ by the relation $m(x) = n_1 Q(x)$. Thus equation (22), multiplied by $n_1$, gives an expression for the mutual inductance of a solenoid and coaxial circle which is equivalent to (56)$A$ and may in fact be derived from the latter by putting $x^2 = r^2 - A^2$ and collecting like terms. This change is similar to that used in obtaining (17) and (18), and the formula thus derived has the advantage, already noted in these cases also, of avoiding the possibility of large values of the coil length in the numerators of the terms. In (22) $A^2/r^2$ is always less than unity.

Similarly, by multiplying equation (21) by $n_1$, a second formula for the mutual inductance of solenoid and coaxial circle is found, which is suitable for short coils, and those cases where the radii are nearly equal. This formula is believed to be new. The fact that (21) is unchanged, when $d$ and $D$ are interchanged, furnished a proof of the principle of interchange of lengths in the special cases of solenoid and circle also.

The equations for $m(x)$, derived from (21) and (22), are to be used twice, when the plane of the circle does not pass through the end of the solenoid.

It is desired to make acknowledgment of preliminary investigations on this subject done in connection with thesis work by T. S. Chen at Massachusetts Institute of Technology.

*Example I.* A mutual inductance problem where both (6) and (7) can be used to check each other.

$A = 25$, $m_2 = 3$, $a = 20$, $m_1 = 2$, $s = 30$ (centimeter units).
$x_1 = 35$, $x_2 = 29$, $x_3 = 31$, $x_4 = 25$

$F_{(x_1)}$ by (6) $= 10{,}000\pi\sqrt{12.80}$ [0.0614 + 2.6824 − 0.6290 − 0.7549 + 0.0299 + 0.0058 − 0.0016] = 156700

$F_{(x_1)}$ by (7) $= 20{,}000\,\pi^2$ [1.7205 − 0.0157 + 0.0017 − 0.0007 − 0.0002 + 0.0003 − 0.0001 − 0.0001) + (−1.0000 + 0.0800 + 0.0064 + 0.0013 + 0.0004)]
$= 20{,}000\,\pi^2$ (1.7057 − 0.9119)
$= 156700$

In a case such as this, where both (6) and (7) are applicable, not many significant figures can be obtained. However, if (6) is used for a much smaller value of $x$, or (7) for a larger value, the last terms may be smaller than $10^{-7}$ and so 7 or more significant figures can be obtained.

*Example II.* $Q(x_1)$ for the coils of example I, by (21),

$= 35\,\pi\sqrt{2000}$ [3.721 − 0.411 − 1.994 + 0.002 + 0.029 − 0.009]
$= 6580$

By (22), $Q_{(x_1)} = \frac{2\,\pi^2 \times 400 \times 35}{\sqrt{1850}}$ [1 + 0.0274 − 0.0049 + 0.0029 + 0.0009 − 0.0014 − 0.0002 + 0.0004 + 0.0005 − 0.0004 − 0.0002] = 6580

*Example III. Two concentric, coaxial coils.*

Inner solenoid, $a = 2$, $2m_1 = 2$
Outer solenoid, $A = 10$, $2m_2 = 5$
(Example 39, page 84, Scientific Paper 169)

$\frac{M}{n_1 n_2} = 160\,\pi^2$ (1.055268 − 1.006331) = 77.279 by (7).

Equation (43) of Scientific Paper 169 gives 77.27980. It is a better series for this case, in which the coils are too short for more than 5 significant figures to be given by

(7), and in which $c^2/Dd = 0.8$ is too large for (6) to be used. However, equation (7) is applicable to coils which are not concentric, while (43) is not.

*Example IV. Two concentric, coaxial solenoids.*

Inner solenoid, $a = 10$, $2m_1 = 20$
Outer solenoid, $A = 15$, $2m_2 = 200$
(Example 43, page 91, Scientific Paper 169)

$$\text{By (7)}, \quad F(110) = 3000\,\pi^2\,(7.401200 - 0.000137 + 0.000001)$$
$$= 3000\,\pi^2 \times 7.401064$$
$$F(90) = 3000\,\pi^2\,(6.082762 - 0.000247 + 0.000001)$$
$$= 3000\,\pi^2 \times 6.082516$$
$$\frac{M}{n_1 n_2} = 6000\,\pi^2\,(7.401064 - 6.082516)$$
$$\frac{M}{4\pi n_1 n_2} = 6213.51$$

This agrees with the values given on page 91 of Scientific Paper 169. On page 92, a solution which occupies more than a page, is given by means of (45), page 65 of that paper, which is a formula for 2 coaxial solenoids which may or may not be concentric. As stated on page 91, if a series formula can give the accuracy required, it is usually preferable to (45). It is evident that, by using more terms of (7) of this paper, more than 6 significant figures could be obtained in this case.

*Example V.* As an example of the use of formula (19) there may be taken the case where

$a = 2$, $A = 3$, $2m_1 = 10$, $2m_2 = 6$, $s = 18$

Assuming further that $n_1 = n_2 = 10$ it follows that the coils have 100 turns and 60 turns, respectively.

$q_1 = 15$, $q_2 = 21$, $\delta^2 = 29$

Then (19) gives

$$M = \frac{7.776\,\pi^2\,10^6}{(315)^2}\,[1 + 0.102358 - 0.002076 - 0.001099 \ldots]$$
$$= 850.17$$

A more convergent series is obtained if the lengths are interchanged, giving

$2m_1 = 6$, $2m_2 = 10$, $s = 18$, $q_1 = 13$, $q_2 = 23$, and $\delta^2 = 13$.

The mutual inductance is then

$$M = \frac{7.776\,\pi^2\,10^6}{(299)^2}\,[1 - 0.005855 - 0.004150 + 0.000392 + \ldots]$$
$$= 850.19$$

If the solution be carried through by (18), $M = 8{,}000\,\pi^2\,[0.989447 - 0.978679] = 850.21$ with $2m_1 = 10$ and $2m_2 = 6$, and if the lengths be interchanged,

$n = 4800\,\pi^2\,[0.991508 - 0.973561] = 850.22$

## Appendix

### Formulas From the Bureau of Standards Collection for the Calculation of Inductance (Scientific Paper 169)

Formulas quoted in this paper are here collected for easy reference.

MUTUAL INDUCTANCE OF COAXIAL CIRCLES

Placing
$a$ = the smaller radius
$A$ = the larger radius
$c = A - a$ = the difference of the radii
$x$ = the distance between their planes

$$r^2 = c^2 + x^2 \text{ and } \alpha^2 = \frac{r^2}{Aa},$$

then Maxwell's series formula, extended by Rosa and Cohen, is

$$M = 4\pi a\left\{\log\frac{8a}{r}\cdot\left(1 + \frac{c}{2a} + \frac{c^2+3x^2}{16a^2} - \frac{c^2+3cx^2}{32a^3} + \frac{17c^4+42c^2x^2-15x^4}{1024a^4} - \ldots\right) - \left(2 + \frac{c}{2a} - \frac{3c^2-x^2}{16a^2} + \frac{c^3-6cx^2}{48a^3} + \frac{19c^4+534c^2x^2-93x^4}{6144a^4} - \ldots\right)\right\} \quad (14A)$$

If the circles are in the same plane, $x = 0$, and this becomes

$$M = 4\pi a\left\{\log\frac{8a}{c}\cdot\left(1 + \frac{c}{2a} + \frac{c^2}{16a^2} - \frac{c^3}{32a^3} + \frac{17}{1024}\frac{c^4}{a^4} - \ldots\right) - \left(2 + \frac{c}{2a} - \frac{3}{16}\frac{c^2}{a^2} + \frac{c^3}{48a^3} + \frac{19}{6144}\frac{c^4}{a^4} - \ldots\right)\right\} \quad (15A)$$

A formula derived from series expansions of certain integrals by Havelock reads

$$M = 4\pi\sqrt{Aa}\left[\left(1 + \frac{3}{16}\alpha^2 - \frac{15}{1024}\alpha^4 + \frac{35}{(128)^2}\alpha^6 - \frac{1575}{2(128)^3}\alpha^8 + \ldots\right)\log\frac{8\sqrt{Aa}}{r} - \left(2 + \frac{\alpha^2}{16} - \frac{31}{2048}\alpha^4 + \frac{247}{6(128)^2}\alpha^6 - \frac{7795}{8(128)^3}\alpha^8 + \ldots\right)\right] \quad (16A)$$

This gives very accurate results for values of $x$ almost as great as the smaller radius. For a given degree of convergence it requires only half as many terms to be calculated as does formula (14)$A$.

MUTUAL INDUCTANCE OF
A SOLENOID AND A CIRCLE IN ITS END PLANE

The mutual inductance of a solenoid of $N$ turns, radius $A$, and axial length $x$, and a circle of radius $a$ in its end plane may be found from Rosa's formula:

$$M = \frac{2\pi^2 a^2 N}{\rho}\left[1 + \frac{3}{8}\frac{a^2A^2}{\rho^4} + \frac{5}{64}\frac{a^4A^4}{\rho^8}X_2 + \frac{35}{512}\frac{a^6A^6}{\rho^{12}}X_4 + \frac{63}{1024}\frac{a^8A^8}{\rho^{16}}X_6 + \frac{231}{4096}\frac{a^{10}A^{10}}{\rho^{20}}X_8 + \frac{429}{8192}\frac{a^{12}A^{12}}{\rho^{24}}X_{10} + \ldots\right] \quad (56A)$$

in which $\rho^2 = x^2 + A^2$

and

$$X_2 = 3 - 4\frac{x^2}{A^2}$$

$$X_4 = \frac{5}{2} - 10\frac{x^2}{A^2} + 4\frac{x^4}{A^4}$$

$$X_6 = \frac{35}{16} - \frac{35}{2}\frac{x^2}{A^2} + 21\frac{x^4}{A^4} - 4\frac{x^6}{A^6}$$

$$X_8 = \frac{63}{32} - \frac{105}{4}\frac{x^2}{A^2} + 63\frac{x^4}{A^4} - 36\frac{x^6}{A^6} + 4\frac{x^8}{A^8}$$

$$X_{10} = \frac{231}{128} - \frac{1155}{32}\frac{x^2}{A^2} + \frac{1155}{8}\frac{x^4}{A^4} - 165\frac{x^6}{A^6} + 55\frac{x^8}{A^8} - 4\frac{x^{10}}{A^{10}}$$

and the general term for the coefficients $X_{2n}$ is

$$X_{2n} = \sum_{p=0}^{n}\frac{(-1)^{n-p}(2n+1)2n(2n-1)\ldots[2n-(2p-2)]}{\left(\frac{p+1}{4}\right)[2.4.6\ldots(2p)]^2}\left(\frac{x}{A}\right)^{2n-2p}$$

when $p = 0$, the term being $4(-1)^n(x/A)^{2n}$.

### Mutual Inductance of Concentric Coaxial Solenoids

Let the radius, axial length, and number of turns for the outer solenoid be $A$, $2m_2$, and $N_2$, and the corresponding quantities for the inner solenoid $a$, $2m_1$, and $N_1$. (This is a special case of figure 1 with $s = 0$.)

Then, if the length of the outer solenoid be greater than that of the inner, the mutual inductance may be calculated by Searle and Airey's formula:

$$M = \frac{2\pi^2 a^2 N_1 N_2}{\rho}\left[1 + \frac{1}{8}\frac{A^2a^2}{\rho^4}\cdot L_2 + \frac{1}{32}\frac{A^4a^4}{\rho^8}\cdot X_2L_4 + \frac{1}{32}\frac{A^6a^6}{\rho^{12}}\cdot X_4L_6 + \frac{1}{32}\frac{A^8a^8}{\rho^{16}}\cdot X_6L_8 + \ldots + \frac{1}{32}\left(\frac{Aa}{\rho^2}\right)^{2n}\cdot X_{2n-2}L_{2n} + \ldots\right] \quad (43A)$$

in which $\rho^2 = m_2^2 + A^2$, and the quantities $X_{2n}$ are derived from the corresponding coefficients in (56)$A$, with $m_2$ in place of $x$, and the coefficients $L_{2n}$ from the substitution of $m_1$ in place of $x$, and $a$ for $A$, in the same equations. Thus

$$L_2 = 3 - 4\frac{m_1^2}{a^2} \qquad X_2 = 3 - \frac{4m_2^2}{A^2}$$

$$L_4 = \frac{5}{2} - 10\frac{m_1^2}{a^2} + 4\frac{m_1^4}{a^4} \qquad X_4 = \frac{5}{2} - 10\frac{m_2^2}{A^2} + \frac{4m_2^4}{A^4}$$

This formula is very convergent, except for coils of nearly equal radii and of lengths which are short, compared with their radii.

For long coils, the coefficients $X_{2n}$ and $L_{2n}$ oscillate between large positive and negative values, rendering it difficult to be sure of the degree of convergence attained.

*Rôiti's Formula.* With the same nomenclature but with

$$\rho_1^2 = (m_2 - m_1)^2 + A^2 \quad \text{and} \quad \rho_2^2 = (m_2 + m_1)^2 + A^2$$

this formula may be written

$$M = 4\pi^2 a^2 n_1 n_2\left[(\rho_2 - \rho_1) + \frac{a^2A^2}{8}\left(\frac{1}{\rho_1^3} - \frac{1}{\rho_2^3}\right) - \frac{a^4A^2}{16}\left(\frac{1}{\rho_1^5} - \frac{1}{\rho_2^5}\right) + \frac{5}{64}a^4A^4\left(1 + \frac{1}{2}\frac{a^2}{A^2}\right)\left(\frac{1}{\rho_1^7} - \frac{1}{\rho_2^7}\right) - \frac{35}{256}a^6A^4\left(1 + \frac{1}{5}\frac{a^2}{A^2}\right)\left(\frac{1}{\rho_1^9} - \frac{1}{\rho_2^9}\right) + \frac{105}{1024}a^6A^6 \times \left(1 + \frac{9}{5}\frac{a^2}{A^2} + \frac{1}{5}\frac{a^4}{A^4}\right)\left(\frac{1}{\rho_1^{11}} - \frac{1}{\rho_2^{11}}\right) - \frac{693}{2048}a^8A^6 \times \left(1 + \frac{2}{3}\frac{a^2}{A^2} + \frac{1}{21}\frac{a^4}{A^4}\right)\left(\frac{1}{\rho_1^{13}} - \frac{1}{\rho_2^{13}}\right) + \frac{3003}{16384}a^8A^8 \times \left(1 + 4\frac{a^2}{A^2} + \frac{10}{7}\frac{a^4}{A^4} + \frac{1}{14}\frac{a^6}{A^6}\right)\left(\frac{1}{\rho_1^{15}} - \frac{1}{\rho_2^{15}}\right) - \ldots\right] \quad (39A)$$

*Maxwell's Formula for Concentric Solenoids of Equal Lengths.* Let the common length be $2m$, and the winding densities, in turns per centimeter, $n_1$ and $n_2$. Then, with $\rho^2 = (2m)^2 + A^2$

$$M = 4\pi^2 a^2 n_1 n_2[2m - 2A\alpha]$$

in which

$$\alpha = \frac{A - \rho + 2m}{2A} - \frac{a^2}{16A^2}\left(1 - \frac{A^3}{\rho^3}\right) - \frac{a^4}{64A^4}\left(\frac{1}{2} + 2\frac{A^5}{\rho^5} - \frac{5}{2}\frac{A^7}{\rho^7}\right) - \frac{35}{2048}\frac{a^6}{A^6}\left(\frac{1}{7} - \frac{8}{7}\frac{A^7}{\rho^7} + 4\frac{A^9}{\rho^9} - 3\frac{A^{11}}{\rho^{11}}\right) - \frac{63}{2(128)^2}\frac{a^8}{A^8}\left(\frac{5}{9} + \frac{64}{9}\frac{A^9}{\rho^9} - 48\frac{A^{11}}{\rho^{11}} + 88\frac{A^{13}}{\rho^{13}} - \frac{143}{3}\frac{A^{15}}{\rho^{15}}\right) - \frac{231}{(512)^2}\frac{a^{10}}{A^{10}}\left(\frac{7}{11} - \frac{128}{11}\frac{A^{11}}{\rho^{11}} + 128\frac{A^{13}}{\rho^{13}} - 416\frac{A^{15}}{\rho^{15}} + 520\frac{A^{17}}{\rho^{17}} - 221\frac{A^{19}}{\rho^{19}}\right) - \frac{429}{2(1024)^2}\frac{a^{12}}{A^{12}}\left(\frac{21}{13} + \frac{512}{13}\frac{A^{13}}{\rho^{13}} - 640\frac{A^{15}}{\rho^{15}} + 3200\frac{A^{17}}{\rho^{17}} - 6800\frac{A^{19}}{\rho^{19}} + 6460\frac{A^{21}}{\rho^{21}} - 2261\frac{A^{23}}{\rho^{23}}\right) \ldots \quad (36A)$$

In this expression the general term of the series in powers of $a^2/A^2$ is, as was shown by Havelock,

$$-\frac{(2n-1)[1.3.5\ldots(2n-3)]^2}{2^{2n+1}n!\,(n+1)!}\left(\frac{a}{A}\right)^{2n}$$

*Gray's Formula.* Gray gave the following formula for the mutual inductance of coaxial solenoids, not concentric. With the notation of figure 1 and

$$q_1 = s - m_2,\ q_2 = s + m_2,\ d_1^2 = A^2 + q_1^2,\ d_2^2 = A^2 + q_2^2$$

Gray's formula becomes

$$M = \pi^2 a^2 A^2 n_1 n_2[K_1k_1 + K_3k_3 + K_5k_5 + \ldots] \quad (40A)$$

in which

$$K_1 = \frac{2}{A^2}\left(\frac{q_2}{d_2} - \frac{q_1}{d_1}\right)$$

$$K_3 = \frac{1}{2}\left(\frac{q_1}{d_1^3} - \frac{q_2}{d_2^3}\right)$$

$$K_5 = -\frac{A^2}{8}\left\{\frac{q_1}{d_1^9}\left(3 - 4\frac{q_1^2}{A^2}\right) - \frac{q_2}{d_2^9}\left(3 - 4\frac{q_2^2}{A^2}\right)\right\}$$

$$k_1 = 2m_1$$

$$k_3 = -a^2m_1\left(3 - 4\frac{m_1^2}{a^2}\right)$$

$$k_5 = a^4m_1\left(\frac{5}{2} - 10\frac{m_1^2}{a^2} + 4\frac{m_1^4}{a^4}\right)$$

### Mutual Inductance by Means of Self-Inductance Formulas

The mutual inductance of 2 coils having the same radii and the same number of turns per unit length may be calculated from a knowledge of several self-inductances.

If the 2 coils be designated as $A$ and $B$, and a coil $C$, having the same radius and winding density, be imagined to exactly fill up the space between $A$ and $B$, the inductance of coils $A$, $B$, and $C$ in series will be

$$L_{ABC} = L_A + L_B + L_C + 2M_{AC} + 2M_{BC} + 2M_{AB}$$

Similarly, the self inductance of the coils $A$ and $C$ in series, and of $B$ and $C$ in series, are given by

$$L_{AC} = L_A + L_C + 2M_{AC}$$
$$L_{BC} = L_B + L_C + 2M_{BC}$$

Eliminating $M_{AC}$ and $M_{BC}$ in the equation above, we find

$$2M_{AB} = (L_{ABC} + L_C) - (L_{AC} + L_{BC}) \quad (51A)$$

If the radii of the 2 coils are equal but their winding densities $n_1$ and $n_2$ are unequal, the expression (51)$A$ may first be calculated, assuming unit winding density on each coil. The result so found, multiplied by $n_1n_2$, is the desired mutual inductance.

The self-inductances in (51)$A$ may, in general, be calculated by Nagaoka's formula and tables. For a coil of $N$ turns, whose axial length $2m$ does not exceed its radius $a$, Coffin's extension of the Rayleigh and Niven formula is accurate and convenient.

$$L = 4\pi aN^2\left\{\log\frac{8a}{2m} - \frac{1}{2} + \frac{1}{8}\frac{m^2}{a^2}\left(\log\frac{8a}{2m} + \frac{1}{4}\right) - \frac{1}{64}\frac{m^4}{a^4}\left(\log\frac{8a}{2m} - \frac{2}{3}\right) + \frac{5}{1024}\frac{m^6}{a^6}\left(\log\frac{8a}{2m} - \frac{109}{120}\right) - \frac{35}{16384}\frac{m^8}{a^8}\left(\log\frac{8a}{2m} - \frac{431}{420}\right) + \ldots\right\} \quad (71A)$$

# An Analysis of Copper-Oxide Rectifier Circuits

By P. O. HUSS
ASSOCIATE AIEE

## Summary

THE analysis of circuits containing copper-oxide rectifiers is based upon the selection of a proper representation of the variable impedance of the rectifier element. In this analysis, the element is replaced by 2 constant resistances effective during the 2 directions of current flow through the rectifier. On the basis of this representation, an equivalent circuit is developed, which is a modification of the usual perfect rectifier circuit. The method is illustrated by analyzing circuits in which the loads consist of resistance and inductance and of resistance and capacitance. The computed results are then compared with observations made by an oscillograph.

## Introduction

Copper-oxide rectifiers are finding greater use in connection with measurement of alternating voltages and currents. This is particularly true in connection with special electrical instruments designed to measure physical quantities such as motion, pressure, etc. It is often desirable to analyze the circuit in order to predict its operation, but the usual assumption, neglecting rectifier imperfections, is frequently not sufficiently accurate.

This paper presents an approximate representation of the copper-oxide rectifier, taking into account its asymmetrical conduction properties. Two constant resistances are introduced, to represent the direct and inverse properties of the real rectifier. Using this approximation, an equivalent circuit is established.

A general discussion of the methods used to analyze circuits, consisting of copper-oxide rectifiers is given, together with a consideration of the circuits for which the rectifier conducts during only part of the cycle. The analysis is made on the assumptions that the applied voltage is sinusoidal with a constant maximum value, and that the successive half-waves are identical.

Circuits of resistance, resistance and inductance, and capacitance in parallel with resistance, are analyzed to show the application of the method presented in this paper. The circuits are also analyzed for the usual idealization of perfect rectifiers. The theoretical wave forms computed by each of these 2 methods is compared with the results obtained by an oscillographic study of an example of each type of load mentioned. The measurements included in this paper were made on commercial rectifiers and are included only as illustrations of the method of circuit analysis.

A paper recommended for publication by the AIEE committee on electrophysics. Manuscript submitted March 10, 1936; released for publication January 15, 1937.

P. O. Huss is research associate at the University of Michigan, Ann Arbor.

## The Rectifier Element

Grondahl[1,2] has given an excellent description of the copper-oxide rectifier and its construction, together with an explanation of some of its properties. The rectifier element consists of a disk of copper upon one side of which an oxide has been formed by heat treatment. Rectification takes place in the area of contact between the copper and its oxide, because the impedance to current flow from oxide to copper is low, while the impedance to current flow, in the opposite direction, is high.

The difference in impedance for the 2 directions of flow presents a problem which has no simple solution, but which is, nevertheless, of much importance. Without an analytical approach, it would be necessary to make an oscillographic study of wave form to determine the behavior of each new circuit. It is desirable to obtain a method of computing results to be anticipated for a given circuit, so that the oscillographic study can be eliminated. This is especially true in the design of instruments using rectifiers.

For circuit analysis, the rectifier must be replaced by some combination of standard impedances. Deutschmann and Schottky[3] presented 4 types of equivalent combinations, of which pure resistance is the simplest, yet representative for many applications. This resistance is a variable depending upon the voltage applied to the rectifier element. The type of variation is shown in figure 1, but actual values will differ depending upon the kind of rectifier and size of disk.

Since the resistance varies continually during the cyclic change of current and voltage, an exact analysis is quite difficult. As an approximation, Cremer[4] replaced the changing resistances by 2 constant values, $D$ and $S$, where $D$ represents an equivalent constant value for current flow from oxide to copper, and $S$ an equivalent constant value for current flow in the opposite direction. These approximations are used in this paper to simplify the study of rectifier circuits. The term "constant rectifier" refers to one in which the approximation of 2 constant resistances is used. A "perfect rectifier" is one in which $D$ is zero and $S$ is infinite.

## Full-Wave Rectifier Circuits

There are 2 standard circuits used to obtain full wave rectification, the transformer bridge and the Graetz bridge, shown in figure 2. The choice between them depends upon the relative cost of rectifier elements and transformer, and also on certain conditions peculiar to

the special problem. Unless otherwise stated, this paper deals with the Graetz bridge only.

The rectifiers in the bridge of figure 2*b* may be replaced by the approximate equivalent resistances, $D$ and $S$, for direct and inverse impedances, respectively, and an alternating voltage of constant maximum value applied. When $a$ has a positive potential, current flows from $a$ to $c$. Rectifiers in legs $ab$ and $dc$ are conducting and are represented by the constant direct resistance, $D$. Rectifiers in legs $bc$ and $ad$ are opposing the flow of current and are represented by the constant inverse resistance, $S$. During the next half-cycle, when $c$ is positive, current flows from $c$ to $a$, opposite to the direction in the previous half-cycle. Thus rectifiers in legs $ab$ and $dc$ now oppose the flow of current and are represented by $S$, while those in legs $bc$ and $ad$ are conducting and are represented by $D$.

If the rectifiers may be assumed to have like characteristics, the entire behavior can be described by one half-cycle. This assumption simplifies the discussion and is

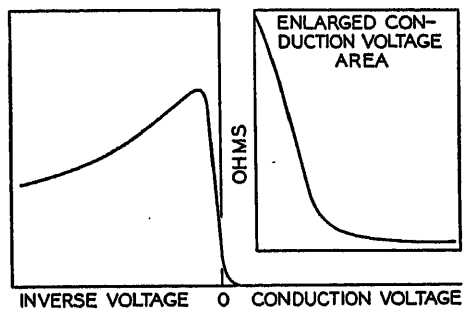

**Fig. 1. Copper-oxide rectifier resistance variation**

used here. Thus the analysis is confined to the half-cycle of voltage, where $a$ is positive, the next half-cycle assumed identical to it.

Analysis of the Graetz bridge circuit of circuits *abc*, *abdc*, and junction $b$ in figure 2*b*, yields the equations

$$Di_D + Si_S = e$$
$$2Di_D + e_L = e$$
$$i_L = i_D - i_S$$

Combining the first and third, gives

$$i_D = \frac{e + Si_L}{D + S} \quad \text{and} \quad i_S = \frac{e - Di_L}{D + S}$$

Substitution of $i_D$ in the second equation above, gives the basic Graetz bridge equation

$$\phi e = e_L + Pi_L \tag{1}$$

where

$$P = \frac{2DS}{D + S} \quad \text{and} \quad \phi = \frac{S - D}{S + D}$$

An equivalent circuit, to represent the constant rectifier with load, can be set up from equation 1. The load current, $i_L$, for a constant rectifier, may be found by adding a resistance, $P$, in series with a perfect rectifier, having the same load, and applying a voltage $\phi e$ to the resulting circuit. This substitution is used here to solve the constant rectifier problem. A circuit of this kind is shown in figure 4*c*.

Applying similar analysis to the transformer bridge in figure 2*a*, the analogous equations become

$$i_D = \frac{2e + Si_L}{D + S}; \quad i_S = \frac{2e - Di_L}{D + S}; \quad \phi e = \frac{P}{2} i_L + e_L$$

where $P$ and $\phi$ are the same as defined above. Thus the constant transformer bridge can be represented by a perfect rectifier bridge with a series resistance, $P/2$, and a voltage $\phi e$ applied to the system.

## Determination of Equivalent Resistances

Even if the curve of d-c values of figure 1 were known, the equivalent dynamic values, $D$ and $S$, could not be easily established and so some method of direct measurement is desirable.

These constants may be determined by 2 sets of measurements on the Graetz bridge. Using the assembled rectifier bridge, measure the alternating current and voltage with effective value meters, for these 2 conditions: (*a*) d-c load terminals open, and (*b*) d-c load terminals shorted. Call the impedance from the first measurement, the open-circuit impedance, $Z_o$, and the impedance from the second measurement, the short-circuit impedance, $Z_s$. Study of the parallel impedances of figure 3 shows that

$$Z_o = \frac{D + S}{2} \approx \frac{S}{2} \quad \text{and} \quad Z_S = \frac{2DS}{D + S} = P$$

Since $S$ is much greater than $D$, the following definitions hold,

$$S \approx 2Z_o; \qquad D \approx P/2; \qquad \phi = \frac{S - D}{S + D} = 1 - \frac{P}{S}$$

$Z_s = P$ is concerned primarily with rectifier conduction, and so in use depends upon the current, while $Z_o$ is concerned primarily with the inverse or leakage characteristic of the rectifier and in use depends upon the voltage.

For any given case, the values of $P$ and $S$ can be found from graphs similar to figure 3, the value of line current determining $P$, and the line voltage determining $S$.

Some precautions must be taken in the measurement of $Z_o$ to obtain consistent and reliable results. A fairly good set of measurements can be obtained by taking the readings with decreasing voltages, controlling the voltage by a tapped transformer rather than with a potentiometer.

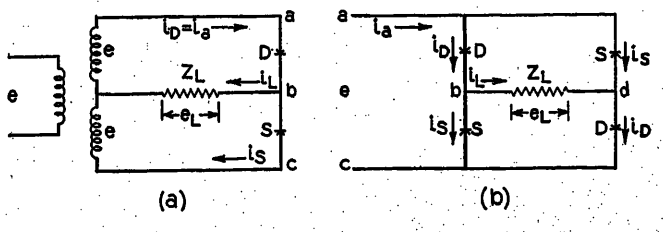

**Fig. 2. Full-wave rectifier circuits**

*a*—Transformer bridge *b*—Graetz bridge

## Analysis of Rectifier Circuits With D-C Loads

Now that the equivalent circuit for the constant rectifier has been established, and an experimental means for finding $P$ and $\phi$ has been presented, a few typical circuits will be analyzed to show the application of equation 1. Comparison of the wave forms obtained by this method will be made with the wave forms obtained by oscillographic study of the circuit. The analysis of these loads will also be made assuming a perfect rectifier, for the purpose of comparing results with those obtained by the constant rectifier method.

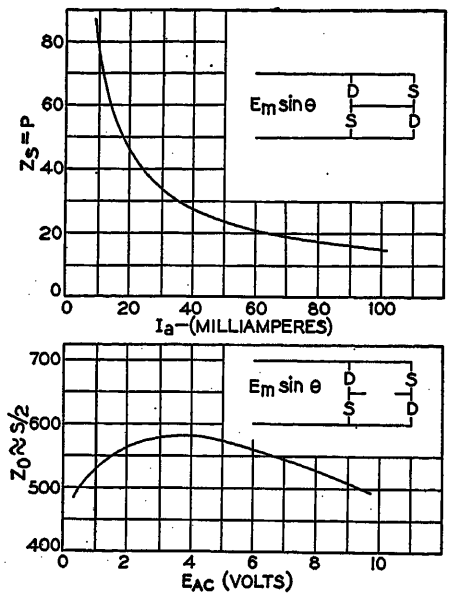

**Fig. 3. Equivalent resistance determination**

Several studies of perfect rectifier circuits have been published. The reader is referred to the series methods presented by Wheatcroft[5] and by Stout.[6] A filter circuit study was made by Lee[7] and the equations for a thyratron rectifier were given by Cockrell.[8]

Distinction must be made, in rectifier work, between 2 kinds of loads;

*a.* Loads for which rectifier conducts during the entire half-cycle. Most of the loads under this group are resistance and inductance in series or pure resistance, but some arrangements of capacitance in parallel with series inductance and resistances fall into this group. A discussion of a load of resistance and inductance in series is presented to illustrate this type.

*b.* A second group of loads are those having parallel capacitance of such magnitude that the load current tends to become negative during the half-wave, with the result that the rectifier stops conducting and a cut-off period must be studied in addition to the usual conduction period. A discussion of this type of load follows and the case of resistance and capacitance in parallel illustrates this kind of load.

The circuit analyses in this paper are made with the following assumptions:

1. The impressed alternating voltage is sinusoidal with a constant maximum value, $e = E_m \sin \omega t = E_m \sin \theta$.

2. It is assumed that the system has been in operation for sufficient time so that a steady state has been reached.

3. The successive half-waves are identical. All wave-forms and developments are based on the half-cycle, $\theta = 0$, to $\theta = \pi$.

4. Since the successive half-waves are identical, the currents must have the same value at $\theta = 0$ as at $\theta = \pi$.

## Load of Resistance and Inductance in Series

As mentioned above, a load of resistance and inductance in series is an example of the group in which the rectifier conducts during the entire half-cycle. See figure 4 for the circuits for this type of load.

### Perfect Rectifier

Refer to figure 4*b* for the equivalent circuit for this case. The rectifier impedance is zero and so the current solution is obtained by applying the voltage directly to the load. The equation for this case is

$$Ri_L + L\frac{di_L}{dt} = E_m \sin\theta$$

which has the solution

$$i_L = K_1 \epsilon^{-a\theta} + K_2 \sin\theta + K_3 \cos\theta$$

where $a = R\omega/L$. $K_1$ is obtained from the condition that $i_L$ is the same for $\theta = 0$ and $\theta = \pi$. $K_2$ and $K_3$ are known from the steady state of the inductive circuit for alternating voltage, so that

$$K_1 = \frac{\omega L E_m}{R^2 + (\omega L)^2} \frac{2}{1 - \epsilon^{-a\pi}}; \quad a = \frac{R}{\omega L}$$

$$K_2 = \frac{RE_m}{R^2 + (\omega L)^2}; \quad K_3 = \frac{-\omega L E_m}{R^2 + (\omega L)^2}$$

### Constant Rectifier

Refer to figure 4*c*. Equation 1 and its discussion show that the constant rectifier can be represented by a perfect rectifier with a series resistance, $P$, and a modified voltage, $\phi e$. Thus the same equations that were developed for the perfect rectifier are valid, except that the

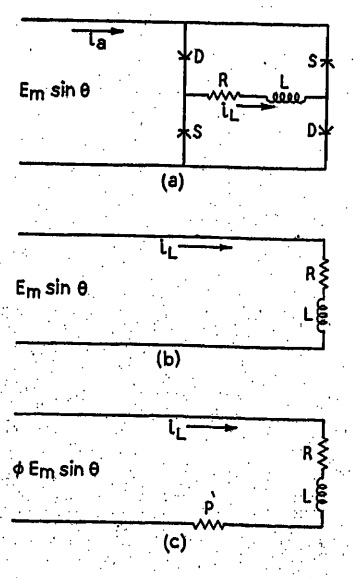

**Fig. 4. Graetz bridge circuits for resistance and inductance in series**

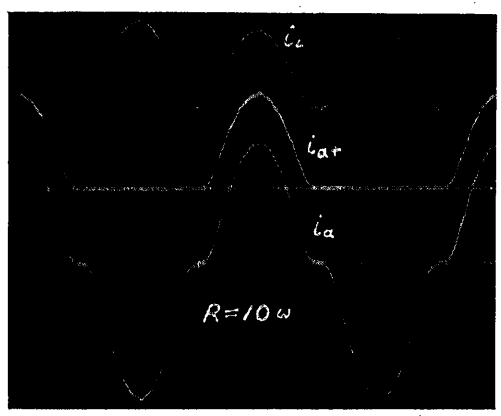
*a*—Conventional circuit, first half-wave

*b*—Equivalent circuit for perfect rectifier

*c*—Equivalent circuit for constant rectifier

resistance term, $R$, is replaced by the term $(R + P)$. Thus we can write the coefficients directly

$$K_1 = \frac{\omega L \phi E_m}{(R+P)^2 + (\omega L)^2} \frac{2}{1 - \epsilon^{-a\pi}}; \quad a = \frac{R+P}{\omega L}$$



$$K_3 = -\frac{\omega L \phi E_m}{(R+P)^2 + (\omega L)^2}; \quad K_2 = \frac{(R+P)^2 \phi E_m}{(R+P)^2 + (\omega L)^2}$$

For resistance only the equations become

$$i_L = \frac{E_m}{R} \sin\theta, \text{ for perfect rectifier}$$

$$i_L = \frac{\phi E_m}{R+P} \sin\theta, \text{ for constant rectifier}$$

Figures 5 and 6 show the comparison of wave-forms computed from the above formulas, with an observed wave-form obtained from loads of resistance and from resistance and inductance in series. Figure 5*a* shows that the computed forms differ from the observed, but the constant rectifier method gives a much closer approximation than the perfect rectifier, the reason being that the load is of the same order of magnitude as the direct resistance of the rectifier and so the rectifier resistance cannot be neglected. A similar discrepancy will be found if the load is of the same order of magnitude as the inverse resistance of the rectifier, in which case the assumption of infinite resistance is in error.

## Circuits That Have Cut-Off

For the group of loads having a cut-off period, the load current tends to become negative at some point in the cycle. The rectifier does not allow this and so a different type of behavior takes place during the rest of the cycle. These loads have 2 or more paths in parallel, one or more of which contain capacitance. A typical circuit of this type is shown in figure 8*a*.

Reference to figure 7 will aid the following discussion. Begin consideration sometime during the conduction period, when the voltage $e$ is the voltage applied to the load, and the circuit follows its normal a-c behavior until $\theta_2$ is reached. At that point the current through leg $D$ reaches zero due to the fact that the condenser discharge becomes sufficient to supply the load.

After $\theta_2$, the current through leg $D$ reverses and legs $ab$ and $dc$ change their characteristic from $D$ to $S$. Legs $bc$ and $ad$ retain their $S$ characteristic since they experience no change in current direction. The circuit is now that for cut-off as shown in figure 8*d*. This cut-off period begins at $\theta_2$, the cut-off angle. Its significance can be most easily seen in the case of a perfect rectifier where $S$ is infinite. At $\theta_2$, the condenser has a charge corresponding to that voltage ($q = CE_m \sin\theta_2$) which must discharge through the resistance path, since the impedance in the outer circuit is infinite, or open circuited. This discharge continues until the voltage across it dies down to the voltage of the next oncoming sine wave, defined

as the cut-in angle at $\theta = \theta_1 + \pi$. At this point the condenser ceases to discharge and again charges according to sine voltage behavior. Thus the conduction period, or normal a-c behavior, continues from $\theta_1$ to $\theta_2$, and the cut-off period, or discharge of condenser, is from $\theta_2$ to $\theta_1 + \pi$.

The discharge path in the constant rectifier case is the resistance branch in parallel with an $S$ combination, shown in figure 8*f*. At $\theta_1$ the legs $ab$ and $dc$ change their characteristic behavior from $S$ to $D$ and at $\theta_2$ change back from $D$ to $S$. Since this change is caused by a reversal of the current through these legs, the current must be equal to zero at the instant of change. But this current is $i_D$. Therefore $\theta_1$ and $\theta_2$ are defined as the values of $\theta$ when $i_D$ equals zero. Since $i_D$ equals zero, it can be seen that $e = e' = e_L$ at $\theta = \theta_1$ and $\theta = \theta_2$. This is a basic fact in solution for the current equations in these circuits.

A uniform procedure in problems of this type is given below and is further illustrated in the circuits following:

1. Set up the differential equation of the circuits for conduction and cut-off periods to obtain the general form of the currents, as well as the exponents of the transient terms.

2. Determine the steady state coefficients using the bridge equation 1 and other usual methods used in circuit analysis, such as parallel relations between the two load branches.

3. Determine the cut-off angle, using the definition that $i_D = 0$. It is necessary to assume that the transient term for the conduction section is zero at cut-off to facilitate solution. This assumption is quite reasonable since $\epsilon^{-a\theta}$ is usually a large damping factor which reduces the transient term to a small quantity by the time $\theta_2$ is reached.

4. Determine the coefficients for the cut-off period using conditions of continuity, voltage equality, or others, at $\theta_2$ and circuit relations during the cut-off period.

5. From conditions existing at $\theta_1 + \pi$ determine the value of the cut-in and the values of the transient term constants. It will be necessary to solve some of these equations by trial since they involve trigonometric and exponential terms.

6. Now knowing the transient term, check back and revise the cut-off angle, if necessary. (The new cut-off solution may be a trial solution.) Then repeat the steps 4 and 5, using the transient term as obtained. Continue until the desired accuracy is reached. Usually the revision produces but minor changes in the values. For simple circuits a graph or table can be set up giving $\theta_2$ and $\theta_1$ for given load conditions.

## Load of Resistance and Capacitance in Parallel

The load of resistance and capacitance in parallel is the simplest kind of load that falls into the cut-off group. The method of solving this circuit is outlined and the main equations given.

### Perfect Rectifier

The equivalent circuits for this case are shown in figures 8*b* and 8*e*. The circuit equations for the 2 periods are:

During the conduction period:

$$i_R = \frac{E_m}{R}\sin\theta \quad \text{and} \quad i_C = \omega C E_m \cos\theta$$

During the cut-off period,

$$e' = he^{-b\theta} \quad \text{where} \quad b = \frac{1}{\omega CR}$$

$$i_R' = -i_C' = \omega b h e^{-b\theta}; \qquad i_L' = i_D = i_S = 0$$

When $\theta$ equals the cut-off angle, $\theta_2$, $i_D = 0$ and $e = e'$

$$\tan\theta_2 = \omega RC \quad \text{and} \quad he^{-b\theta_2} = \omega C E_m \sin\theta_2$$

At the cut-in angle for the next half-cycle, $\theta = \theta_1 + \pi$, $e = e'$, also $\sin\theta_1 = (\sin\theta_2)e^{-b(\theta_1+\pi-\theta_2)}$

Knowing the coefficient, $h$, the cut-off and cut-in angles,

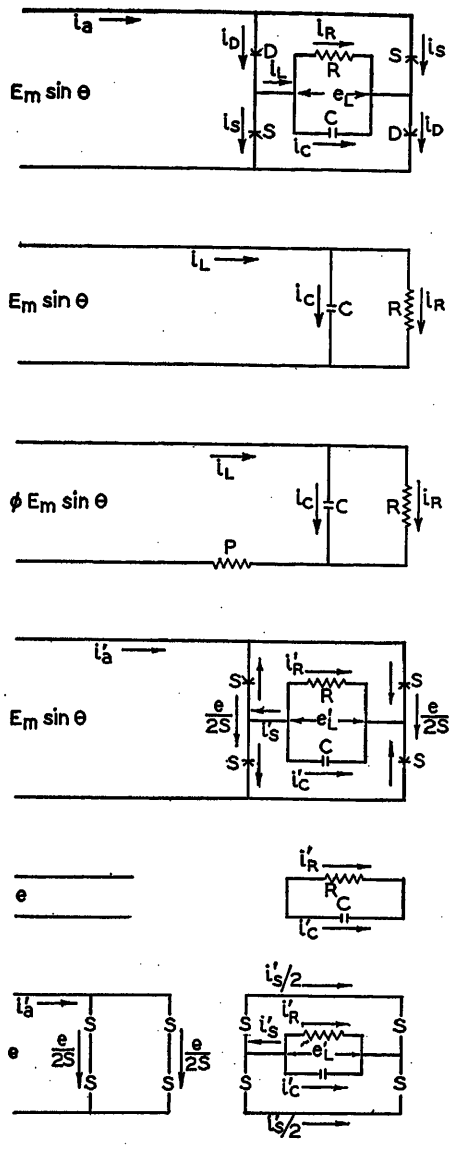

**Fig. 8**

a—Conduction period currents

b—Equivalent circuit for perfect rectifier, during conduction

c—Equivalent circuit for constant rectifier, during conduction

d—Cut-off period currents

e—Equivalent circuits for perfect rectifier, during cut-off

f—Equivalent circuit for constant rectifier, during cut-off

$\theta_2$ and $\theta_1$, the entire circuit behavior is determined for the perfect rectifier.

CONSTANT RECTIFIER

Figure 8*c* again shows the equivalent circuits for this case. The bridge equation 1 for this kind of circuit becomes:

$$e_L = \frac{q}{C} = Ri_R = \phi e - Pi_L$$

during the conduction period. This equation has the solutions

$$q = -\frac{H_1}{\omega a}\epsilon^{-a\theta} - \frac{H_2}{\omega}\cos\theta + \frac{H_3}{\omega}\sin\theta$$

$$i_C = \frac{dq}{dt} = H_1\epsilon^{-a\theta} + H_2\sin\theta + H_3\cos\theta, \text{ where } a = \frac{R+P}{\omega PRC}$$

$$i_R = K_1\epsilon^{-a\theta} + K_2\sin\theta + K_3\cos\theta$$

During cut-off period, see figure 8*f*, the circuit equations are,

$$Ri_R' = Si_S' = \frac{q'}{C}$$

which give

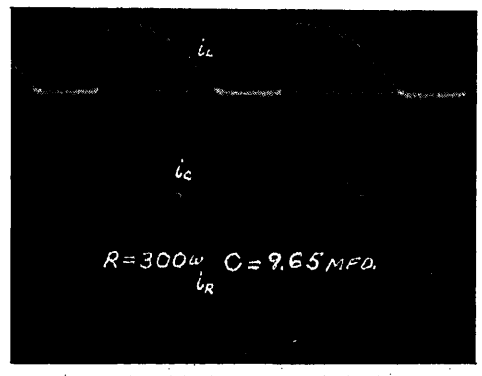
$$q' = h\epsilon^{-b\theta}; \quad i_C' = \omega bh\epsilon^{-b\theta}; \quad i_R' = \frac{h}{RC}\epsilon^{-b\theta}$$

$$i_S' = -i_L' = \frac{h}{SC}\epsilon^{-b\theta}$$

$$b = \frac{R+S}{\omega RCS}$$

$$i_D' = \frac{e}{2S} - i_S'; \quad i_S = \frac{e}{2S} + i_S'$$

Solving for the coefficients results in



$$H_1 = -\omega aRCK_1; \qquad H_2 = -\omega RCK_3; \qquad H_3 = -\omega RCK_2$$

$$K_2 = \frac{(R+P)\phi E_m}{(R+P)^2 + (R\omega CP)^2}$$

$$K_3 = -\frac{\omega RCPE_m}{(R+P)^2 + (\omega RCP)^2}$$

$$h\epsilon^{-b\theta_2} = CE_m \sin\theta_2$$

Assuming that the transient term, $K_1\epsilon^{-a\theta}$, is zero at $\theta = \theta_2$, due to high rate of decay as mentioned in the

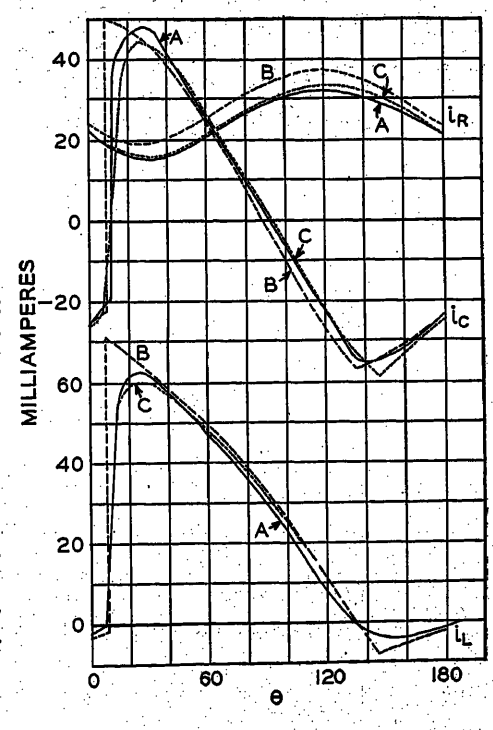


**Fig. 9. Comparison with typical case of resistance and capacitance in parallel**

*A*—Oscillogram

*B*—Perfect rectifier

*C*—Constant rectifier

$R$ = 300 ohms, $C$ = 9.65 microfarads, $E_m$ = 14.1 volts, $\omega$ = 377

method of solution, the condition that $i_D = 0$ at $\theta = \theta_2$, becomes

$$\tan \theta_2 = \frac{\omega RC\,(\phi\, RS)}{(\omega\, RCP)^2 + (R+P)^2 + \phi S(R+P) + \phi SP(\omega RC)^2}$$

which reduces to the perfect rectifier form

$$\tan \theta_2 = -\omega RC$$

for $P = 0$ and $S = \infty$. $H_1$ and $K_1$ can now be determined from the boundary conditions that exist at the cut-in angle, $\theta = \theta_1 + \pi$, namely, $i_D = 0$ and $e' = e_L = e$. Next find $K_1\epsilon^{-a\theta_2}$ to see if further revisions are needed, or if that term is negligible as was assumed in finding $\theta_2$.

Figure 9 shows the relation between the wave-forms observed and those obtained from the equations developed here. The first solution was satisfactory since the transient term became very small at $\theta_2$.

## Load of Capacitance in Parallel With Resistance and Inductance in Series

The solution of more complicated circuits, especially those having cut-off, becomes rather difficult when treated in general form. In a given numerical case the coefficients and exponents can be evaluated as soon as found, thus reducing the length and difficulty of the computations. A common circuit can be obtained by putting inductance in series with the resistance in the previous case. Figure 8 can be likewise modified to fit this case. The method of solving this case for a constant rectifier is outlined here, and the resulting wave-forms compared with an observed wave-form obtained from a typical case, see figure 10.

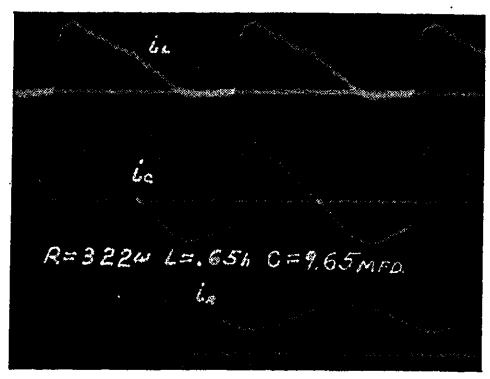
Set up the differential equations for the circuits and solve them for the general form of the current equations for both conduction and cut-off periods. These will be in the form

$$i_C = H_1\epsilon^{m_1\theta} + H_2\epsilon^{m_2\theta} + H_3 \sin\theta + H_4 \cos\theta$$

$$i_R = K_1\epsilon^{m_1\theta} + K_2\epsilon^{m_2\theta} + K_3 \sin\theta + K_4 \cos\theta$$

$$i_C' = h_1\epsilon^{n_1\theta} + h_2\epsilon^{n_2\theta}$$

$$i_R' = k_1\epsilon^{n_1\theta} + k_2\epsilon^{n_2\theta}$$



where

$$m = -\frac{R}{2\omega L} + \frac{1}{2\omega PC} \pm \sqrt{\left(\frac{R}{2\omega L} - \frac{1}{2\omega PC^2}\right) - \frac{1}{\omega^2 LC}}$$

$$n = -\frac{R}{2\omega L} + \frac{1}{2\omega SC} \pm \sqrt{\left(\frac{R}{2\omega L} - \frac{1}{2\omega SC}\right)^2 - \frac{1}{\omega^2 LC}}$$

Assuming the transient terms to be zero at $\theta = \theta_2$, and using the condition that $i_D = 0$, the cut-off angle, $\theta_2$, can be determined. The other coefficients can be found by using circuit relations and boundary conditions existing for the problem at hand. Solution of cut-in angle conditions gives the values of $\theta_1$ and the transient term coefficients.

Knowing the transient terms, check back and find a revised $\theta_2$, using the values found above, instead of zero first assumed. If necessary, repeat the computation for the cut-off currents, revising $\theta_1$ and obtaining a second value for the transient terms, and then a third value of $\theta_2$, etc. The number of repetitions necessary depends upon the accuracy desired. For the comparative curves shown in figure 10, 2 revisions were made, but the first produced the greatest change. In many problems it is possible to stop with the first analysis.

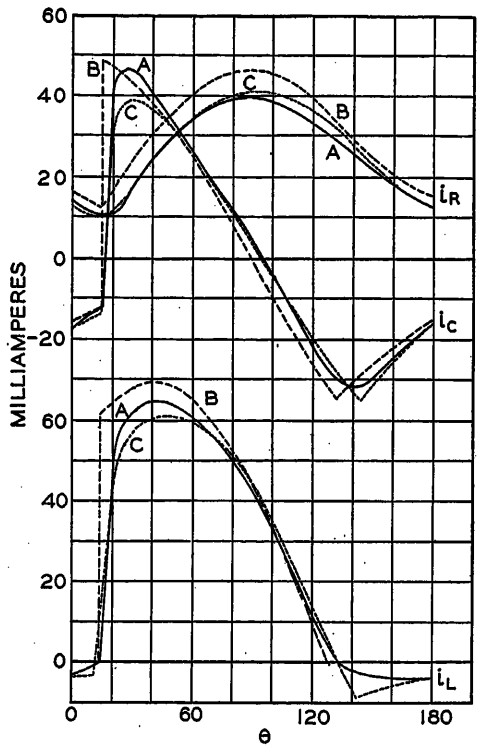


**Fig. 10. Comparison with typical case of resistance and inductance in parallel with capacitance**

*A*—Oscillogram
*B*—Perfect rectifier

$R$ = 322 ohms, $L$ = 0.65 henry, $C$ = 9.65 microfarads, $E_m$ = 14.2 volts, $\omega$ = 377

## Conclusion

This paper has presented a useful method of analyzing the behavior of copper-oxide rectifier circuits. The varying resistance characteristic of the rectifier element is replaced by 2 constant resistances, $D$, effective for direct flow, and $S$, effective for inverse flow. This approximate representation of the rectifier is called the "constant rectifier."

This approach gives solutions of a highly satisfactory degree of accuracy. Under certain load conditions, there

# Effect of Varying Weather Conditions on Energy Required for Traction and Heating of Multiple-Unit Trains

By H. E. PRESTON
NONMEMBER AIEE

THE HEATING of passenger cars electrically together with the additional energy required for traction purposes when cold weather prevails cause increases in operating expenses which are of great importance on the Illinois Central Railroad where power is purchased.

This article deals primarily with the experience of the Illinois Central in operating its electrified suburban service in Chicago during the past 9 years.

Before discussing the accompanying curves which are based on average conditions a brief summary of weather conditions in Chicago and data on the Illinois Central equipment follows.

The daily range of temperature for Chicago is 14 degrees between normal maximum and normal minimum temperatures. The record minimum is −23 degrees and the record maximum is 105 degrees.

The average temperatures for the past 64 years are as follows:

| Jan. | Feb. | Mar. | Apr. | May | June | July |
|---|---|---|---|---|---|---|
| 24.5 | 26.6 | 35.7 | 47.1 | 57.4 | 67.6 | 72.7 |
| **Aug.** | **Sept.** | **Oct.** | **Nov.** | **Dec.** | **Year** | |
| 71.6 | 65.3 | 53.8 | 40.2 | 29.0 | 49.3 | |

The average hourly velocity of the wind in all directions is 11 miles per hour.

The average number of days during the year when the minimum temperature is 32 degrees or below is 108.

The average number of days during the year when the minimum temperature is 0 degrees or below is 8.

During the past 9 years there have been approximately 210 days each year when heating was used on the cars for at least a portion of the day.

There are 280 cars in multiple unit service. All of the cars are heated with electric heaters of the enclosed element type, operating on 1,500 volts direct current, and equipped with thermostatic control set to maintain a temperature of 56 degrees Fahrenheit. The cars have approximately 4,500 cubic feet of air space and seat 84 passengers. Each car is equipped with 29,500 watts in heaters located under the rattan-covered seats. The motorman's cab is equipped with a 3,000-watt heater. The cars are insulated with hairfelt under the composition floors and 3-ply Salamander applied to the sides and roof sheets. Ventilation is provided by monitor sash ventilators.

During the past 9 years there has been an average of 495 scheduled trains daily except Sundays and holidays, and there has been operated an average of 824,000 car miles per month.

The average distance between stops including all classes of service is approximately 0.96 mile.

During the winter season of 1933 a unit of the equipment, comprising a motor car and a trailer car, was equipped with graphic meters which recorded the operations of the heating relay and the current in the traction motors. Integrating meters were also installed on this unit to measure separately the energy used by the traction motors, the air compressor motor, the motor generator set, and the heater circuits. This specially equipped unit was operated in regular service similar to any of the other equipment and a record kept of the meter readings at the conclusion of each trip together with other pertinent data such as, the class of service rendered by the train, the weather conditions and the position of the cars in the train when consisting of more than 2 cars. Personal observations were made at various times to enable an accurate interpretation of the meter readings to be made.

The energy used for traction will be considered for the purposes of this article as including in addition to the energy used by the motors and their control equipment, the total line loss between substations and trains, the energy used by the air compressors, the energy used by the motor generators on the cars which charge the batteries and supply the lighting circuits, and all other d-c output from the substations excepting energy used for heating of the cars.

The relation between average kilowatt-hours per car mile and temperature is shown in curve *A* of figure 1 and was drawn from the d-c substation output load records combined with a daily record of the movement of the cars including the car miles operated.

From the information obtained in the above manner it was found that the increase in kilowatt-hours per car mile over the summer requirement commenced at approximately 60 degrees and between 60 and 45 degrees the increase was due entirely to the heating in the cars. In the kilowatt-hours per car mile-temperature curve it will be noted that at 60 degrees the consumption is 4.30 kilowatt-hours per car mile and at 45 degrees it is 4.73 kilowatt-hours per car mile. For this range of temperature of 15 degrees the difference in consumption is 0.43 kilowatt-hour per car mile and the curve is a straight line. This difference is equivalent to an increase of 0.0286 kilowatt-hour per car mile per degree due to the heating of the cars.

Daily records of the train operations included total car miles operated during the morning and evening peak demand hours and also the length of time the cars were in service during these hours, which gave the total number of "car hours" in service. From this information it was found that with the heaters on continuously the maximum

A paper recommended for publication by the AIEE committee on transportation. Manuscript submitted November 4, 1935; released for publication May 1, 1936.

H. E. PRESTON is power supervisor of the Illinois Central Railroad, Chicago.

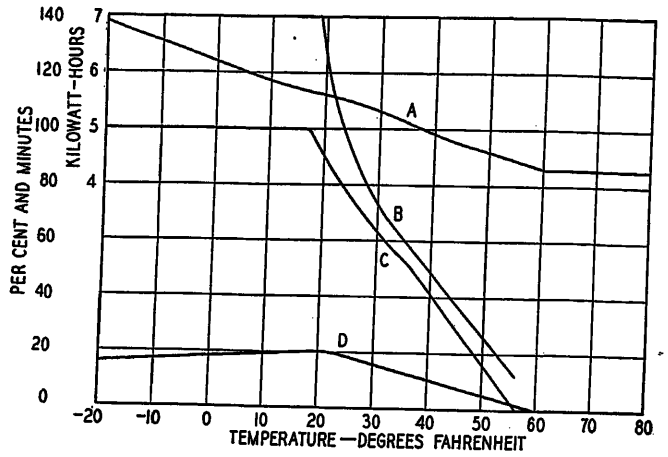

**Fig. 1. Curves showing effect of temperature on train heating and traction requirements in suburban service of the Illinois Central system**

*A*—Average kilowatt-hours per car mile

*B*—Average time in minutes elapsed before thermostat opens heater circuit when heating a cold car in storage yards

*C*—Per cent of time heater circuit is closed for trains in service and handling passengers

*D*—Per cent of the total energy consumption due to heating in the cars

possible heating that can be used would increase the consumption 1.13 kilowatt-hours per car mile over the consumption when no heat was being used.

Dividing this maximum possible heating of 1.13 kilowatt-hours per car mile by the increase of 0.0286 kilowatt-hour per degree of temperature obtained above we get a range of temperature of 40 degrees during which the energy for the heating of the cars increases. This increase is at the rate of 0.67 per cent per degree between 60 and 20 degrees. As the heating of the cars commences at approximately 60 degrees this means that at 20 degrees the energy required for heating is constant and at the maximum amount possible.

Curve *C* shows the per cent of the time the heater circuits are closed on trains in service and handling passengers after the cars have been heated previously a sufficient length of time to operate the thermostat if the weather conditions permit. This curve was drawn from the meter records obtained from the specially equipped unit and it will be noted that at approximately 17 degrees the heaters are on continuously.

The above statements regarding heating apply to cars in service.

It has been the practice on the Illinois Central to start heating the cars approximately one hour before departure from storage yards when the temperature is below freezing, and when the weather is more severe this preheating time is increased. When the temperature is colder than 10 above zero it has been found desirable to have the heat on continuously.

The energy required to heat the cars prior to their departure from the storage yards increases materially the average kilowatt-hours per car mile on days when the temperature is below freezing.

Curve *B* shows the elapsed time in minutes between the time the heat is turned on in a cold car standing in the storage yards until the thermostat operates to open the heater circuit.

The ventilation provided in the cars affects the energy consumption necessary for heating. The number of changes of air per hour in the cars is determined by the number of ventilators opened together with the frequency of stops requiring opening of the car doors. It is customary to provide more ventilation in smoking cars than in other cars in the train by opening more ventilators. In colder weather patrons remain inside the heated shelters provided on the elevated platform until the doors of the trains are opened causing congestion by not entering doors of the train farther away from the shelters. This causes longer loading and unloading time at stations which increases the length of time the doors are opened and resulting in the heat being dissipated more quickly.

Considering the heat emitted by the passengers themselves as it affects the energy consumption for heating the cars no definite conclusion could be arrived at. The indications are that the more passengers handled the more often the vestibule and diaphragm doors are opened by the passengers walking from one car to another which increases the ventilation in the cars and offsets the heat gained from the passengers themselves.

At temperatures below freezing it is noticeable that a majority of the passengers will close the doors between the vestibule and the body of the car, whereas, at more moderate temperatures these doors remain opened. This reduces slightly the percentage of the time the heat would be on at temperatures below freezing were these doors not closed and accounts for curve *C* not being a straight line.

After a car has been heated to a maximum according to the prevailing temperature there is considerable heat stored in the heaters themselves as well as other metal parts of the cars. To derive the maximum benefit from this stored heat the operating instructions to the trainmen provide for pulling the heater circuit switches in all cars at specified points before arriving at terminals on those trains that are to be tied up in storage yards. It has been found that no inconvenience is experienced in pulling heater switches from 15 to 20 minutes before arrival at destination. The economy resulting from this practice is worth while especially where it reduces the demand charges.

Referring to curve *A* it will be noted that the summer requirement is constant at 4.3 kilowatt-hours per car mile and starting at 60 degrees the consumption increases in a straight line at the rate of 0.67 per cent per degree to a temperature of 45 degrees due entirely to heating in the cars. Colder than 45 degrees the rate of increase is greater than that required for heating alone, until at 20 degrees above zero the total increase over the summer requirement is 1.3 kilowatt-hours per car mile as compared to a maximum possible increase due to heating alone of 1.13 kilowatt-hours per car mile. This additional increase or difference of 0.17 kilowatt-hour per car mile is due to the fact that these lower temperatures are experienced during

(*Concluded on page 366*)

# The Capacitance of a Parallel-Plate Capacitor by the Schwartz-Christoffel Transformation

By HARLAN B. PALMER
MEMBER AIEE

AN EXACT method of calculating the capacitance of a parallel-plate air condenser, taking into account its fringing effect, has been suggested by J. J. Thomson[1] and more completely worked out by A. E. H. Love.[2] The purpose of this paper is to promote familiarity with this mathematical technique by making it more readily accessible to American engineers. In addition to the exact method, a number of approximate methods are included.

The capacitance of a condenser consisting of a single pair of very long parallel plates in air is usually calculated by the formula

$$C = \frac{w}{4\pi d} \text{ statfarads per centimeter} \qquad (1)$$

This formula neglects the fringing of the flux and the flux which passes between the back sides of the plates, and consequently the true value may be several thousand per cent greater than indicated. An error of this magnitude would occur, for example, if equation (1) were applied to a pair of very long thin rectangular bus bars separated by many times their width.

## The Schwartz-Christoffel Transformation

The general problem of mapping polygons was first investigated by Schwartz[3] and Christoffel.[4] Since numerous explanations of this general method are available in English,[5,6] only a brief outline will be included here.

In the map of any electric field, the flux and potential lines intersect each other at right angles and, if the scales of flux and potential are made equal, the areas formed by the 2 families of intersecting lines are so-called curvilinear squares. If the field map, originally plotted in a complex plane $Z$, is replotted in a complex plane $W$, where $W$ is any analytic function of $Z$, the orthogonal intersections and curvilinear squares will be preserved. The Schwartz-Christoffel transformation consists of finding that particular functional relationship between $Z$ and $W$ which makes the transformed areas true straight-sided squares. In other words, the change of variable has the effect of warping the original boundary conditions or electrodes (between which the flux and potential lines are unknown curves) into new boundary conditions (between which the flux and potential lines are uniformly spaced straight lines) without changing the capacitance. The Schwartz-Christoffel transformation does not determine $Z = f(W)$ directly, but first determines both $Z$ and $W$ as functions of an auxiliary variable $\zeta$.

$$Z = f_1(\zeta) \qquad (2)$$

$$W = f_2(\zeta) \qquad (3)$$

In some cases it is possible to eliminate $\zeta$ between equations (2) and (3). In other cases the relation between $Z$ and $W$ must be kept in parametric form.

## $Z$ Plane

The ($Z = x + jy$) plane, in which the given boundaries of the parallel-plate condenser are plotted, is shown in figure 1*a*. The Schwartz-Christoffel transformation applies only to those 2-dimensional field problems whose boundaries are the straight sides of a polygon. The boundaries of this problem consist of the 2 plates which are equipotential surfaces, the zero flux line passing between the centers of the inside surfaces of the plates, and the maximum flux line passing (through $\infty$) between the centers of the back sides of the plates. This figure, resembling a double cross, is virtually a polygon whose sides have collapsed until they are contiguous, as examination of the slightly expanded view in figure 1*b* will reveal.

## $\zeta$ Plane

The auxiliary ($\zeta = \xi + j\eta$) plane is shown in figure 2. Due to symmetry, only the right-hand half of the $Z$ plane and the upper half of the $\zeta$ plane need be considered. The 6 vertices of the $Z$ polygon (lettered *a*, *b*, *c*, *d*, *e*, *f*) may be

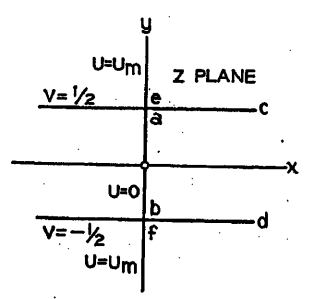

Fig. 1a

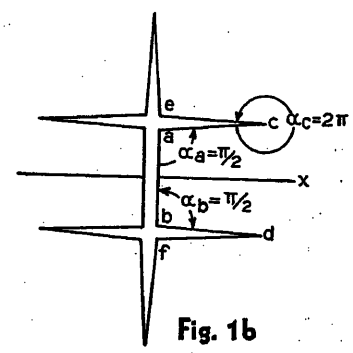

Fig. 1b

transformed into the similarly lettered points on the $\xi$ axis of the $\zeta$ plane. Furthermore the extremities of the $y$ axis become the extremities of the $\xi$ axis. Thus the problem has been resolved into finding the capacitance between 2 plates (shown by heavy lines *a-c-e*, and *f-d-b* in figure 2) lying in the same plane and having widths of $(1/k - 1)$ and being separated a distance of $(1/k + 1)$, center to center.

A paper recommended for publication by the AIEE committee on electrophysics. Manuscript submitted August 29, 1936; released for publication November 16, 1936.

HARLAN B. PALMER is associate professor of electrical engineering at the University of Colorado, Boulder.

1. For all numbered references, see list at end of paper

## W Plane

The $(W = U + jV)$ plane is shown in figure 3 and has co-ordinates $U$ (representing flux) and $V$ (representing potential). The area plotted in this plane is a rectangle bounded by the sides $(V = {}^1/_2)$, $(V = -{}^1/_2)$, $(U = U_m)$, and $(U = -U_m)$. Thus the problem has been further resolved into finding the capacitance of an equivalent parallel-plate condenser (shown by the heavy lines of figure 3) in which fringing is absent and all of the flux

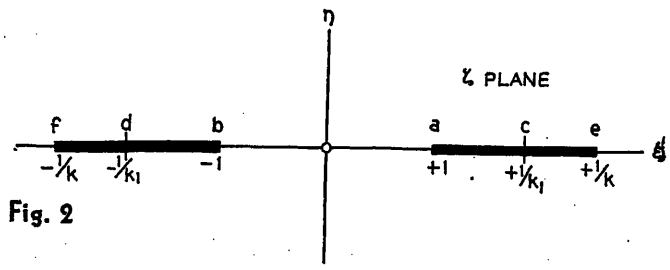

Fig. 2

passes with uniform density between the inside surfaces of the plates. Hence equation (1) may be applied. Since the capacitance of this equivalent condenser depends only upon the ratio $R$ of plate width to plate separation, the separation (equal to potential since the potential gradient is uniform) has been arbitrarily chosen as unity, while the width or $R$ (equal to flux) is as yet undetermined.

## Transformation Equations

The functional relationship transforming the vertices of any polygon in one complex plane into specified points all on one axis of another complex plane may be found by solving equation (4).

$$Z = A\int[(\zeta - \xi_a)^{m_a}(\zeta - \xi_b)^{m_b}(\zeta - \xi_c)^{m_c} \dots (\zeta - \xi_n)^{m_n}]d\zeta \qquad (4)$$

The $\xi_n$'s are the co-ordinates of the $n$ points into which the $n$ vertices are to be transformed. The exponents $(m_n)$ are given by $m_n = (\alpha_n/\pi) - 1$, where the $\alpha_n$'s are the angles of the polygon to be transformed. See figure 1*b*.

Transforming from $Z$ to $\zeta$ and referring to figures 1*a*, 1*b*, and 2,

$\xi_a = 1$ $\quad m_a = (\pi/2\pi) - 1 = -{}^1/_2$

$\xi_b = -1$ $\quad m_b = (\pi/2\pi) - 1 = -{}^1/_2$

$\xi_c = 1/k_1$ $\quad m_c = (2\pi/\pi) - 1 = 1$

$\xi_d = -1/k_1$ $\quad m_d = (2\pi/\pi) - 1 = 1$

$\xi_e = 1/k$ $\quad m_e = (\pi/2\pi) - 1 = -{}^1/_2$

$\xi_f = -1/k$ $\quad m_f = (\pi/2\pi) - 1 = -{}^1/_2$

$$Z = A'\int\frac{(\zeta^2 - 1/k_1^2)d\zeta}{\sqrt{(\zeta^2 - 1/k^2)(\zeta^2 - 1)}}$$

This is an elliptic integral and may be treated by formula 569, reference (7) to give the result,

$$Z = A[k_1^2E(\phi,k) - (k_1^2 - k^2)F(\phi,k)] + C$$

The arbitary constants $A$ and $C$ may be evaluated by inserting the boundary conditions,

$Z = 0$ when $\zeta = \sin\phi = 0$; therefore $C = 0$

$Z = \pm j$ when $\zeta = \sin\phi = \pm 1$; therefore $A = \dfrac{j}{k_1^2E - (k_1^2 - k^2)K}$

$$Z = j\frac{k_1^2E(\phi,k) - (k_1^2 - k^2)F(\phi,k)}{k_1^2E - (k_1^2 - k^2)K} \qquad (5)$$

Inserting in equation (5) the additional boundary condition,

$Z = 0 \pm j$ when $\zeta = \sin\phi = \pm 1/k$

the relation, $k_1^2 = k^2K'/E'$ results.

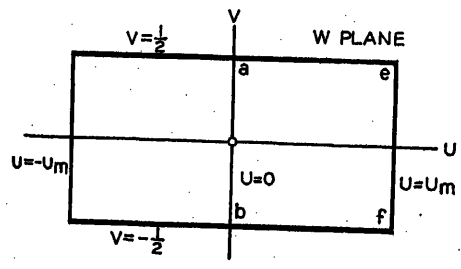
For the evaluation of elliptic integrals having upper limits greater than 1, see reference (8), page 43.

Inserting in equation (5) the final boundary condition,

$Z = R \pm j$ when $\zeta = \sin\phi = \pm 1/k_1$

the relation

$$R = \frac{K'E'(\beta,k) - E'F'(\beta,k)}{(E' - K')K + K'E} \qquad (6)$$



results

where

$$\sin^2\beta = \frac{K' - E'}{K'(1 - k^2)}$$

The combination of complete elliptic integrals in the denominator of equation (6) is identically equal to $\pi/2$, being the celebrated formula of Legendre. For a given value of the ratio $R$ it is impossible to determine $k$ except by trial and error. Values of $R$ have been calculated for

Fig. 3

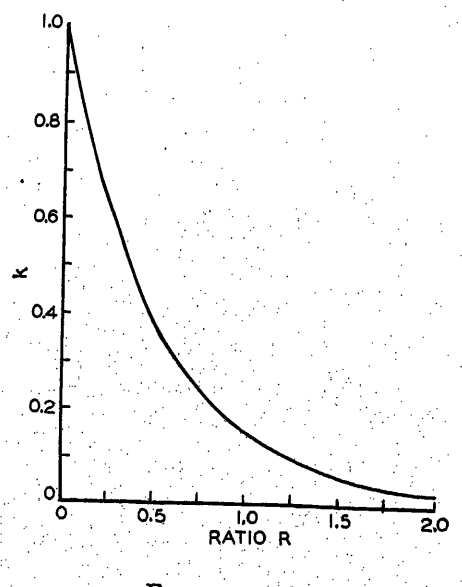


Fig. 4. Equation 6

many values of $k$ between 0.02365 and 1.0 with the results shown graphically in figure 4.

The transformation equation from $Z$ to $\zeta$ becomes, after evaluating all constants except $k$ which can only be expressed implicitly as in equation (6),

$$Z = j\,2/\pi\,[K'E(\phi,k) - (K' - E')F(\phi,k)] \tag{7}$$

Transforming from $W$ to $\zeta$ and referring to figures 2 and 3,

$\xi_a = 1$ $\qquad m_a = (\pi/2\pi) - 1 = -1/2$

$\xi_b = -1$ $\qquad m_b = (\pi/2\pi) - 1 = -1/2$

$\xi_e = 1/k$ $\qquad m_e = (\pi/2\pi) - 1 = -1/2$

$\xi_f = -1/k$ $\qquad m_f = (\pi/2\pi) - 1 = -1/2$

$$W = B' \int \frac{d\zeta'}{\sqrt{(\zeta^2 - 1/k^2)(\zeta^2 - 1)}}$$

$$W = BF(\phi,k) + C$$

Inserting the boundary conditions,

$W = 0$ when $\zeta = \sin\phi = 0$; therefore, $C = 0$.

$W = \pm j^{1/2}$ when $\zeta = \sin\phi = \pm 1$; therefore, $B = j/2K$

$$W = j\,\frac{F(\phi,k)}{2K} \tag{8}$$

Eliminating ($\zeta = \sin\phi$) between equations (7) and (8),

$$Z = 2/\pi\,[2(E' - K')KW + jK'E(am - j2KW,k)] \tag{9}$$

## Calculation of Capacitance

Corresponding to the given ratio $R$ of plate width to plate separation, determine the modulus $k$ from figure 4.

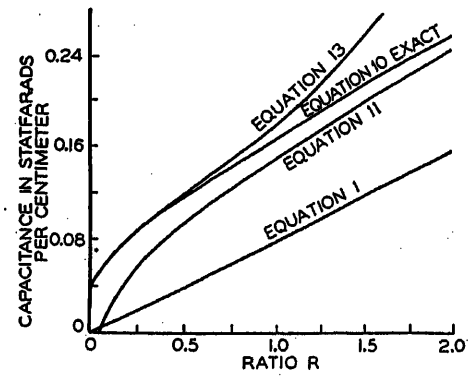

Fig. 5

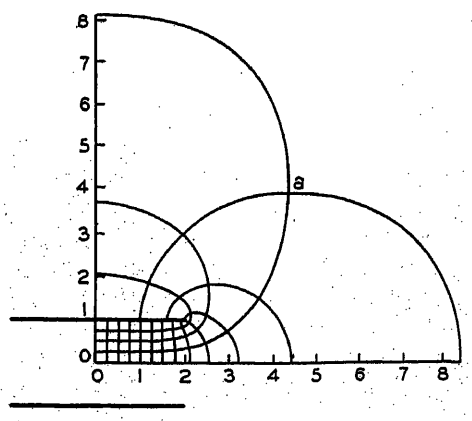

Fig. 6. Map of electric field of parallel-plate capacitor

From a table of elliptic integrals[7,9] determine the complete elliptic integral $K$ and the complementary elliptic integral $K'$.

Since the 2 axes drawn through the origin in figure 3 represent the zero-potential and zero-flux lines respectively, the point $e$ represents half of the total flux and half of the potential difference between plates. The value of $\zeta$ corresponding to point $e$ is $1/k$, and $\phi = \sin^{-1} 1/k$. Substituting this value of $\phi$ in equation (8),

$$W = U + jV = j\,\frac{K - jK'}{2K}$$

$$\begin{aligned} U_m &= K'/2K \\ V &= 1/2 \\ C &= U/4\pi V \\ C &= K'/4\pi K \end{aligned} \tag{10}$$

For example: when

$$\begin{aligned} R &= 2 \\ k &= 0.02365 = \sin 1.355 \text{ degrees} \\ k' &= 0.99972 = \sin 88.645 \text{ degrees} \\ K &= 1.571 \\ K' &= 5.131 \\ C &= 0.2599 \text{ statfarad per centimeter} \end{aligned}$$

By equation (1)

$C = 0.1592$ statfarad per centimeter

## Approximate Formulas

1. For very large values of $R$, there is an approximate formula due to Bromwich and given by Love,[2] as follows:

$$C = R/4\pi[1 + (1/\pi R)(1 + \log 2\pi R)] \tag{11}$$

For a value of $R = 2$, $C = 0.2486$ which is only 4.35% low.

2. Maxwell[11] obtained a result which is quite similar to equation (11) by using condenser plates of semi-infinite extent and investigating the field in the vicinity of the finite ends. This simplifies the transformation from $Z$ to $W$ by eliminating the 4 polygonal right angles at $a$, $b$, $e$, and $f$ in figure 1$a$ and substituting a zero polygonal angle where the plates meet at infinity. Maxwell's result, making certain other simplifications which are justified for large values of $R$, is as follows:

$$C = R/4\pi\{1 + (1/R\pi)\,[1 + \log\,(1 + \pi R)]\} \tag{12}$$

3. It has been found that for small values of $R$ (less than one), the capacitance of a parallel-plate condenser is approximately the same as for 2 round conductors having diameters of $1/2$ the plate widths and being separated center to center, by the same amount as the separation between the plates. The capacitance in this case is given by

$$C = \frac{1}{4\,\log\,(4/R)} \tag{13}$$

Although no mathematical justification for equation (13) has been discovered, it has been checked against the exact equation at many points and found to be surprisingly accurate.

Capacitances of parallel-plate condensers, for values of $R$ less than 2, have been calculated from equations (1), (10), (11), and (13). The results are shown in figure 5.

## Field Map

The Schwartz-Christoffel transformation, in addition to supplying an exact method for the calculation of the capacitance of a parallel-plate condenser, makes it possible to map the entire electric field. One quadrant of the field map, for $R = 2$, is shown in figure 6. The points of intersection of the flux and potential lines were calculated from equation (9). The increment for both flux and potential is $^1/_8$. There are 4 potential tubes and approximately 13 flux tubes, making the capacitance

$$C = \frac{13}{(4\pi)\ 4} = 0.2599 \text{ statfarad per centimeter.}$$

Any intersection such as point "$a$" in figure 6 may be calculated as follows:

$k$ = 0.02365 (See figure 4)
$k'$ = 0.99972
$K$ = 1.571018
$K'$ = 5.131306
$E$ = 1.570579
$E'$ = 1.001295
$U$ = $U_m - 1/8 = K'/2K - 1/8$ = 1.50812
$V$ = 1/8
$F(\phi,k)$ = $0.3927 - j4.7386$ (equation 8)
$F(\phi,k)$ = $0.3927 + j0.3927 - jK'$

$$\sin\phi = \frac{1}{ksn\ (0.3927 + j0.3927)} \qquad sn\ (u \doteq jK') \equiv \frac{1}{k\ sn(u)}$$

$\sin\phi$ = $56.5048 - j50.9732$ reference (10) equation 760.1
$E(\phi,k)$ = $1.5375 - j5.1456$ reference (8) pages 33, 34, 83
$Z$ = $4.37 + j3.99$ equation (9)

## Symbols Used in This Paper

$C$ = capacitance
$w$ = semiplate width
$d$ = semiplate separation
$R$ = ratio of plate width to plate separation
$Z,W,\zeta$ = complex variables
$x,y$ = co-ordinates of $Z$
$U$ = co-ordinate of $W$ denoting flux
$V$ = co-ordinate of $W$ denoting potential
$\xi,\eta$ = co-ordinates of $\zeta$
$A,A',B,B',C$ = constants of integration
$\alpha_n$ = angle of polygon in $Z$ plane
$a,b,c,d,e,f$ = vertices of polygon in $Z$ plane
$k_1$ = arbitrary constant
$k$ = modulus of ellipitc integrals
$k'$ = complementary modulus = $\sqrt{1 - k^2}$
$sn\ u$ = elliptic function
$F(\phi,k)$ = elliptic integral of first kind
$E(\phi,k)$ = elliptic integral of second kind
$K$ = complete elliptic integral of first kind
$E$ = complete elliptic integral of second kind
$K'$ = complete complementary integral of first kind
$E'$ = complete complementary integral of second kind.

## Effect of Weather Conditions on Energy Required for Multiple-Unit Trains

(*Continued from page 362*)

the winter months when due to reduced hours of daylight an increased amount of lighting is used in the cars, the air compressors also do more work as the temperature lowers and in addition to this is the fact that inclement weather increases the standing time at stations requiring more traction energy to be used to maintain schedules.

Between 45 and 20 degrees the increase in kilowatt-hours per car mile due to traction which includes all auxiliaries, etc., other than heating appeared to be made up entirely of the above mentioned causes and there was little indication that increased bearing friction or wheel flange resistance entered into it.

Proceeding along the curve $A$ it may be assumed that at temperatures below 20 degrees any further increase in kilowatt-hours per car mile is due to traction and auxiliaries other than heating. Commencing at 20 degrees and colder the traction energy increases at the rate of 0.75 per cent per degree expressed as a per cent of the summer requirement.

Assuming that the energy required for heating increases at a uniform rate to the point where it is constant and at a maximum, the per cent of the total energy consumed which is due to heating may be calculated and this result is plotted as curve $D$. The difference between curve $D$ and 100 per cent is the percentage of the total energy used for traction and auxiliaries other than heating.

## An Analysis of Copper-Oxide Rectifier Circuits

(*Continued from page 360*)

is noticeable departure in wave form between the real rectifier and the approximation, as shown by the non-sinusoidal shape in figure 5*a*. However, in these cases, the assumption of a constant rectifier is a decided improvement over that of a perfect rectifier.

An equivalent circuit was established for this constant rectifier and its application to various types of loads discussed. A few standard circuit analyses were presented and the resulting computed wave-forms compared with observations. Thus this paper presents a method of obtaining the current forms present in a rectifier circuit,

which yields better results than the perfect rectifier idealization and yet is not much more difficult to use. By using the equivalent circuit as developed in equation 1 and shown in figures 4 and 8, the series method outlined by Stout[6] can be applied to the constant rectifier circuits.

## List of Symbols

$D$ = equivalent rectifier resistance to current in the direction $Cu_2O$ to Cu
$S$ = equivalent rectifier resistance to inverse currents
$P = \frac{2DS}{D+S}$, analogous circuit constants to replace constant rectifier in determining $i_L$
$\phi = \frac{S-D}{S+D}$
$Z_O$ = impedance of bridge with d-c terminals open
$Z_S$ = impedance of bridge with d-c terminals shorted
$e$ = $E_m \sin \theta$, applied voltage, ($\theta = \omega t$)
$e_L$ = load voltage during conduction
$e'$ = load voltage during cut-off
$q$ = condenser charge during conduction
$q'$ = condenser charge during cut-off
$i_L$ = $i_R + i_C$ total load current during conduction
$i_R$ = resistance branch current during conduction
$i_C$ = condenser branch current during conduction
$i_L'$, $i_R'$, $i_C'$ = currents during cut-off
$i_D$ = current through bridge leg acting as $D$
$i_S$ = current through bridge leg acting as $S$
$i_S'$ = current through bridge legs due to $e'$
$i_a$ = total line current

# Discussions

## Of AIEE Papers—as Recommended for Publication by Technical Committees

ON THIS and the following 3 pages appear discussions submitted for publication, and approved by the technical committees, on papers presented at the general technical sessions of the AIEE South West District meeting Dallas, Texas, October 26–28, 1936. Authors' closures, where they have been submitted, will be found at the end of the discussion on their respective papers.

Members anywhere are encouraged to submit written discussion of any paper published in Electrical Engineering, which discussion will be reviewed by the proper technical committee and considered for possible publication in a subsequent issue. Discussions should be submitted to C. S. Rich, secretary, technical program committee, AIEE headquarters, 33 West 39th Street, New York, N. Y.

## A Disturbance Duration Recorder

**Discussion of a paper by C. H. Frier published in the September 1936 issue, pages 1025–8, and presented for oral discussion at the general technical session of the AIEE South West District meeting, Dallas, Texas, October 26, 1936.**

R. K. Honaman (Bell Telephone Laboratories, Inc., New York, N. Y.): Mr. Frier's paper offers an ingenious scheme for making a record of time durations of the order of magnitude of those ordinarily involved in voltage surges. As the author has pointed out, the ability to measure and record intervals of the order of magnitude of a few cycles to a few seconds is, particularly in certain cases, very desirable. It may be of interest, therefore, to present an alternative method for making such records which engineers interested in this problem might find helpful.

The possibility of initiating the operation of the recorder by means of an electron tube control instead of the contact-making voltmeter is one which suggests itself and is recognized by the author in the paper. Such a device would have the advantage not only of additional speed in operation to avoid part of the delay of 1 to 3 cycles inherent in the contact-making voltmeter, but also would be more rugged.

An arrangement for accomplishing this could be set up by means of tubes rectifying the 60-cycle current from the power line using the d-c output against a bias to trigger an electron tube with a relay in the anode circuit. Such an arrangement would necessitate the use of a resetting circuit for the tube but means of accomplishing this are available. A vacuum tube with a marginal relay operating in its plate circuit has also been suggested.

In the recording of the duration itself, another scheme, the principle of which has been suggested by Mr. L. K. Swart, is worth consideration. This depends upon the relationship between the voltage across the terminals of a condenser and the time during which the condenser has been charged. The practical working out of the suggestion is accomplished by having the initiating device, whether it be a contact-making voltmeter or electron tube trigger arrangement, connect a capacitor of appropriate size in series with a charging battery and a resist-

ance at the beginning of the period whose duration is to be measured. The size of the capacitor and the resistance and the voltage of the battery are so proportioned that the condenser will not be fully charged for the maximum interval to be measured. At the end of the interval the capacitor is disconnected from this circuit and switched by means of a relay to the grid of a high-impedance vacuum tube, in the plate of which is inserted a graphic voltmeter. The leakage can be made sufficiently small so that the graphic voltmeter swings to a point corresponding to the voltage of the capacitor which, in turn, bears a definite relation to the time interval during which it has been charged. Thus the graphic meter can be made to indicate the time at which the surge took place and by means of its deflection, the duration of the disturbance. The deflection would be calibrated in units of time. By means of electron-tube circuits and fast relays the delay in connecting and disconnecting the capacitor and the charging circuit can be made as low as the order of $^1/_2$ cycle (0.008 second).

If, in such an arrangement the charged capacitor were left connected to the grid of the low-leakage vacuum tube, the graphic meter would continue to read for a considerable period, this reading falling off slowly as the leakance of the circuit discharged the condenser. This falling off can be made so slow that the voltage will be reduced only a negligible amount in a minute. It is only necessary to maintain the charge long enough to permit the graphic meter to record the deflection, and relay circuits would be arranged to short circuit the capacitor after a sufficient interval has elapsed to give a satisfactory deflection. This interval can be arranged to suit the characteristics of the graphic meter itself.

It should be noted that the ability of this instrument to measure successive surges would depend upon the rate at which the graphic meter chart is moved. It could not differentiate between surges closer together than the time interval required to move the paper a distance sufficient to separate the pen traces.

## Electrical Features of the Texas Centennial Central Exposition

**Discussion and author's closure of a paper by John Fies published in the October 1936 issue, pages 1060–74, and presented for oral discussion at the general technical session of the AIEE South West District meeting, Dallas, Texas, October 26, 1936.**

**C. M. Cutler** (nonmember; General Electric Company, Cleveland, Ohio): The architecture is modern in character but still reflects some of the feeling of the old Spanish missions of Texas. The texture of the wall surfaces is similar. The effect depends principally upon mass, form, painted decoration, and sculpture. The fact that the majority of the buildings are to be used for subsequent state fairs and regional expositions made it desirable to use a method of illumination which would allow the equipment to be removed during the time the exposition is not in use and store it. The lack of maintenance and protection during the large part of the year when the buildings would be unoccupied made it rather impractical to use many of the newer forms of architectural elements, such as recesses, panels of translucent materials, etc., except in a few cases. Consequently, the logical method of illumination is principally floodlighting with the units located in specially designed pits, concealed behind landscaping, installed in setbacks, or placed in towers. In all cases however, lighting was particularly designed for each building.

**W. E. Folsom** (nonmember; Dallas Power and Light Company, Dallas, Texas): Interior lighting in Centennial areas of important buildings uses on the average, over 4 watts per square foot. This is in a combination of indirect and controlled direct lighting systems—the latter in the form of recessed reflectors with either flush louvers, silver-bowl lamps, or diffusing glass panels. Louvers are of either concentric or geometric types designed in general with light cut-off of about 30 degrees from vertical. Silver-bowl lamps are effectively used in shallow recessed reflectors with comparatively wide openings. The several thousand reflectors used in exposition areas are for the most part of special design, spun of aluminum with etched or specular reflecting surfaces made lasting by the Alzak treatment. Reflector units are of 5 general types with a large variety of assemblies possible and providing desirable interchangeability.

The effectiveness of the many types of interior and exterior lighting units was not left to chance—but tested in a lighting laboratory established for the purpose. Spectacular effects were experimented with thoroughly before final designs were determined.

**G. M. Buchanan** (nonmember; General Electric Company, Dallas, Texas): The absence of windows in the exhibit buildings is worthy of comment. An inspection of the Centennial in the daytime will reveal the desirable artificial lighting in the exhibit buildings. A much more pleasing effect is secured by all artificial lighting than could be secured by a combination of varying daylight and artificial lighting.

Mr. Fies stated for interior lighting 2 to 20 watts per square foot is used, giving a maximum of 40 foot candle. Some of you, not directly concerned with the application of good lighting, may not realize what this means in view of the fact that most of the lighting is indirect. You note the desirability and excellent lighting jobs on the interior of the exhibit buildings.

I want to call your attention to the 870 kw of mobile colored lighting on "Esplanade of State." This is an outstanding installation and the night show place on the Centennial grounds. A national expert in exposition lighting remarked as he viewed the "Esplanade of State" at night—"this, in my opinion, has never been equaled in any installation." I have often been asked how it is that the tower on the Federal Building is so evenly illuminated from top to bottom. The answer is 8 watts per square foot as mentioned in Mr. Fies' paper. The average intensity is 50 foot candle which is so high for floodlighting that any variation in intensity from top to bottom is not noticeable.

The parapet on the Ford Building has 15 watts per square foot or approximately 100 foot candle and is visible a great distance at night. In the Ford Building the daylight effect secured by the combination incandescent and mercury lamps used for the interior lighting is very interesting. The permanent street lighting system as installed by the city and exposition is unusual in that it is economical to maintain, yet has an entirely different appearance from the conventional street lighting standard, and this feature is particularly desirable in expositions. An opportunity to view the exposition grounds from a distance at night will show the desirable effect created by the battery of 24 36-inch searchlights. These searchlights make the exposition visible from a great distance at night and with the color screens offer a suitable climax to the lighting system when viewed from inside the grounds.

**R. W. Roessler** (Westinghouse Electric & Manufacturing Company, Dallas, Texas): The author is to be commended on his most interesting paper on the electrical features of the Texas Centennial Central Exposition. The exterior and interior lighting of all the buildings within the Centennial grounds definitely proves that full co-operation between the illuminating engineer and the architect is essential; and in this case, resulted in an outstanding lighting spectacle.

Illumination of the streets and grounds of the expositon indicates that careful study was given to provide adequate lighting and still blend in with the building architecture and other surroundings. It is interesting to note the clever manner in which the different street and grounds lighting fixtures were designed and placed, eliminating clashing effects. The lighting and power distribution system of the Centennial Exposition in itself shows thoughtful planning and good engineering. The magnitude of this system can only be realized when we note that the demand varies from 8,200 to 9,000 kw and that the system handles approximately 2,600,000 kilowatt-hours per month. The type of load served, the importance of uninterrupted service, and all other demands on this system are even more exacting than those of a fair sized municipality requiring the same kilowatt demand.

**A. E. Allen** (General Electric Company, Dallas, Texas): There is one point that seems worthy of additional emphasis, and that is the figure of 1.5 watts per square foot connected load for the entire exposition. This may not seem very much, but it is greater than for any previous world's fair. Some of this increase may be attributable to the large use of air conditioning by the major exhibitors, but lighting did not suffer by diversion of current for air conditioning, for this exposition, in my judgment, is outstanding in its lighting effects. Chicago's Century of Progress was remembered for its extensive use of gaseous tube lighting, and the Texas Centennial Exposition may be remembered for its large scale of mobile color lighting. The combination of the electronic valve with saturable core reactors makes possible a perfect control for blending

and changing color effects. The huge power loss formerly experienced in the use of resistance dimmers is avoided, and the control is so flexible that the colors may be changed without reducing the intensity of light on the building. The colors may be mixed to produce lovely pastel shades, and blended into innumerable combinations, or primary colors used as desired. There is little doubt that an even greater use of mobile color lighting will be made in the expositions planned for New York and for San Francisco in 1939.

**M. C. Hughes** (Texas Agricultural and Mechanical College, College Station): Unless I am mistaken, I believe that the incandescent electric lamp was not used at the Paris Exposition of 1881. I wonder whether or not Mr. Fies, in this connection, was referring to arc lights as incandescent lighting rather than the Edison carbon lamp which was generaly referred to as incandescent lighting. According to my information, illumination at the Paris Exposition of 1881, in so far as it was electrically lighted, was produced by the arc lamp.

If I am mistaken in this matter, I should like very much to be corrected, because it seems to me that the history of the early uses of light should be kept as straight as possible.

**John Fies:** These discussions, in the author's opinion, are all well founded and contribute materially to the value of the paper. The author herewith expresses his appreciation of all discussions submitted and offers the following comments as a closure to the discussions.

*a.* In Mr. Cutler's discussion reasons for the types of lighting and architecture are mentioned. These reasons should be of particular interest to those who may become associated with this field of lighting. We regret that space in the paper did not permit details of the interesting engineering problems.

*b.* In Mr. Folsom's discussion it is pointed out that the lighting as seen at the Exposition has proved to be a definite stimulus to the lighting business, particularly within the area of less than a day's ride from Dallas. This is important. It is a challenge to the builders of future fairs to provide lighting of types that will afford such a definite stimuli.

*c.* In Mr. Buchanan's discussion, reference is made to artificial versus natural light. We find some natural light on the Natural Resource Exhibit in the Transportation Building at the Exposition. This is an excellent exhibit but an illumination man in viewing it is well aware of how much more effective it would have been had it been presented in artificially lighted cases. No criticism is offered, as this exhibit is a remarkable exhibit, assembled quickly, and consequently was too late to be incorporated in the lighting plans.

*d.* In Mr. Roessler's discussion, reference was made to the importance of uninterrupted service. The local power company was given the responsibility of providing reliable electric service to the 38 points of delivery. From the beginning of the Fair to date there have been no primary interruptions of consequence. When we consider that all branch secondary feeders have their source at the mentioned points of delivery it becomes evident that if primary service is reliable then practically all service is reliable and troubles are necessarily restricted to small circuits and small areas. There have been, to date, no complaints relative to continuity of electric service.

*e.* In Mr. Allen's discussion, reference is made to the figure 1.5 watts per square foot. This figure is conservative and is based upon gross area. If we exclude from our figures certain areas used for stables for Cavalcade horses and for storage of miscellaneous material, that is, areas not accessible to visitors to the Exposition, we would have to propose a figure in excess of 2 watts per square foot for 145 acres.

*f.* Professor Hughes is his discussion mentioned that my reference to the use of incandescent lamps at the Paris Exposition in 1881 might be questioned. The author agrees with Professor Hughes that such a statement should be further supported when it pertains to past history and when it may not agree with generally accepted information on the subject. It may have been better had the paper stated that the incandescent lamp was "shown on a relatively large scale" rather than "used," yet the showing may also have constituted the using although the arc light was undoubtedly used extensively. The statement used in the paper was based upon a paragraph found in a very excellent and carefully written book "Electricity at the Columbian Exposition" copyrighted in 1894 and written by John P. Barrett, Chief of Department (probably electrical), Columbian Exposition, Chicago, 1893. It is reasonable to expect that Mr. Barrett had assembled by 1893 considerable authentic information relative to the use of electricity at expositions prior to that date, hence, we owe him our confidence in the credibility of the statement contained in his book as follows:

"Between 1878 and 1881 so many improvements had been made in the utilization of the electrical current for lighting purposes, and so great was the public interest in the subject, that the ever memorable electrical exposition of 1881 was held at the Palais de l'Industrie. It was then that incandescent lighting was first shown on anything like a large scale, and formed with the telephone the chief element of success for that exposition. Arc lighting was also indulged in commercially."

# Experiences With a Modern Relay System

**Discussion and author's closure of a paper by G. W. Gerell published in the October 1936 issue, pages 1130–6, and presented for oral discussion at the general technical session of the AIEE South West District meeting, Dallas, Texas, October 28, 1936.**

**Robert Treat** (General Electric Company, Schenectady, N. Y.): This paper brings out very convincingly the great value of records obtained by means of an automatic oscillograph to an operator who is determined to keep his system in the pink of condition, so to speak, without at the same time incurring large and unjustifiable expenditures. The many ways in which oscillographic records of accidental system disturbances can be of value to the operator, may roughly be classified into 5 groups.

## 1. Continuing Check on the Timing and Correct Operation of Relays and Circuit Breakers

Early in our studies of power system instability, it became apparent that a major improvement in stability could be obtained at relatively low cost by keeping the duration of short circuits to a minimum. As a result, high-speed clearing of faults began to be used on new projects; and many existing breakers and relays were speeded up in order to improve system performance during transients caused by short circuits. It was realized that if the stable operation of the system were to depend on high-speed clearing of faults, it would certainly be very desirable that the operator should have available a means for knowing absolutely that faults were actually being cleared in the expected times. There was no way of being sure that relays and breakers would perform in the same way during accidental short circuits that they did during periodic tests of individual devices. Hence it appeared desirable to secure a check on breaker and relay performance during actual operation. The time intervals which it was necessary to measure were very small, since the entire short circuit might last only 6–8 cycles. The only solution seemed to be an automatic oscillograph which should be capable of starting its record at the very beginning of a short circuit.

With some misgivings on the part of the commercial department, the General Electric Company undertook the development of such an oscillograph. The general specifications were in part as follows:

*a.* It must be capable of being put into operation automatically by a system disturbance.

*b.* It must furnish a clear, usable record, which began within 1/2 cycle of the incidence of the short circuit.

*c.* It must run for an adjustable predetermined time, but it must continue in operation if the initiating cause still existed at the end of that time.

*d.* It must be so designed as to obviate the necessity for changing the film or paper after each record was made; but it must also be possible to remove each record immediately if desired.

*e.* It must be so simple to operate, adjust, and maintain that it could be installed in power stations and substations, and operated and serviced by men who had no previous experience with oscillographs.

*f.* It must be priced so that operators would feel that they could afford to use it.

All these specifications were met. Although this device was not put on the market until early in the depression, nearly 50 of them made by one manufacturer alone are now yielding useful and valuable information of accidental system disturbances such as described by the author of this paper.

## 2. Evidences of System Instability, and of the Appropriate Remedy

Oscillograms of system disturbances are helpful in indicating any tendency of the system to become unstable during or subsequent to accidental faults. Since the likelihood of instability increases with system load, this should be very important now that

utility loads are again increasing so rapidly. When it becomes necessary to bolster up the system stability, oscillograms of part disturbances will often yield valuable information which aids greatly in making an intelligent decision as to which remedial measures will be the most effective per dollar of expenditure.

3. Check on Stability Calculations

Many calculations have been made of the probable performance of systems from the stability standpoint. Although the background of this phenomenon is now well understood, and the results of stability calculations made today contain little of the guess work which entered the computations made even as recently as 7 or 8 years ago, it is still desirable to obtain a check on the assumptions and calculations. Checks obtained by means of staged tests are not altogether satisfactory for the reason that it is undesirable that these tests should cause disturbances to service. This necessitates their being made, if at all, under artificial conditions (such as during light load or with considerable reserve generating capacity connected) which seldom, if ever, exist during normal operation. Oscillograms of accidental system disturbances, however, yield data which serve as a very satisfactory check on the results of stability calculations. Obviously a complete check cannot be obtained from any one disturbance and it is necessary to accumulate the data over a considerable period in order to get a fairly complete comparison of predicted with actual performance.

4. Information Concerning the Values and Phase Positions of the Voltages and Currents of the 3 Phases, and Concerning the Sudden or Momentary Changes in These Values

Practically every relay engineer is occasionally faced with seemingly inexplicable misperformance of his relays. Sometimes relays do not trip when they should; more frequently they trip when apparently they should not. Subsequent tests of the offending devices frequently reveal no reason for their apparent misbehavior. As pointed out by the author of this paper, the automatic oscillograph shows that the currents and voltages in individual phases sometimes jump around in magnitude and phase position during faults and subsequent breaker operations in a most unexpected and apparently erratic manner. From this information it is learned that some of the apparently incorrect relay operations were, in reality, absolutely correct under the conditions which existed; but that the conditions themselves were entirely different from those contemplated when the relay application was made. While this may be of only academic interest when the relay engineer has to explain to his boss why the relaying went haywire, it is of far more than academic interest when he has to decide what ought to be done about it.

5. Reduction in the Time of a Patrol Crew in Locating a Flashover After an Outage

Even though a line successfully returns to service immediately, some operating companies make a patrol after every outage, in order to determine whether the damage is sufficient to require maintenance at some convenient time. As pointed out by the author of this paper, his company and some others have found that it is possible from the information on the oscillograms to determine very closely where the failure occurred, and thus save much time of the patrol crew. Although the author gives no indication of the saving in patrol expense resulting from this practice, it is suspected that this item alone, which was quite unforeseen when the development was first undertaken, is sufficient to justify an automatic oscillograph. If this be true, all the other advantages are obtained for nothing.

Some companies have found that the damage from any single flashover is so slight that they do not feel warranted in patroling a line after each interruption; rather, a thorough inspection is made at the end of each season. It seems entirely probable that if these companies had this means of sending the patrol crew right to the point of flashover, they would feel justified in availing themselves of the additional security of an inspection after each line outage.

The prominence given to the value of oscillograms of accidental system disturbances in this paper is indeed gratifying to one who was partially instrumental in encouraging the original development, and who has strongly felt that the information yielded by an automatic oscillograph was worth far more than its cost. Although many companies which have not yet installed automatic oscillographs are inclined to look upon them as luxuries, which, however desirable, can ill be afforded when they can hardly get money enough for necessary bread and butter, I do not know of a single operating company which has ever bought an oscillograph, that could be induced to part with it for several times the price paid, if it could not be replaced. I suppose the psychology is the same as with an electric refrigerator, or an automobile—it is a luxury until you get your first one; after that, it is a necessity which you are ever after at a loss to understand how you did without, so long.

G. W. Gerell: Concerning Mr. Treat's remarks it might be noted that automatic oscillographs, as available today, are quite reliable, and in general do meet the specifications which he imposed.

In regard to system instability, records obtained from the oscillograph have shown definitely that a number of incorrect operations have resulted from instability and have further indicated remedial steps necessary in the relay equipment to prevent its repetition.

It may be well to mention here that the case of trouble described in connection with the oscillogram of figure 3 of the paper was included, to open up this important subject of, "how fast a relay may operate and still give a correct tripping impulse." It is suggested that considerable thought should be given to this.

As Mr. Treat mentions, the location of line faults from data supplied by the oscillograph has been of great assistance to the patrol crews. But, it will not necessarily reduce patrol expense, inasmuch as the patrol crews cannot be reduced in number. In many instances patrol crews have inspected a line, finding nothing. Later the location was given them from the data secured from the oscillograph. A second patrol was invariably successful.

## Steinmetz Painting Presented to High School

AN oil painting of Doctor Charles P. Steinmetz (A'90, M'91, F'12, past-president, deceased October 26, 1923) has been presented by the General Electric Company to a new $3,000,000 high school in Chicago, Ill., that has been named for the scientist. The painting shows Doctor Steinmetz at his desk about 3 months before his death, and is the work of H. M. Mott-Smith. It was presented by E. W. Allen (A'03, F'22) vice-president of the General Electric Company, who is shown at the extreme left with Mayor Edward J. Kelly of Chicago at his side. At the right is Daniel F. O'Hearn, principal of the school, and Theodore Luga, a student and son of an immigrant, who accepted the gift for the school.

## Of Institute and Related Activities

# The Institute's 1937 Winter Convention

TERMED by President A. M. MacCutcheon, "one of the busiest, most stimulating, and most interesting" conventions that he had ever attended, the Institute's 1937 winter convention drew to a close with a total registration of 1,165. Perhaps one of the busiest attendants at the convention was President MacCutcheon himself. An unusually large number of committee meetings was held, and for the first time the board of directors met on 2 successive afternoons during convention week.

Details concerning registration and attendance are given in the accompanying tabulations. Although the total registration was somewhat less than last year's total, the attendance at various sessions and activities was good and in some cases exceeded last year's attendance. The drop in registration, as may be noted from an accompanying tabulation, was primarily among those from the New York Section territory for which the registration was 68 less than last year. Another interesting fact, shown by another tabulation is that the attendance at the smoker, which is believed to have set a new record, was higher than the number registered. This is evidence of the fact that many attended the convention who did not register, so that the actual total attendance was somewhat higher than the registration figures show.

Details concerning the various features of the convention are given in the following paragraphs and on subsequent pages.

H. S. Osborne, chairman, technical program committee, speaking on the technical sessions at the opening session of the convention. Seated on the platform, left to right, are Director R. W. Sorensen, of Pasadena, Calif., President A. M. MacCutcheon of Cleveland, Ohio, H. R. Beardsley of Brooklyn, N. Y., chairman of the winter convention committee, and A. G. Oehler, chairman of the New York Section

### Noble Prize Presented at Opening Session

The convention was officially opened at 2 p.m. on Monday, January 25, by C. R. Beardsley, chairman of the general winter convention committee, who extended a very cordial welcome to all those attending. Following his remarks, President MacCutcheon announced that the Alfred Noble prize for 1936 had been awarded to Abe Tilles, instructor in electrical engineering at the University of California, Berkeley, and counselor of the Institute's University of California Branch. (Details of this award and a biographical sketch of Doctor Tilles appeared in the news pages of the January issue.) President MacCutcheon outlined briefly the details of the award and sketched the recipient's career.

In Doctor Tilles's absence, the prize was presented to R. W. Sorensen, professor of electrical engineering at the California Institute of Technology, Pasadena, and a director of the AIEE, who accepted it in behalf of Doctor Tilles.

### President MacCutcheon's Address

Following presentation of the Noble prize, Chairman Beardsley introduced President MacCutcheon, who spoke on the subject "The Challenge of 1937." In this address, President MacCutcheon amplified his message to the membership published in the February issue. He emphasized particularly the importance of increased activity on the part of the Sections and Branches during 1937, urging that each Section appoint at least one technical committee. "Such Section technical committees," he said, "can develop subjects of unusual interest, and recommend authors of unusual ability, reporting to the national technical committee having jurisdiction. Among our membership are many potential authors who would be willing to devote their time to the preparation of a paper desired by the profession and asked for by fellow Section members. Such papers, when published, would be accompanied by proper recognition to the Section submitting the paper. By this means the technical activities could be made more widely representative, and more fully meet the desires of the membership.

"I feel that the Institute has reason to be truly proud of the fine work being carried on through the Branch organization, but still more can be accomplished in 1937. With the young men in the Branches lies the future of the profession and the future of the Institute. . . .

Concerning the movement under way to broaden the activities of the Institute, President MacCutcheon said: "In 1936, many devoted Institute members, several special committees, and the board of directors have canvassed possibilities in connection with broadening the scope of Institute activities. Should papers be prepared and presented dealing with the relations of the engineer to society, with the engineer's relation to war, with the engineer's relation to the distribution of electrical products, with the engi-

neer's relation to unemployment, with the engineer's relation to natural resources? Personally, I feel that there should be a sane and intelligent broadening of our activities, provided that in so doing we are following the fundamental principles for which the society was organized. . . ."

He closed by urging "each member . . . to join with the vice-presidents, the other directors, and myself, in the resolve to do all in our power to meet the inspiring challenge of 1937."

### Doctor Osborne's Remarks

Following President MacCutcheon's address, H. S. Osborne, chairman of the Institute's technical program committee, spoke as follows on the technical sessions of the convention:

"In preparation for such a convention as this, the technical committees and the technical program committee consider the whole wide range of the professional activities of Institute members. From the various suggestions which are developed by this review a program is adopted, based upon the combined judgment of these committees regarding what at the moment will be of greatest interest and value.

"One feature of this convention, as well as other recent conventions, to which I should like to call your attention is the technical conferences. As you will note there are 4 of these on the present program. The technical conference might be defined as a meeting without the publication of papers. Since these conferences involve very little expenditure, it would be practicable to hold a large number of them in connection with our conventions if they are desired by the membership. Many such conferences might lead up to the future publication of papers summarizing the outcome of the conference or of a series of conferences. The appearance of these conferences on the program is an illustration of the fact that the technical program committee is experimenting with new methods of expanding and enriching the technical activities of the Institute.

"The fact is that the field of activity which is described in our Constitution as "the theory and practice of electrical engineering and of the allied arts and sciences" is rapidly growing. As a result of this vitality it is natural that there should always be a problem of how best to meet the varied interests and desires of the Institute membership. It has been suggested that some members would like to see more attention given in Institute programs to subjects of broad general interest, particularly to subjects in which engineering and the social sciences are both involved. Also, we know that some members would like to have more opportunity for discussion at the Institute meetings of specific subjects on the frontier of technological advance. While such subjects from their nature would often, taken individually, be of immediate interest only to a relatively small number of members, taken in the aggregate they may be of interest to a large number.

"These considerations illustrate the desirability of a careful review of the Institute program having in mind the wide scope of interest of the Institute membership and also the limitations in the amount of money which can be spent. This whole question is being carefully studied by the committees most directly concerned. I speak of these matters here to ask your help as members of the Institute. If you have ideas regarding the programs of future meetings which you think will help the Institute to meet in the broadest and most satisfactory way the needs of the membership, please give these suggestions to any member of a technical committee or of the technical program committee. I know that these will be helpful to them. It may not be possible to apply all such suggestions but I assure you that they will all be gratefully received and carefully considered."

Following Doctor Osborne's remarks, the first technical sessions of the convention assembled.

**Analysis of Registration at Recent Winter Conventions**

| District | 1934 | 1935 | 1936 | 1937 |
|---|---|---|---|---|
| New York City and Foreign (3) | 812 | 694 | 697 | 629 |
| North Eastern (1) | 179 | 194 | 219 | 222 |

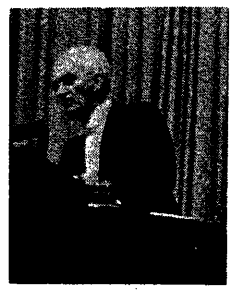
| North Western (9) | 0 | 1 | 3 | 1 |
| Totals | 1,227 | 1,114 | 1,231 | 1,165 |

### Technical Sessions

With the exception of the sessions on electric welding and tensor analysis, reports of the technical sessions are not given here since all papers presented have been published in Electrical Engineering, and since all written discussions approved by the technical program committee will appear in subsequent issues. At the session of welding, only one previously published paper was presented, the remainder of the program including a demonstration lecture and a special address. The tensor sessions, included several informal discussions by invited nonmember guests. Brief reports of these 2 sessions are given on succeeding pages.



Attendance at the technical sessions, as reported by the technical program committee, is given in an accompanying tabulation. The count in each case was an instantaneous one taken about 1½ hours after the session began. The total attendance at any one of the sessions may have been somewhat greater, if those who stayed for only a brief interval were included.

### Technical Conferences

As mentioned by Doctor Osborne in his remarks at the opening session of the convention, 4 technical conferences were held on the following subjects: education; network analysis and synthesis; sound; and performance standards and test codes for rotating machinery. All these conferences were featured by interesting informal discussions. At some of them official actions were taken by the sponsoring committees. Brief reports of these conferences are given on succeeding pages.

### Address "Power and People"

Following the Edison Medal presentation ceremonies, which took place at a special session of the convention on Wednesday evening, January 27 (reported in succeeding pages), an address entitled "Power and People" was delivered by John C. Parker, vice-president, Consolidated Edison Company of New York, Inc., to those assembled for that occasion. Doctor Parker pictured the place of power, particularly electric power, in the lives of people. Speaking of the work of engineers, who provide the mechanisms necessary for the furnishing of power in usable forms, he said: "The engineer does not live a life of isolation, but on the contrary works with and through other men. His work, . . . involves understanding of, and adjustment to and co-operation with other men . . . His work is definitely more social than that of the physician or of the lawyer or of the minister of souls or of the exponent of the creative arts, each of whom, in a large degree, works as an individual. In that very fact, however, the engineer has at once a satisfaction and a limitation of his social contacts. With

other men, largely of identical or at least of closely related interests and limitations, he finds satisfaction for his desires for human contact and such satisfaction easily enough so preoccupies his time that he can easily fail of social understanding of the people whom his profession serves or of the social significances of his own work. . . ."

"In consequence of engineering remoteness, we perhaps become obsessed with the technical beauties and interests of our work and with the human problem of co-ordination with our fellows in creation and miss some perspective of how our works touch on the larger interests of society. . . ."

E. R. Thomas, chairman of the inspection trips committee

Concerning the public's interest in power, Doctor Parker said in part: "There is a general public interest in the problems of power production and distribution that is way out of proportion to any significance that even so important an art has in the affairs of men. This would be puzzling if it were only a recent phenomenon. It is not the less disturbing because of the fact that it has been developed over a period of years by an ill-considered but perfectly honest enthusiasm which has mistaken simultaneity of occurrence for a relation of cause and effect."

Speaking of power in industry, he said: "American industry did not set out with the idea of trying to apply power to industrial production and thereafter discover the means for utilizing power. . . . The power industry saw a commercial opportunity and observed a social responsibility. . . ." Later, he compared the importance of power in industry with that of design for production, modern materials, machine tools, use of tolerance limits, interchangeability of parts, standardization, the use of limit gauges. "All of these elements put together," he said, "might have accomplished nothing had it not been for the superb achievements of distribution which have brought the end results of industry to the final user.

"Note well that every one of these elements. . . has been essential to modern industrial life as we know it; even more than that, has been essential to modern non-industrial living. Our enthusiasm for one of these elements in which we may happen to be particularly interested—let us say, power—should not run away with our sense of proportion. On the contrary, it seems to me that our pride in our own service becomes greater if we have an adequate picture of where it fits in as an essential and considerable element of something enormously bigger than itself."

Regarding the place of electricity in home and farm life, Doctor Parker said in part: "We need not be at all deprecatory of the importance of our power developments as service to the home or to the farm merely because we may be realistic in our apprehension of the fact that many other things enter into life and that the life is more than meat and the body more than raiment. It is understandable, though not by virtue of that at all defensible, that the specialist should develop an unrestrained enthusiasm for his particular field of human endeavor and that his extreme loyalty might communicate his zeal to others. What is not perhaps quite so clear is that economic, social, and political injuries may result from these widespread and exaggerated enthusiasms. Not alone as a matter of humane consideration, but in self defense against the reactions of disappointed hope, we must be at pains not to arouse desires that we cannot gratify or which, gratified, will be found not all that the body or the soul of man craves."

"Important as is power as an adjunct to factory, farm and home," he concluded, "it, in and of itself, will not revolutionize life. We are, in our most profound relations, biologic creatures and all the conscious mechanical and technical efforts in the world are small factors in determining the essential well-being of our lives. To the extent that we have made our lives in their superficial details depart from our biologic origins, we find the mechanisms of living important. They will be the more important if our perspective keeps them in the proper relation to the other elements of living and to life itself."

Full text of Doctor Parker's address appears on pages 305–11 of this issue.

**Attendance at Special Features of Recent Winter Conventions**

| Feature | 1935 | 1936 | 1937 |

## Future AIEE Meetings

**North Eastern District Meeting**
Buffalo, N. Y., May 5–7, 1937

**Summer Convention**
Milwaukee, Wis., June 21–25, 1937

**Pacific Coast Convention**
Spokane, Wash., Aug. 30–Sept. 3, 1937

**Middle Eastern District Meeting**
Akron, Ohio, Fall 1937

### Inspection Trips

As in previous years, the last day of the convention was reserved entirely for inspection trips. Trips were held also on other days of the convention. As a special attraction, a post-convention trip to Bermuda was offered at special rates. About 28 people took advantage of this opportunity to enjoy a mid-winter trip to this popular resort. With the exception of the trip to inspect the mercury turbine of the Public Service Electric and Gas Company at Kearny, N. J., all trips were held as scheduled. Registration for the various trips is indicated in an accompanying tabulation.

The excellent variety of trips, together with the orderliness with which arrangements were made and carried out, elicited many favorable comments. The success of this part of the convention program reflected the efforts of the hard-working chairman of the committee, E. R. Thomas, and of his colleagues: H. C. Anderson, H. M. Case, P. T. Coffin, G. E. Dean, Henry Kurz, W. J. Quinn, H. O. Siegmund, H. B. Stoddard, R. H. Twiss, and W. Y. Vedder.

| Public Service Electric & Gas Company, Kearny generating station, mercury turbine | (Cancelled) |
| Total | 926 |

### Smoker

The success of this year's smoker can be judged best by the attendance, 1,175, which is believed to be a record for winter convention smokers. The affair was held in the Grand Ballroom of the Hotel Commodore. An excellent dinner was served, followed by a stage show featuring a pleasing variety of entertainment by well-known radio and motion-picture stars. Ray Perkins, well known for his work on the radio, was master of ceremonies.

E. S. Banghart was chairman of the smoker committee; he was assisted by W. H. Farlinger, H. E. Farrer, P. G. Fredericks, W. H. Harden, W. Jordan, J. E. McCormack, E. J. D. Paterson, R. E. Powers, T. D. Reimers, T. O. Rudd, H. C. Schlaikje, D. W. Taylor, and E. F. Thrall.

### Dinner-Dance-Buffet Supper

As usual, the dinner-dance proved to be the social high light of the convention. It was held at the Hotel Astor, and was followed by a buffet supper, a feature that has become popular in recent years. A total of

335 attended the dinner-dance, and 250 the dance-buffet supper; some of these attended both, but it is estimated that about 500 were present at the combined affair. Those serving on the dinner-dance committee were: C. M. Gilt, *chairman;* F. L. Aime, T. S. Bacon, L. W. Codding, H. E. Farrer, L. P. Ferris, J. E. Goodale, S. B. Graham, Thomas Maxwell, J. A. McHugh, J. H. Pilkington, and Tomlinson Fort.

### Women's Activities

A program of special entertainment was arranged for the women attending the convention. On Tuesday a group of about 50 visited the Van Gogh Exhibition at the Museum of Modern Art, after which the group inspected the Pedach Exhibition of Decorating Arts and Crafts, at Radio City. This was followed by tea at 4:00 p.m. in the British Empire Exhibition Room at Radio City, after which the group visited the Museum of Science and Industry. After dinner, there was a back-stage tour of the Radio City Music Hall, followed by attendance at the show in that theater. The most popular single event on the women's program was the luncheon and bridge held at the Engineering Woman's Club on Wednesday afternoon.

In addition to the foregoing, some of the women attended some of the regularly scheduled inspection trips, particularly those to the New York Stock Exchange and to the Steamship "Monarch of Bermuda." Serving on the women's committee were: Mrs. George Sutherland, *chairman;* Mrs. E. S. Banghart, Mrs. C. R. Beardsley, Mrs. O. B. Blackwell, Mrs. H. C. Dean, Mrs. Tomlinson Fort, Mrs. C. M. Gilt, Mrs. H. H. Henline, Mrs. A. H. Kehoe, Mrs. E. B. Meyer, Mrs. A. G. Oehler, Mrs. G. S. Rose, and Mrs. H. R. Woodrow.

### Directors and Committees Meet

The Institute's board of directors met during the convention, as is the usual custom. A meeting of the national nominating committee also was held, at which nominees for election to Institute officers for the year 1937–38 were selected. Reports of both these meetings appear in succeeding pages.

**C. M. Gilt (left) chairman of the dinner-dance committee, and E. S. Banghart, chairman of the smoker committee, comparing notes**

Many of the Institute's committees also met during the convention; these were as follows: technical program; research; power generation; production and application of light; standards; electrochemistry and electrometallurgy; automatic stations; Sections; electronics; electrophysics; membership; Group III of the subcommittee on conductors, towers, and wood poles of the power transmission and distribution committee; transformer subcommittee of the electrical machinery committee; and the protective devices committee and its subcommittees on (1) lightning arresters, (2) relays, (3) circuit breakers, switches, and fuses, and (4) fault-current-limiting devices. A scheduled meeting of the committee on electric welding was not held. A luncheon meeting of Student Branch counselors was held, and the newly appointed special committee on broadening of Institute activities also met. Reports of most of these meetings are presented in succeeding pages.

Much credit is due the general committee for the success of the 1937 winter convention. C. R. Beardsley was chairman of this committee; other members were: T. F. Barton, O. B. Blackwell, H. E. Farrer, E. E. Dorting, A. G. Oehler, C. S. Purnell, S. A. Smith, Jr., George Sutherland, and F. P. West.

## AIEE Directors Meet During the Winter Convention

THE regular meeting of the board of directors of the American Institute of Electrical Engineers was held at Institute Headquarters, New York, at 2:00 p.m., on Tuesday, January 26, 1937, adjourning at 5:35 p.m. until 2:00 o'clock the following afternoon, January 27.

There were present: *President*—A. M. MacCutcheon, Cleveland, Ohio. *Past-President*—J. B. Whitehead, Baltimore, Md. *Vice-Presidents*—O. B. Blackwell, New York, N. Y.; C. V. Christie, Montreal, Que.; R. H. Fair, Omaha, Neb.; C. F. Harding, Lafayette, Ind.; W. H. Harrison, Philadelphia, Pa.; N. B. Hinson, Los Angeles, Calif.; A. C. Stevens, Schenectady, N. Y. *Directors*—F. M. Farmer, New York, N. Y.; N. E. Funk, Philadelphia, Pa.; H. B. Gear, Chicago, Ill.; F. E. Johnson, Columbia, Mo.; C. R. Jones, New York, N. Y.; P. B. Juhnke, Chicago, Ill.; W. B. Kouwenhoven, Baltimore, Md.; Everett S. Lee, Schenectady, N. Y.; K. B. McEachron, Pittsfield, Mass.; L. W. W. Morrow, Corning, N. Y.; C. A. Powel, East Pittsburgh, Pa.; R. W. Sorensen, Pasadena, Calif. *National Treasurer*—W. I. Slichter, New York, N. Y. *National Secretary*—H. H. Henline, New York, N. Y.

Minutes of the board of directors meeting of October 20, 1936, were approved. The minutes of the executive committee meeting held on December 10, 1936, were approved with an amendment changing the name of the special committee on broadening of Institute activities, which was appointed by the executive committee, to "special committee on Institute activities," this committee to prepare for a discussion at the 1937 summer convention of the subject of desirable topics for presentation at Institute meetings and for publication, and to be discharged upon presentation to the board of directors of its report on this session.

Actions of the executive committee under date of November 2, 1936, on applications were reported and approved, as follows: 3 applicants transferred to the grade of Fellow; 1 applicant elected to the grade of Fellow; 19 applicants transferred and 13 elected to the grade of Member; 69 applicants elected to the grade of Associate; 905 Students enrolled.

A report of a meeting of the board of examiners held on January 20, 1937, was presented and approved. Upon the recommendation of the board of examiners, the following actions were taken: 1 applicant was elected to the grade of Fellow; 31 applicants were elected and 5 were transferred to the grade of Member; 97 applicants were elected to the grade of Associate; 204 Students were enrolled. The finance committee reported monthly disbursements as follows: December, $17,647.61; January, $25,368.21; report approved.

The final report of the special committee to consider Associate dues and related matters was submitted, with the recommendation that the present constitution and bylaws be unchanged. The board voted that the committee's report be accepted and published in Electrical Engineering, and that the committee be discharged. (The report appears elsewhere in this issue.)

Upon the recommendation of the committee on co-ordination of Institute activites, the following schedule of meetings in 1938 was adopted: winter convention, New York, N. Y., January 24–28; North Eastern District meeting, Pittsfield, Mass., in the spring; summer convention, Washington, D. C., June 20–24; Pacific Coast convention, Portland, Ore., dates to be determined later.

Approval was given to the dates of August 30 or 31 to September 3 for the 1937 Pacific Coast convention, already scheduled to be held in Spokane, Wash.

Upon the recommendation of the committee on student Branches, the board authorized the organization of student Branches of the Institute at Columbia University, New York, N. Y., Northwestern University at Evanston, Ill., and Tulane University, New Orleans, La.

The president was empowered to appoint 2 representatives of the Institute upon the council of the American Association for the Advancement of Science for the year 1937.

G. G. Post was appointed a representative of the Institute upon the Commission of Washington Award for the unexpired term, ending August 1, 1938, of William B. Jackson, deceased.

The committee on award of Institute prizes reported its recommendations on various suggestions for modifications in the rules for the award of Institute prizes. The board voted its approval of the recommendations, which involved the following changes in the rules and the reprinting of

the pamphlet containing the rules:

(1) Provision that the national prize for branch papers will be based upon the student year July 1 to June 30, inclusive, rather than the calendar year as at present. This is in accordance with the recommendation of the conference of officers, delegates, and members held in Pasadena, Calif., in June 1936. It is recommended that this change be brought about by the adoption of the following specific changes in the present rules.

Page 3, paragraph at the bottom of the page beginning "Only papers presented. . . ., etc."—Modify to read as follows:

"For the national best paper prize and the national prize for initial paper, only papers presented during the calendar year shall be considered except those for the best paper prize in the class of public relations and education. In this class all papers presented subsequent to those considered at the time of the last previous award in this field and prior to the end of the last calendar year will receive consideration. For the national prize for Branch papers only papers presented during the preceding academic (college) year shall be considered.

"All papers approved by the technical program committee . . ., etc."

Page 6, paragraph 6—Modify to read as follows: "Only papers presented during the calendar year shall be considered for the prize for best paper and for initial paper. Only papers presented during the preceding academic (college) year shall be considered as eligible for the Branch paper prize. They must be submitted in duplicate by authors, or by officers, of the Section, Branch, or District concerned to the District secretary on or before the following dates: best paper and initial paper, February 15; Branch paper, July 15."

If this recommendation is adopted, it is understood that the committee on award of Institute prizes will this year consider for the national Branch paper prize only papers presented between January 1 and July 1, 1936.

(2) Provide for a District prize for a graduate student paper. This is in accordance with a previous recommendation of the prize award committee, approved by the board of directors on May 25, 1936, but not heretofore incorporated in the rules for national and district prizes.

At the top of page 6, add item 4, prize for graduate student paper.

"4. The District prize for graduate paper may be awarded for the best paper based upon graduate work and presented at a national, District, Section, or Branch meeting of the Institute. At the time of presentation, the author must be a graduate student and either a member or an enrolled Student of the Institute. In the case of co-authors, the graduate requirement applies to all and the membership requirement applies to at least one of the coauthors."

Page 6, paragraph 6—Modify the revision set forth under item 1 above to read as follows:

"Only papers presented during the calendar year shall be considered for the prize for best paper and for initial paper. Only papers presented during the preceding academic (college) year shall be considered for the prize for Branch paper and for graduate student paper. They must be submitted in duplicate by authors, or by officers of the Section, Branch, or District concerned to the District secretary on or before the following dates: best paper and initial paper, February 15; Branch paper and graduate student paper, July 15."

A report of the Institute policy committee on recommendations of the committee on safety codes for an expansion of that committee's scope was presented and approved. The report included the statement: "It is the feeling of this committee that there are many types of activity looking to increased safety, which lie beyond the normal purposes of the AIEE. It is felt that any expansion of the Institute's work on safety should be limited strictly to the technical and engineering aspects of safety, and particularly should not conflict with the safety work of any other organization." It recommended that "the chairman of the committee on safety codes be informed that the board of directors is interested in the possibility that the Institute, within its proper scope, may make further contributions to the cause of safety than it is now doing, and will welcome any specific suggestions to this end from the committee on safety codes."

The publication committee reported that it is making a thorough study of publication policy, and certain recommendations, including increases in the budget for ELECTRICAL ENGINEERING for the present year, were approved. The committee may submit additional recommendations after further consideration and discussion of the matter at the conference of officers, delegates, and members during the summer convention.

President MacCutcheon presented abstracts of reports which he had received, upon his request, from the technical committees and several of the general committees. The board referred these reports to the chairman of the committee on co-ordination of Institute activities for a survey of committee activities and any recommendation he may have for the Board.

The final report of the special committee to revise Section territories was presented. The board voted that the committee's report be accepted, that the actions recommended be adopted, the changes to become effective August 1, 1937, and that the committee be discharged with the thanks of the board.

Reference was made to the publication in the December 1936 issue of ELECTRICAL ENGINEERING of a report of the committee on professional recognition of Engineers' Council for Professional Development, which had not yet been approved by ECPD, and comments on which were invited. This report was referred to the committee on economic status of the engineer, with the understanding that a notice would be published in ELECTRICAL ENGINEERING that the report had been referred to this committee, the chairman of which has requested that Institute members send to him their comments on the subject. (This notice appears elsewhere in this issue.)

Other matters were discussed, reference to which may be found in this or future issues of ELECTRICAL ENGINEERING.

## Nominating Committee Announces Candidates

A complete official ticket of candidates for the Institute offices that will become vacant August 1, 1937, was selected by the national nominating committee at its meeting held at Institute headquarters, New York, N. Y., January 26, 1937. This committee, in accordance with the constitution and by-laws, consists of 15 members, one selected by the executive committee of each of the 10 Geographical Districts, and 5 selected by the board of directors from its own membership.

The following members of the committee were present: A. W. Berresford, New York, N. Y.; O. B. Blackwell, New York, N. Y.; C. V. Christie, Montreal, Canada; N. E. Funk, Philadelphia, Pa.; E. E. George, Chattanooga, Tenn.; K. L. Hansen, Milwaukee, Wis.; R. E. Kistler, Seattle, Wash.; H. S. Lane, San Francisco, Calif.; T. H. Morgan, Worcester, Mass.; J. W. Ramsay, Austin, Tex.; R. W. Sorensen, Pasadena, Calif.; A. C. Stevens, Schenectady, N. Y.; A. L. Turner, Omaha, Neb.; J. B. Whitehead, Baltimore, Md., and W. E. Wickenden, Cleveland, Ohio; also H. H. Henline, New York, N. Y., secretary of the committee.

The following is a list of the official candidates selected by the committee:

FOR PRESIDENT

W. H. Harrison, assistant vice-president, department of operation and engineering, American Telephone and Telegraph Company, New York, N. Y.

FOR VICE-PRESIDENTS

I. Melville Stein (Middle Eastern District, number 2) director of research, Leeds & Northrup Company, Philadelphia, Pa.

Edwin D. Wood (Southern District, number 4) general superintendent, Louisville Gas & Electric Company, Louisville, Ky.

L. N. McClellan (North Central District, number 6) chief electrical engineer, U.S. Bureau of Reclamation, Denver, Colo.

J. P. Jollyman (Pacific District, number 8) hydroelectric and transmission engineer, Pacific Gas & Electric Company, San Francisco, Calif.

M. J. McHenry (Canada District, number 10) manager, Toronto district, Canadian General Electric Company, Ltd., Toronto, Ont.

FOR DIRECTORS

C. R. Beardsley, superintendent of distribution, Brooklyn Edison Company, Inc., Brooklyn, N. Y.

V. Bush, vice-president and dean of engineering, Massachusetts Institute of Technology, Cambridge, Mass.

F. H. Lane, manager, engineering division, Public Utility Engineering & Service Corporation, Chicago, Ill.

FOR NATIONAL TREASURER

W. I. Slichter, professor of electrical engineering, Columbia University, New York, N. Y.

The constitution and by-laws of the Institute provide that the nominations made by the national nominating committee shall be published in the March issue of ELECTRICAL ENGINEERING. Provision is made for independent nominations as indicated in the following excerpts from the constitution and by-laws:

CONSTITUTION

Sec. 31. Independent nominations may be made by a petition of twenty-five (25) or more members sent to the National Secretary when and as provided in the By-Laws; such petitions for the nomination of Vice-Presidents shall be signed only by members within the District concerned.

BY-LAWS

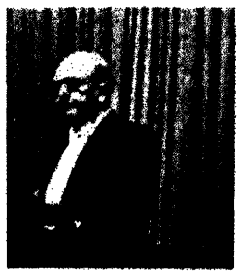
Sec. 23. Petitions proposing the names of candidates as independent nominations for the various offices to be filled at the ensuing election, in accordance with Article VI, Section 31 (Constitution), must be received by the secretary of the National Nominating Committee not later than March twenty-fifth of each year, to be placed before that committee for inclusion in the ballot of such candidates as are eligible.

On the ballot prepared by the National Nominating Committee in accordance with Article VI of the Constitution and sent by the National Secretary to all qualified voters during the first week in April of each year, the names of the candidates shall be grouped alphabetically under the name of the office for which each is a candidate.

(Signed) National Nominating Committee
by H. H. Henline, *Secretary*

BIOGRAPHIES OF NOMINEES

In order that those not personally acquainted with the nominees may know something of them and their qualifications for the Institute offices for which they have been nominated, brief biographical sketches are given in the "Personals" columns of this issue.



# Edison Medal for 1936 Presented to Alex Dow

FOR "outstanding leadership in the development of the central station industry and its service to the public," the 1936 Edison Medal, highest award of the AIEE, was presented to Doctor Alex Dow, president, Detroit (Mich.) Edison Company, at a special session of the Institute's 1937 winter convention, on the evening of January 27. Doctor Dow has been a member of the Institute for 44 years, having been elected an Associate in 1893, and transferred to the grade of Fellow in 1913. He has been president of the Detroit Edison Company since 1913.

A. M. MacCutcheon, president of the Institute, presided over the ceremonies, introducing first H. P. Charlesworth, past-president of the Institute, and chairman of the Edison Medal committee, who briefly outlined the history of the medal and the terms of its presentation. Mr. Charlesworth's remarks follow:

## Past-President Charlesworth Outlines History of Medal

"The Edison Medal was founded by an organization of associates and friends of Thomas A. Edison who desired to commemorate the achievements of a quarter of a century in the art of electric lighting with which Edison had been so prominently identified.

Past-President Charlesworth outlining history of medal

"It was decided that the most effective means of accomplishing this object was by the establishment of a gold medal which could serve 'as an honorable incentive to scientists, engineers, and artisans to maintain by their works the high standard of accomplishment' which had been set by Edison. The American Institute of Electrical Engineers was invited to undertake the responsibility of making the awards. The Institute accepted and organized the Edison Medal committee, or board of award, composed of 24 members.

"Three of these members are appointed each year by the president of the Institute to serve for a term of 5 years each; 3 are elected each year by the board of directors from its own membership to serve for a term of 2 years each; the other 3 members are *ex-officio*, the president, the national treasurer, and the national secretary of the Institute.

"The by-laws of the committee provide for making one award each year, and the deed of gift specifies that the award shall be made to some one resident in the United States or Canada, for meritorious achievement in electrical science, electrical engineering, or the electrical arts.

"The medal was designed by James Earle Fraser, and carries on the obverse the portrait of Thomas A. Edison, and on the reverse an allegorical conception of the genius of electricity crowned by fame."

## Louis H. Egan Eulogizes Doctor Dow

Following Mr. Charlesworth's remarks, President MacCutcheon introduced Louis H. Egan (A'08, M'15) president, Union Electric Light and Power Company, St. Louis, Mo., a long-time friend, close associate, and great admirer of Doctor Dow. Mr. Egan outlined some of Doctor Dow's accomplishments as president of the Detroit Edison Company, and related many interesting anecdotes demonstrating his fine personal characteristics.

Going back 35 years, Mr. Egan told of his first meeting with the medalist, on which occasion he (Mr. Egan) was seeking employment (which he obtained). Speaking of these early associations, he said in part: "Mr. Dow was beyond belief in his method of treatment and in the rare privilege that came to be mine of being welcomed into their home. There I came to understand one of the reasons for his success, and she is here tonight; I would indeed be derelict if I didn't mention and give full credit to the very delightful and lovely hospitality that she offered to me at that time—Mrs. Dow."

"I am not going to undertake," Mr. Egan continued, "to tell you here tonight very much, if anything, about the big boilers, or about the unusual transmission system, and the substations, and the stores department, and how we handled the meters, and all the rest of this, our public relations, and so forth. You will hear those from others, possibly, and if you don't, you can find them out very readily. They have been published many times.

"I should like to tell you just a little of the human side of this gentleman that we are honoring here tonight. I will mention just in passing, if I may, something about this company that he runs, and, rather than going to one of his intimate friends, or refreshing my own recollection on the subject, I should like to take a chapter out of the book of...the Public Utilities Commission of the State of Michigan. It is paraphrased a little, because I think I write it better than they do. It may be briefed in spots, but it is designed to serve its purpose here and the basis of it can be found in the decision of that commission; it says this:

" 'The Detroit Edison Company was organized in 1903 under the laws of the state of New York. At that time Michigan did not have corporation laws suitable to the operations of the Detroit Edison Company, which they proposed to conduct.

" 'At the time of its organization, the Detroit Edison Company took over the Edison Illuminating Company, Detroit and Michigan corporation, which had been organized under the Michigan laws, and also the Peninsula Electric Light Company, a Michigan corporation which had been organized in 1898.

" 'The Eastern Michigan Edison Company was incorporated July 24, 1906, under the laws of the state of New York, as a subsidiary of the Detroit Edison Company, for the purpose of doing certain classes of business, most of it privately owned. Electrical properties in the southeastern part of the state have since been consolidated in the Detroit Edison Company. Briefly, it covers practically all of Michigan within 50 or 60 miles of the city of Detroit, and recently it purchased the property, plant, and facilities of the Michigan Electric Power Company, operating in what is known as the thumb of Michigan. The territory served by the company has a population of approximately 2,500,000 people.

" 'The growth of the company since its organization in 1903 has been phenomenal. At the close of that year it had, according to its books, total fixed capital of less than $7,000,000. At the end of 1935, its total fixed capital was something like $290,000,000. Thus we see that in 33 years, beginning with 1903, the total fixed capital of this utility was multiplied by more than 42 times.

" 'In addition to serving electric light and power in the territory above described, the company supplies an extensive steam heating service, principally in Detroit. The investment which might properly be allocated to the steam-heating business approximates $15,000,000. It also has a small amount of manufactured-gas business.

" 'The Edison Company has grown greatly with the growth of the southeastern part of Michigan. When the company began business in 1903, the population of its territory was only about 300,000. It is now about 8 times that amount. During its existence it has purchased and taken over about 50 electric light and power plants previously owned by municipalities or by small utility companies.

Louis H. Egan sketching high lights in life of medalist

" 'It owns and operates some 7 or 8 rather small water powers on the Huron River; although most of its energy is generated in steam plants located in the vicinity of Detroit, it has one rather large steam plant near its gas utility at Marysville.

" 'The Utility under consideration has always taken care of the interests of the public. It has been a very important factor in the phenomenal growth of the territory it serves. It was one of the first utilities in the country to begin the electrification of rural territory, and at the present time about 75 per cent of the farms in its territory that it has occupied for a considerable period of time have been electrified.

" 'The stock of the company is widely distributed. It has almost 14,000 stockholders. There is no doubt about the fact that the Detroit Edison Company is one of

the outstanding electric utilities in this country. It is not owned by any holding company. It is an independent concern. Ever since its organization it has been most efficiently managed and operated. Its head during its entire history has been Alex Dow, one of the foremost electric light and power men in the United States.'

"I think probably that is the greatest tribute that has ever been paid by a regulating body to the electric light and power industry, to the man who headed a company, in this whole country, since regulation began. It is merited beyond belief. For over 40 years he has been the guiding factor and the principal factor in the creation of this company. It is recognized both in the United States and abroad as a model example of its kind."

Mr. Egan next spoke of Doctor Dow's broad general interests, mentioning specifically several widely divergent subjects with which he is conversant.

Speaking of Doctor Dow's achievements in the electric power industry, Mr. Egan said: "Would you like to know somebody who thought of most of the things that come to your minds about the light and power industry today, thought of them 25 years ago, and forgot them? If you think that you are about to develop something new in this industry, I warn you, because I have made the mistake, you had better go back and dig up the proceedings of the National Electric Light Association, and of the Association of Edison Illuminating Companies, and there you will find them expounded about a quarter of a century ago by Mr. Dow. It doesn't make any difference whether it deals with customer relations, whether it deals with street lighting, whether it deals with the contacts of municipalities, or government control; it is all there. I have looked them up and read them.

"What a great treat it must be to all these thousands and thousands of young men and women, just as it was to me, to come in contact with a mind of that kind in this business! I can't begin to tell you the thankfulness that is in my heart for the things that he did to me, sound, true, sane, stable principles that he has followed and preached since he started.

"You talk about there being no romance in business! Only careless, foolish people say that. A young boy in Scotland—nobody to help him—an orphan in his early years, people to assist; he starts out by just sheer industry, perseverance, the will to make good, he comes to this country, takes half a dozen simple jobs of one kind or another, all the time storing up in this retentive memory of his the things that are going to be to his advantage in the future.

"Finally he lands in Detroit to put in a municipal street lighting system, and, after he did it, the local company said: 'There is the type man we want.'

"He has been there 41 years doing that job. Why, it is an inspiration beyond belief! It is the kind of thing that is the United States of America at its best."

Concerning Doctor Dow's humanitarian activities, Mr. Egan said: "What he has done for people all over this country will never be known." He then mentioned several specific instances in which Doctor Dow had rendered personal assistance to people in need.

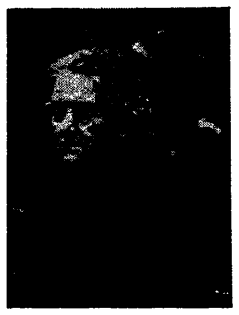
"His breast is shining with unseen medals for the goodness that he has done," Mr. Egan concluded. "I could continue this eulogy for a long, long time It has been said and said well that a big enterprise is a shadow of a man. Perhaps those who don't think well imagine it becomes trite, but it is true; it never was more fully exemplified than it was in this case.

"But the sun is setting, and the shadow becomes long. It isn't a dark shadow. It is a shadow that shines with a roseate light, a white shadow, if you will, the kind of shadow that will last forever in the district where it has first fallen, and that is what his shadow will be on his chosen state and his chosen city."

**President MacCutcheon (right) presenting medal and certificate to Doctor Dow**

## Doctor Dow Responds

Immediately following Mr. Egan's address, President MacCutcheon presented the medal and certificate to Doctor Dow, who responded, in part as follows:



**Doctor Dow responding**

"...I plead guilty to having contributed to the development of the central station industry. I found myself in that industry, to my own great surprise, dealing with, to begin with and for several years almost continuously, properties that had been failures, trying to put them on their feet, succeeding quite a bit; at other times saying that in this particular case what was wanted was not a diagnosis and medication but a postmortem. These things happened, and that experience, I know, was exceedingly valuable to me in teaching me the things that just could not be done in that industry....

"By the time that I got through listening to the...remarks of Louis...I came to the conclusion that I must have failed in my vocation; instead of being an electric-light man doing the day's work as it came along, the best I knew how, glad when the day was done, I ought to have been a missionary or a member of a settlement, preaching the gospel... I am glad that that destiny... miscarried. I am afraid that I should have been even more weary of it than I have been at times of the day's work as it is.

"...I wish you would think of me as somebody who has just, as I have already said, done the day's work as it came to him, looked ahead, saw what could be foreseen, sometimes having a vision that was almost prophetic... At times it has been given to me to see what was coming and to see the possibilities of meeting the on-coming event in such manner as would conduce to the welfare of the service for which I was responsible; that I have taken that service seriously I wish you would think of as being assured of.

**Mrs. Dow after the ceremonies**

"As far as investment goes, it is rather a serious matter to be responsible for $300,000,000 of other people's money. As far as the care and welfare of employees go, for groups that have ranged in the last few years, even during the depression period up to about 8,000 people, and as far as service to the public goes, that Mr. Egan has stated to you; and it is a service that is unusual, exceptionally comprehensive, covering and trying to reach, everybody.

"We have been able there to have accepted by our authorities the doctrine of the economic area, separating out from individual municipalities, each insisting upon having its own accounting and its own particular rate schedule...and we have an integrated area there that is willing to be dealt with as a whole. That is the correct theory, we believe. I know that I was one of the first to point out that that was how it should be, that a service such as the central station service is, could not be congeries of local services, but must be a broad service extending over the area which was economically one area; and that is what has been sought by my people and by myself.

"Now...I have by example as well as by precept shown what may be done, shown that it is possible to get along peacefully, shown that it is possible to have no labor trouble (and I speak for myself personally, and I am touching wood when I say that in these troublesome days—touching wood and making a little prayer that it will continue). I began to boss men when I was a 14-year old boy. The men never bothered me because they were all quite willing to be bossed—it saved them from doing any thinking; but the boys of my own age, or a little older, I had to fight it out with every confounded one of them before I could get peace. I don't know any other way to get peace either in business or in politics, but to fight it out when you have to—to avoid it as long as you can but to fight it out when you have to.

"So it has gone, and, to play fair with these divergent interests and interests that may become divergent, has been my job in life—that much more than any choice in engineering matters or any development of new principles or any application of established principles.

"Let me confess here...that I have almost forgotten what it is to be an electri-

cal engineer.... I have to tell them [electrical engineers] when they come and talk to me about something new: 'Now that is all right, but settle down and tell it to me in words of one syllable.' Usually it is possible to do that and I, having no facilities whatever in the language of the mathematician and the symbols in which he expresses an idea concisely and clearly,...am glad to revert to the one-syllable plan.

"...Forty-five or 50 years ago I knew all there was to know about telegraphy, but now I don't even know the language. And it is so with many, many matters of electrical engineering nowadays... Still, I have an understanding mind; still, I am glad to have a new problem brought to me, glad to hear how it has been solved, and glad to settle down and think about it and think how that is going to fit into my day's work, into the problem of serving 600,000 customers scattered over 6,500 square miles, and that is what engineering means to me; but as for being an electrical engineer—no....

"...I found the United States, when I came to them, more than 50 years ago, a place that welcomed the youngster who was willing to take it as he found it, who had no call to show it the error of its ways, and was not only willing to take things as he found, but also willing to work hard at whatever work Providence put before him. I turned my hand to a good many things. I had a certain facility at mechanical employments.

"Before I was 20 years old I came to the United States, and I ultimately landed... into the electric light and power industry, and have stayed with it, grown up with it, was an early operator in that industry and have seen it become what it is. That has taken above all things an understanding of the American people. It has taken an infinite patience. It has taken that foresight with which I thank the Lord He has given me a certain amount of. It has taken the judgment as to what should be done when one felt what was coming. So far I have had good fortune. I hope it will continue. I trust it will continue....

"Still, after all, in these matters for which I have been given much praise tonight, I have tried to understand, I have tried to make it easier for those who needed help, and tried when it was necessary to speak the truth without malice. I have tried to be patient. I have tried even to suffer fools gladly, although that has been perhaps the most trying thing that I have had to do....

"As it is, it is anything but engineering. I wouldn't unless I were an engineer by thought and by a certain amount of training be where I am, but it is anything but engineering in the day's work; it is finance, it is management, it is law, it is politics—which I don't approve of at all. You know, you need a big sense of humor to keep your patience with politics....

"As for taking care of my people, well, and other people—things that have been wished upon me: I never believed in welfare systems—no welfare system that I know of, and that applies to a little bit of an organization...right up to the wonderful scheme for the betterment of 15 or 20 million people that we now have on our lists, so many of them capitalized with 3 or 4 initials...As to these things, I admit having done what came to my hand, and I have summed up my philosophy of such matters in a very, very few words: ...Do what you can, what is within your powers, what is within your duty, if it may so happen, for ...,the person—man or woman—who does need help; do it quietly and kindly, without any fuss and botheration. Don't do it mechanically. Do it personally. If you cannot do it personally yourself, at least see that the job is done. Delegate it to someone that is light of hand and will not try to make people feel grateful. That kind of gratitude I don't much like. It reminds me of that definition of gratitude: 'Gratitude is a lively sense of favors to come.' Do it quietly, as I have said; do it patiently and kindly; thank God that you have had the chance to do it; and, forever afterward, keep your mouth shut about it.

"I think I have said a plenty. Thank you for listening, and this [the medal] I am highly honored by."

# Reports of 15 Committee Meetings Held During the Winter Convention

BRIEF reports of the meetings of 16 Institute committees and subcommittees held during the Institute's recent winter convention are presented herewith, as prepared by the committee chairmen or from notes submitted by them. These reports cover meetings of 2 general committees, 6 technical committees, and 7 subcommittees of technical committees. Reports of the meetings of 4 subcommittees of the protective devices committee have been combined with that of the parent committee.

No report of the meeting of the committee on electrophysics was submitted, but according to Chairman R. C. Mason that committee "met to consider plans for future activities." In addition, no report of the standards committee meeting is included here, but actions of this committee on items of interest to the membership are reported in the "Standards" columns elsewhere in this issue. A scheduled meeting of the committee on electric welding was not held.

## Membership Committee

By G. A. Kositzky, Chairman

Some 21 of the members of the national membership committee attended the meeting of the committee held January 27, 1937, at national headquarters in New York during the recent winter convention. The several matters of routine business that were discussed have been reported to all members of the committee through the medium of the minutes of the meeting.

Special attention was called to the new pamphlet containing an article by E. S. Lee, former national membership chairman, entitled "Membership in the American Institute of Electrical Engineers." This article is highly informative concerning Institute activities, and has been distributed by mail to all Institute members. These booklets are available from national headquarters.

## Sections Committee

By W. H. Timbie, Chairman

The Sections committee is unanimous in believing that a thoroughgoing survey should be undertaken immediately of the activities of the Sections. The majority believes that a "field survey" should be made by a competent investigator; the rest are of the opinion that a questionnaire survey is all that is necessary. Consequently, it is proposed that a special survey be made, the committee sending to the chairman of each Section a "self-analysis blank," by means of which each Section chairman, assisted by his Section secretary, may analyze the activities of his Section stating specifically:

*A.* Aims or objectives of the Section.

*B.* Activities now carried on to attain these objectives.

*C.* Critical examination of the results of these activities.

*D.* Necessary or desirable change in activities.

The objective of this survey is: first, that the Sections examine themselves in order to crystallize their objectives and reasons for and results of their activities; second, from a study of the returns the Sections committee hopes to obtain facts and data that will enable it to assist the several Sections in reaching a clearer understanding of the aims and in more effective methods of obtaining them.

It is especially desired that ways may be opened up for: (*a*) further co-operation between a Section and other community-minded groups that would profit by the help of the engineer; (*b*) more effective co-operation between the Sections committee and the various Sections; (*c*) greater co-operation between Sections. This preliminary survey should likewise give a fair indication as to whether a "field survey" is necessary or desirable.

The committee plans to co-operate to the fullest extent with the newly appointed special committee on the broadening of Institute activities.

## Automatic Stations Committee

By M. E. Reagan, Chairman

Because of the enthusiastic reception that has been accorded the subcommittee's report on supervisory control and telemetering, by operating people, it was decided to bring this report up-to-date and request its publication in ELECTRICAL ENGINEERING. The subcommittee appointed to follow this program is as follows: Chester Wallace, American Telephone and Telegraph Company, New York, N. Y.; P. A. Borden, Bristol Company, Waterbury, Conn.; M. E. Reagan, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.; and A. E. Anderson, General Electric Company, Philadelphia, Pa.

It was suggested that the committee undertake a study of operating practice on short-circuiting or open-circuiting of neutral-grounding resistances in case of circuit

breaker failure on ground faults. It was believed, however, that this was a function of the committee on power transmission and distribution. It was decided to offer the assistance of the automatic stations committee to the committee on power transmission and distribution in co-ordinating any investigation of this problem.

A request for a round-table discussion on automatically controlled hydroelectric generating stations at the Institute's 1937 summer convention was discussed at some length. It was decided that the committee would sponsor such a meeting if the convention committee considers that there is enough general interest in the subject. At the request of the summer convention committee, the automatic stations committee will co-operate in a general discussion on "control" to be held at that convention.

Preliminary reports were made by 2 subcommittees on the general subjects of:

(*a*) Battery-charging methods in unattended stations.

(*b*) Reclosing of breakers on bus-differential operation.

AIEE Standards No. 26, which is now undergoing consideration by the American Standards Association, was again reviewed.

## Committee on Electrochemistry and Electrometallurgy

By F. O. Schnure, Chairman

On the subject of electrolytics, the committee is now formulating plans for a round-table conference to be held in connection with the Institute's forthcoming summer convention. It is the committee's plans to broaden the scope of the intended discussion by inviting to participate in it, members of other technical societies interested in the various aspects of the general subject of electrolytics. As chairman of the committee to plan this conference, N. R. Stansel of the industrial engineering department, General Electric Company, Schenectady, N. Y., and former chairman of the committee on electrochemistry and electrometallurgy, was appointed. Looking forward to the 1938 winter convention, the committee also is considering the possibility of developing for the program of that convention a symposium on the subject of electrolytics, or some other subject growing out of the intended summer-convention round-table conference.

There was considerable discussion on the question of a "definition of the committee's function." As this is now "defined" or understood, the scope of the committee's activities can include either the thermal applications of electricity, the electrolytic applications of electricity, or both. To study the subject and report later to the committee a recommended definition of function and scope of activity, a subcommittee has been appointed.

Brought forth during the committee's general discussion were strong suggestions to the effect that the Institute membership should be "classified according to interests and professional work."

## Committee on Protective Devices

By J. P. McKearin, Chairman

Rules were adopted to govern the standing subcommittees of this committee in the preparation of their annual reports. These reports are to show the extent of the subcommittee programs and to give all members of the protective devices committee and all members of all the subcommittees the benefit of a record of the work that has been done, so as to maintain the continuity of subcommittee work from year to year.

A resolution was adopted, recommending to the Institute's standards committee that the revised AIEE Standards No. 22, on "air switches," be published in report form.

Arrangements were made to obtain improvements in the report on Standard No. 23, for "relays," to bring these Standards up to date.

Plans were made for participation by this committee with the committees on power transmission and distribution and electrical machinery in a proposed joint session at the Institute's 1937 summer convention on "lightning protective equipment and insulation co-ordination." Considerable interest has been shown in this type of session.

### Circuit Breakers, Switches, and Fuses

The subcommittee on circuit breakers, switches, and fuses, H. J. Lingal, chairman, made further plans for its work on recommendation for improvements in AIEE Standards No. 19, for "oil circuit breakers," and proposed Standards No. 25, for "fuses above 600 volts." This work is the result of suggestions received from the industry at large in response to the invitation for opinions, criticisms, and suggestions printed on the recently published reports on these 2 standards.

### Relays

The subcommittee on relays, E. E. George, chairman, reviewed its program, which includes: "application of electronics to relay protection," "trend of distribution relay protection," "standardization and simplification of relay design and application," and "high-speed protection and reclosing."

### Fault-Current-Limiting Devices

The subcommittee on fault-current-limiting devices, J. O'R. Coleman, chairman, reviewed its program and made further plans for its work which includes "a survey of grounding practices," "mutually-coupled reactors," and preparation of new standards for "fault current limiting devices for neutral grounding."

### Lightning Arresters

The subcommittee on lightning arresters, J. R. North, chairman, gave further consideration to arrangements for the proposed joint session at the summer convention and discussed its work on other projects which include: "testing procedure for lightning arresters," "performance characteristics of lightning arresters," "performance characteristics of the various forms of protective gaps," "application of lightning arresters," "specific lightning arrester protection problems," and the preparation of a new standards for "protective gaps."

Chairman North says that the lightning arrester subcommittee has a rather extensive program outlined for the year. He has prepared the following report of the meeting of that subcommittee from reports presented by the sponsors of each of the "sub-groups" on the scope and status of their work.

*Testing Procedure for Lightning Arresters—Herman Halperin.* This group is determining proper methods and test procedure for ascertaining the condition of lightning arresters in service and as received from the manufacturers. Both station and line type arresters are included. Suitable

## Membership—

Mr. Institute Member:

The young engineer looks to the leaders in his profession for guidance and inspiration—for leadership. The American Institute of Electrical Engineers is leadership in organized form; it represents and speaks for all electrical engineers as a group.

An interested and inclusive membership assures you of a strong, representative, and effective organization. You can do yourself and your associate engineers, who are not members, a service by securing their applications or by sending their names to your membership committee.

Vice-Chairman, District No. 5
National Membership Committee

test procedures are being drafted, and arrangements are being made for disseminating this information.

*Performance Characteristics of Lightning Arresters—K. B. McEachron.* This group is assembling specific and comparative information regarding the 60-cycle and protective characteristics of modern lightning arresters. Present published data regarding arrester characteristics is not on a uniform basis and is, therefore, not directly comparable. It is planned to have the results of this work in shape for submitting as a tentative report at the Institute's 1937 summer convention.

*Rod Gaps, Expulsion Gaps, and Deion Gaps—J. J. Torok.* The possibility of developing AIEE Standards for gaps and the performance of different types of protective gaps was discussed in considerable detail, and it was decided that the preparation of standards should await the results of the "Manufacturers' Inter-Company Laboratory Group" studies which are now in progress. In the meantime, a summary outlining the status of protective gaps generally is to be prepared so that this information may be readily available for use.

*Application of Arresters and Influence of Station Equipment—J. R. North.* This sub-group is dealing particularly with the proper application of lightning arresters and the standardization of terminology regarding arrester connections as used with distribution transformers. A memorandum covering this work will be sent out to the members of the subcommittee for consideration within the next few months.

*Specific Protection Problems—A. H. Sweetnam.* The proper means of protecting various equipment, including constant current transformers, regulators, line switches in open position, etc., is being studied by this sub-group and a memorandum summarizing current practices is to be prepared and distributed as a matter of information.

*Proposed Institute Papers.* Several papers proposed for presentation before the Institute were discussed. Three papers were proposed as part of a joint symposium on the subject of "Protective Equipment and Insulation Co-ordination," and it was decided that every effort should be made to insure the placing of this joint session on the program for the 1937 summer convention.

## Committee on Production and Application of Light

By A. L. Powell, Chairman

Following a review of the work of the committee for the year to date, the chairman pointed out that one technical paper* and several brief contributions† on recent advances in the field of illumination are now awaiting publication in ELECTRICAL ENGINEERING. Inasmuch as the Institute's publication committee has decided that it is expedient to publish more items of general interest, the committee decided to re-establish its policy of supplying a series of short illumination notes so that the editor might have these on hand for use as filler material when occasion arises. Members of the committee were urged to prepare such items on current advances in illumination that come to their attention and submit them to the chairman.

Plans for the session on lighting to be held during the Institute's 1937 summer convention were discussed, and the desirability of avoiding a parallel session was emphasized. There was some discussion also of the various papers proposed for presentation at that session.

* See pages 319–24.
† See pages 302–04.

## Committee on Power Generation

By G. M. Armbrust, Chairman

Recent developments in subjects pertaining to the work of the committee were discussed.

It is the opinion of the committee that sufficient new material for papers is available for a session on power generation at the Institute's 1938 winter and the following summer conventions.

The committee will endeavor to arrange symposia covering 2 or 3 subjects such as "superimposed units, their economic advantages and justification," and "parallel operation of power plants and interchange of power over transmission systems."

## Committee on Research

By W. B. Kouwenhoven, Chairman

This meeting was attended by 18 members. F. M. Farmer reported that funds had been raised for carrying on the investigation on the "stability of impregnated paper insulation" under the direction of Doctor J. B. Whitehead of Johns Hopkins University. He also reported that the work had been started December 1. The supervisory committee co-operating in this investigation consists of H. H. Race, *chairman*, General Electric Company, Schenectady, N. Y.; R. W. Atkinson, General Cable Corporation, Perth Amboy, N. J.; W. F. Davidson, Brooklyn (N. Y.) Edison Company; R. J. Wiseman, Okonite Company, Passaic, N. J.; and K. S. Wyatt, Detroit (Mich.) Edison Company. This committee reported that it had met with Doctor Whitehead and had unanimously agreed to a definite plan of procedure in carrying out the investigation. Mr. Farmer then reported on the status of the funds for the "investigation in the field of electric shock." He stated that the necessary funds had not been fully raised and that the balance is expected to be available within a short time.

Mr. Farmer also reported on the list of research projects that the research committee has circulated in the past, which list he is now revising. He especially requested the members of the committee to furnish him with suggestions; suggestions from others also are welcome. He reported that the previous lists had proved very useful.

A discussion followed of the methods by which members of the committee could best co-operate with their local Institute Sections. It was decided that each national committee member should offer his services to the chairman of his local Section.

The Committee decided to hold a session at the Institute's 1937 summer convention; 4 papers were proposed for this meeting.

The committee also discussed the question of rural electrification and the problems that exist in that field. K. K. Paluev presented an excellent summary of the economic features of rural electrification. The chairman was instructed to present this to the newly appointed special committee on Institute activities.

## Electronics Subcommittee

By H. M. Turner, Chairman

At the meeting of this subcommittee, which is a joint subcommittee of several of the Institute's technical committees, further consideration was given to plans for the 1937 summer convention. It is hoped that the electronics subcommittee will have at least one formal paper (preferably from the Milwaukee, Wis., region) and a conference on electronics with emphasis on industrial applications. The details will be worked out with the convention committee in the near future.

Preliminary plans were made looking toward a rather ambitious program for the AIEE winter convention in 1938. It seems likely that 2 sessions will be required to cover adequately the various phases of electronics, and there probably will be a conference which will permit a more complete and informal discussion of points brought out in the formal presentation. The electronics subcommittee will work with other committees in bringing into focus electronic developments and applications and in unifying them for the benefit of the Institute membership. It will continue the symposium idea that was so successful 2 years ago, but on a somewhat different basis.

Several subjects that have been proposed were considered from the standpoint of their suitability for discussion at the Institute's 1938 winter convention.

## Group III of Subcommittee on Conductors, Towers, and Wood Poles

By Edwin Hansson, Chairman

This was a routine meeting of this group, which is one of 3 groups of the subcommittee on conductors, towers, and wood poles, of the Institute's power transmission and distribution committee. Group I is concerned with towers; group II with wood poles, and group III with conductors. Group III was established for the purpose of studying particularly the question of vibration in transmission line conductors, and to establish satisfactory endurance limits. This work is progressing.

## Transformer Subcommittee

By I. W. Gross, Chairman

Transformer standards came up for extensive discussion at the meeting of this group, which is a subcommittee of the Institute's committee on electrical machinery. The sectional committee on transformers of the American Standards Association for some time has been preparing, and now is about to issue, a report on a proposed American Standard on power transformers that is scheduled to embrace the AIEE standard "transformers, induction regulators, and reactors (AIEE No. 13), the AIEE publication "Recommendations for the Operation of Transformers" (AIEE No. 100), and the AIEE proposed "Test Code

for Transformers." The AIEE transformer subcommittee is keeping closely in touch with this development, co-operating with the ASA sectional committee on transformers, and expects to keep in touch with the situation until such time as the expected reports shall have run the gamut of evolution and emerged in final form.

With reference to present impulse tests, the subcommittee unanimously agreed to alter the method of designating impulse voltages as used in the impulse testing of transformers—from inches-of-gap to kilovolts—without in any way changing the magnitude or character of the tests. This is a change in terminology only, leaving test procedure unchanged.

To study and later to recommend practical methods for the drying out of transformers in the field, a subcommittee group has been set up. Recognizing that circumstances frequently prevent the shipment of damaged apparatus from the field to laboratories, repair shops, or other concentration points fully equipped with rehabilitation equipment, and recognizing also the limitation of equipment and specially trained personnel in the field, the subcommittee's desire is to establish specifications of practical procedure that will obviate the possibility of damage to transformers that would result from exceeding safe temperature limits during the dry-out period.

To bring up to date the information concerning impulse strength of transformers, a subcommittee technical paper was proposed to give full consideration to this as well as to other related phases of the general problem of insulation co-ordination.

Methods of making front-of-wave impulse tests on transformers were discussed at some length. Consensus of opinion, however, was to the effect that further study is required before any standard could be promulgated.

The problem of establishing, in terms of the normal clearance of the bushing alone, minimum limits of acceptable (or safe) mechanical clearance between bushing terminals and case or other nearby integral parts of a transformer was discussed and assigned to a sub-group for further study and later report.

Comments and suggestions pertaining to any of the foregoing points are solicited by the subcommittee.

# Reports of 4 Technical Conferences Held During the Winter Convention

TO PROVIDE opportunity for the informal "round-table" discussion of technical subjects of a specialized nature, 4 "technical conferences" were held during the Institute's 1937 winter convention, under sponsorship of 3 technical committees and 1 subcommittee. Brief reports of these conferences are presented here. These reports have been prepared by the presiding officers of the respective conferences, except for the conference on test codes for rotating machines, which was prepared by the chairman of the sponsoring technical committee.

## Education

By O. W. Eshbach, Chairman

This morning-long round-table conference sponsored by the Institute's committee on education drew an attendance of more than 40 committee members and other interested persons, taxing the facilities of the board room where the meeting was held.

Although several different subjects pertaining to the committee's work were entered for discussion, the major portion of the time was devoted to a general discussion concerning some of the many factors involved in the current program of the Engineers' Council for Professional Development incident to the accrediting of engineering curricula in the principal educational institutions in the United States. Recent experiences incident to this accrediting program in the New England and Middle Atlantic areas were discussed at length, and special attention was given to an informal outline and explanation presented by Doctor A. B. Newman covering the long-established accrediting practice of the American Institute of Chemical Engineers.

Concerning the question of what constitutes adequate and otherwise acceptable "minimum standards" of engineering education, the general consensus of opinion was that this highly ramified subject presented many related aspects such that there can be no written specification but the judgment of experienced people must prevail.

The committee discussed its plans for participation in the program of the Institute's forthcoming summer convention, and laid definite plans for a 1938 convention program appointing a "steering committee" consisting of O. W. Eshbach, chairman of the committee on education; Dean J. W. Barker of Columbia University; and Professor Robin Beach, head of the department of electrical engineering, Brooklyn Polytechnic Institute.

## Network Analysis and Synthesis

By Edward L. Bowles, Chairman

At this conference, which is the second of its type to be sponsored by the Institute's committee on communication, the subject of special network problems that have arisen in connection with the design of radio receivers was presented for discussion as follows:

1. SIDELIGHTS ON THE MULTIPLEX ANTENNAPLEX SYSTEM, by V. D. Landon (this subject deals with filters, amplifiers, and transformers involved in the operation of an antenna system over a wide range of frequencies).
2. CONSTANT-$k$ MULTITRANSFORMER FILTERS FOR COVERING A WIDE RANGE OF FREQUENCIES, by H. A. Wheeler.
3. DRIVING A FILTER FROM A REACTIVE GENERATOR, by H. A. Wheeler.
4. THE USE OF THE MU-BETA DIAGRAM IN THE ANALYSIS OF FEED-BACK CIRCUITS, by H. F. Mayer.
5. THE PROPERTIES OF DIRECTIVE MUTUAL REACTANCE OBTAINED BY THE USE OF VACUUM TUBES, by H. A. Wheeler.

The presentation elicited a very wholesome discussion which was entered into freely by the many individuals whose work dealt with problems in or relating to the field of radio receiver design. From the observers point of view, it was gratifying to see such freedom of discussion and apparent lack of hesitation in the expression of opinion.

The subject of the program quite naturally led to the conclusion that very soon the field of network theory will be generally recognized to include active circuit elements, such as vacuum tubes, and other general circuit elements as, for example, the already applied piezo-electric crystal, and

A group of alumni of the University of Illinois attended the smoker held during the Institute's 1937 winter convention, including 11 members of the class of 1909 all of whom had not been together at one time since graduation. Left to right, seated: H. A. McCrea (A'23, M'30) Boston, Mass.; E. C. Nein, New York, N. Y.; D. A. Henry, New York; P. M. Farmer (M'19) New York; and R. E. Doherty (A'16, M'27, past-chairman of committee on education) Pittsburgh, Pa.; standing: H. C. Dean (A'26, M'29, chairman of board of examiners) New York; E. D. Doyle (A'09, F'27) Philadelphia, Pa.; A. B. Campbell (A'20, M'24) New York; H. D. Braley (A'18) New York; B. M. Fast, New York; I. W. Fisk (A'10, M'13) New York; W. C. Nein (A'08, M'25) New York; M. E. Reagan (A'20, M'30, chairman of committee on automatic stations) East Pittsburgh, Pa.; H. G. Wood (A'23, M'28) Harrison, N. J.; E. S. Lee (A'20, F'30, past-chairman of membership committee) Schenectady, N. Y.; H. O. Siegmund (A'19, M'27) New York; and H. H. Henline (A'19, M'26, national secretary) New York

that future applications of these newer circuit elements will lead to great departures from what may be termed conventional selective network design.

The substantial attendance at both this conference and the one held during the 1936 winter convention is, it appears, an indication of the worth-while nature of meetings of this character which, if they are continued in a vigorous manner, should serve a very useful purpose in aiding the development and application of network theory through personal contact and free and liberal interchange of ideas.

## Sound Measurement

By P. L. Alger, Chairman

Specialists of other organizations, as well as Institute members attended this conference, which was sponsored by the subcommittee on sound of the Institute's standards committee. A draft of a proposed test code for the measurement of apparatus noise was reviewed and approved in final form for submission to interested individuals and organizations for approval and subsequent printing by the Institute. This new code is based upon the already published American Standards for acoustic terminology, sound measurements, and sound level meters (*Z*24.1, *Z*24.2, and *Z*24.3). These standards, however, only define means of measuring the sound level at any single point in space and give no information on how to describe the noise produced by apparatus, which involves taking a number of sound-level readings at different locations around the apparatus, and evaluating the effects of ambient sound level, sound reflections from walls and other parts of the environment, and transmitted vibrations. The new code describes both factory and field test procedures necessary for these purposes, but leaves to the individual manufacturer, industry, or user of apparatus the specification of the number of measurements, distances, and other factors, which may be most suitable in any particular circumstances.

The code should serve a useful purpose in educating both makers and users of apparatus to their separate responsibilities for securing quieter living conditions, and in enabling the various causes of unsatisfactory noise conditions to be more quickly traced and remedied.

Following the discussion on this test code, the question of further activity of the subcommittee on sound was considered briefly. It was decided that the subcommittee should continue its work, chiefly for the purposes of education and organized discussion of noise problems. In this connection, it was suggested that a joint round-table session might be held with the Institute's committee on electrical machinery to discuss questions related to the use of elastic mountings for electric motors and transmitted noise problems.

## Test Codes for Rotating Machinery

By J. L. Hamilton, Chairman, Committee on Electrical Machinery

This report gives a brief résumé of the development of test codes for rotating electrical machinery, and presents an outline of the discussion and action taken at this conference, which was sponsored by the committee on electrical machinery. G. A. Waters, chairman of the induction machinery subcommittee, presided. Future activities of the committee in connection with each of the codes are indicated.

In May 1929, the board of directors of the Institute approved a proposal of the standards committee calling for the development of test codes for the principal types of electrical machinery and apparatus. The actual formulation of a series of such codes was then placed by the standards committee in the hands of the committee on electrical machinery. In July 1931 that committee made its first report, submitting "Test Code for Transformers." The "Test Code for Synchronous Machines" was the second, and "Polyphase Induction Machines" the third of the proposed series. A test code for d-c machines is being developed at the present time. That the electrical industry might become fully cognizant of the work that has been undertaken and at the same time obtain a clear picture of the proposed contents of such codes, the standards committee arranged for their publication as reports in pamphlet form.

In order to determine the performance characteristics of electrical machines, methods of testing, or test codes, have been developed and are in common usage. It is the purpose of these test codes to provide in convenient reference form the more generally applicable and accepted methods of conducting and reporting tests of a commercial nature, which apply to the fulfillment of performance guarantees and to acceptance tests. It is not intended that the codes shall cover all possible tests or those of a research nature. It must be recognized that the selection of the most suitable test depends upon local conditions and the degree of precision desired.

The subcommittee on synchronous machines has prepared another preliminary report on a proposed test code for synchronous machines which was printed January 1937 and is available for distribution.

The discussion of test codes for synchronous machines developed some suggested changes which were referred to the chairman of the subcommittee on synchronous machines for consideration and action.

The first preliminary test code on polyphase induction machines was printed and distributed in January 1935. Many valuable suggestions for changes and improvements in this preliminary code have been received and considered; these were incorporated in a report by the subcommittee on polyphase induction machines and were considered at this round-table conference. The conference approved the releasing for publication of the code for polyphase induction machines after the editing committee has completed its work. It has not yet been decided as to whether this test code will be recommended to the standards committee as a second preliminary report or otherwise.

The work on the test code for d-c machines had developed to the point where a few copies of a preliminary report on the proposed code were distributed in January 1937 for use at this conference. Suggested improvements in the preliminary report were referred to the chairman of the subcommittee for consideration and action. The subcommittee's final report will probably be printed as a preliminary report on a proposed test code for d-c machines.

The committee on electrical machinery takes this occasion to draw attention to the value of criticisms based upon experience. Any suggestions looking toward improvement in these codes will be welcome for guidance in the preparation of future editions.

# ASTM Standards on Insulating Materials

A compilation of all the standards of the American Society for Testing Materials pertaining to electrical insulating materials has been issued in a 1936 edition which includes a number of revised test methods covering the following: varnishes, solid filling and treating compounds, sheet and plate materials, natural mica, untreated paper, insulating oils, and varnished cloths and tapes. Revised specifications cover friction tape, black bias-cut varnished tape, and asbestos yarns, tape, and roving.

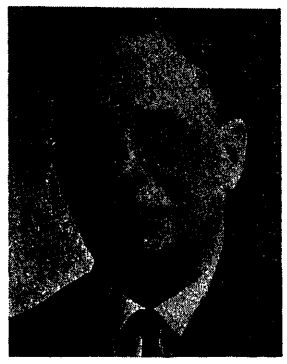
In addition, standards are given also for rubber gloves, rubber matting, electrical cotton yarns, silk and cotton tapes, pasted mica, and slate; also rubber insulating tape, flexible varnish tubing, and electrical porcelain. Test procedures cover thickness testing, impact resistance, thermal conductivity, and resistivity. The 1936 report of committee *D*-9 on electrical insulating materials is included; this report outlines the extensive research and standardization work being carried on by the committee. Copies, in heavy paper cover, can be obtained at $2 each from ASTM headquarters, 260 South Broad Street, Philadelphia, Pa.

# Springfield Section Offers Electronic Course

A course of instruction in electron theory, tubes, and circuits is being given under auspices of the AIEE Springfield Section in order to provide an opportunity for acquiring knowledge of an increasingly important subject at reasonable cost. Classes meet weekly, the course covering approximately 18 weeks, and each class is limited to 25. Preference is given to members of the AIEE, but nonmembers are admitted upon the payment of $1 in addition to the regular $10 fee for the course. For the additional fee, nonmembers become local members of the Section for the remainder of the Section year.

The course is planned for beginners in the study of electron theory, but students are expected to have a working knowledge of a-c and d-c theory and electrical-engineering terminology. D. E. Noble (A'32) assistant professor of mechanical engineering at Connecticut Agricultural College, has been chosen as instructor for the course.

# Doctor Elihu Thomson Honored at Welding Session



PRESENTATION and discussion of the paper "Resistance Welding Circuits" by C. L. Pfeiffer (A'21, M'27) constituted the first item on the program of the session on electric welding held during the Institute's recent winter convention. This paper was published in the August 1936 issue of ELECTRICAL ENGINEERING, pages 868–73. At the conclusion of the discussion, a demonstration lecture entitled "Some Fundamental Phenomena of the Electric Arc" was presented by Doctor C. G. Suits of the research laboratory, General Electric Company, Schenectady, N. Y. Following Doctor Suits's lecture and the ensuing discussion, Herman Lemp (A'89, F'13) consulting engineer of the Ingersoll-Rand Company, New York, N. Y., presented reminiscences of Professor Elihu Thomson's fundamental invention of electric resistance welding. His address was supplemented by remarks by Albert L. Rohrer (A'87, M'88) retired, Maplewood, N. J., who is said to be the only living witness of Professor Thomson's early efforts to develop the resistance-welding art. H. M. Hobart, chairman of the Institute's committee on electric welding, presided at the session; he was assisted by K. L. Hansen, ex-chairman of the committee on electric welding, and W. E. Crawford, a member of the committee for the past 5 years.

### LECTURE BY DOCTOR SUITS

Doctor Suits has supplied the following abstract of the material used in his demonstration lecture:

*Contemporary Arc Theory.* The Compton theory of the electric arc serves as the foundation for the development of the modern thermal concept of the high pressure discharge. Measurements of arc-core temperatures made by several methods, such as (1) from gas density, by X ray absorption (VonEngel and Steenbeck), (2) spectrographic observations (Ornstein), or (3) by the velocity of sound waves (Suits), show that the arc core is a body of gas ionized to a degree determined by its temperature of approximately 5,000 degrees Kelvin. In this high-temperature arc core the current conduction is by a thermal ionization process in quantitative agreement with Compton's theory in cases where the measurables are known. On the basis of this picture the core of an arc in air has the following properties: Its temperature lies in the range of from 4,000 to 7,000 degrees Kelvin; its composition is of the order of 20 per cent $N_2$, 25 per cent O, 55 per cent N; partial pressure of electrons is $10^{-4}$ atmospheres; the mean density is 0.00003 or approximately $^1/_{30}$th that of air at the same pressure and at room temperature; the gas viscosity is approximately 0.0016, which is nearly as great as that of water at the boiling point; the effective ionization potential lies in the range between 8 and 15 volts.

*Arcs at Very High Pressures.* New arc data presented in the practically unexplored field of very high gas pressures. To cover this range several experimental chambers are employed. Transient arc stability is studied in a very small chamber up to pressures of 50 atmospheres. A second chamber, which employs a window, allows measurements of current, current density, and electric gradient up to 200 atmospheres. A third hydraulic-ram chamber allows measurements of current, voltage, and light quality up to 3,500 atmospheres. It has actually been used with nitrogen up to 1,275 atmospheres (18,800 pounds per square inch). In general, it is found that the current density, electric gradient, and arc luminosity increase with pressure. Probably the most important result of this study is the following correlation: Arcs in various gases and at various pressures develop the same current density and electric gradient at the pressures for which the heat transfer is the same. Thus the arc in hydrogen at one atmosphere should have the same current density and electric gradient as the arc in nitrogen at approximately 100 atmospheres, in agreement with experiment. Using this correlation law, arc properties can be predicted in a pressure range for which the measurements may be difficult or impossible. The generality of the theory awaits more complete measurements, but in the cases of nitrogen and hydrogen the agreement with experiment is as good as the knowledge of heat transfer allows.

**Doctor Thomson**

Following his talk, Doctor Suits demonstrated some of his results by throwing an enlarged image of an experimental electric arc onto a ground-glass screen so that those in the audience could see.

*Experiment 1.* This showed the arc between pure carbon electrodes, with an arc length of 3 millimeters, and an arc current of 6 amperes (d-c). From the image projected on the screen, the arrangement and position of the electrodes and the dimensions of the arc column could be seen for comparison with the following experiments.

*Experiment 2.* For the same electrodes, arc length, and arc current, the arc in hydrogen at a pressure of 1 atmosphere was shown. The much smaller diameter of arc column with resultant increase in current density appeared from the reduced size of the image.

*Experiment 3.* For the same conditions as for experiments 1 and 2, the arc was shown in commercially pure nitrogen at a pressure of 1 atmosphere. This arc appeared to have characteristics quite identical with those of the arc in air.

*Experiment 4.* For the same electrode arrangement and current the arc was burned in nitrogen at a pressure of 80 atmospheres. At this pressure the arc cross-section decreased and the current density was nearly as great as in hydrogen at 1 atmosphere. When the pressure was reduced from 80 atmospheres to 1 atmosphere, the continuous increase in arc diameter with decrease in pressure was visible.

In the discussion that followed, the opinion was expressed that the results presented by Doctor Suits are of fundamental importance in the study of the electric arc, and that a published paper reporting those results would prove highly valuable for reference purposes.

### TALKS BY MESSRS. LEMP AND ROHRER

The following summary of remarks by Herman Lemp and Alfred L. Rohrer was prepared by Doctor G. E. Claussen of The Engineering Foundation, who attended the session.

Mr. Lemp referred to the Franklin Institute lectures in 1878 by Professor Thomson, in which electrical discoveries were discussed. It was at this time that Professor Thomson commenced experiments leading to the development of electric resistance welding. He discharged a Leyden jar through the secondary of a Ruhmkorff coil. The ends of the primary, being close together, were found to have stuck together as a result of the discharge. Following the lead provided by this experiment, Professor Thomson was able in 1885, to make practical applications of electric resistance welding, as it is now known.

Mr. Lemp then interrupted his remarks to introduce Mr. Rohrer, another former associate of Professor Thomson. Mr. Rohrer made a verbal sketch of the qualities that characterized all of Professor Thomson's work and made him a supreme experimentalist and scientist. Professor Thomson was among the first to become convinced that all metals and alloys are weldable by the resistance process. The Ruhmkorff coil used by Professor Thomson in his early experiments, and having a capacity of 2,000 to 3,000 amperes is still in existence at Thomson's laboratory, Lynn, Mass. Mr. Rohrer concluded his remarks by contrasting the experimental equipment for resistance welding used by Professor Thomson in the eighties with present-day resistance-welding machines of several types used extensively in industry.

After Mr. Lemp had shown slides of resistance-welding equipment, he resumed his reminiscences of the early developments of the Thomson electric resistance welding concern. He presented brief biographies of several engineers who made noteworthy contributions to that development, including the following Institute members: Walter S. Moody (A'06, F'12), Russell Robb (A'93, M'95), G. F. Sever (A'94, F'12), A. R. Everest (A'04, M'04); Messrs. Robb and Everest are deceased. Mr. Lemp referred particularly to several of the outstanding achievements of the Thomson concern in the field of transformer and rotary convertor construction. Among other in-

teresting anecdotes, he recounted the experiences he had in applying electric resistance heating to the local annealing of hardened steel, such as armor plate, for the United States Navy. The process was first applied in the construction of the famous battleship "Oregon" shortly prior to the war of 1898. Mr. Lemp also made it plain that the scope of the activities of the Thomson concern was international.

At the conclusion of Mr. Lemp's talk, those in attendance voted to send the following telegram to Professor Thomson:

"We, members and guests of the American Institute of Electrical Engineers, here assembled, in reviewing the past, present and future of an art created by your vision and perseverance, send greetings to you and the assurance of our appreciation of what your work has meant to industry and the arts, and which in the hands of capable young engineers is bound to become more valuable as time goes by on the foundation laid down by you."

Before the meeting was adjourned, President MacCutcheon spoke briefly, stressing especially the importance of resistance welding to electrical engineers, first, because the process is fundamentally electrical, and second, because the process is very widely used in the construction of electrical machinery.

# Usefulness of Tensors Probed at Convention Session

WITH E. E. Dreese (M'25) chairman, electrical engineering department, Ohio State University, Columbus, presiding, more than 100 attended both the morning and afternoon sessions on tensor analysis, held on Tuesday, January 26, during the Institute's recent winter convention. The following 5 papers, all published in ELECTRICAL ENGINEERING, were presented:

1. THE TENSOR—A NEW ENGINEERING TOOL, A. Boyajian. April 1936 issue, pages 856–62.

2. TENSOR ALGEBRA IN TRANSFORMER CIRCUITS, L. V. Bewley. November 1936 issue, pages 1214–19.

3. TENSOR ANALYSIS OF MULTIELECTRODE TUBE CIRCUITS, Gabriel Kron, November 1936 issue, pages 1220–42.

4. DYADIC ALGEBRA APPLIED TO 3-PHASE CIRCUITS, A. Pen-Tung Sah, August 1936 issue, pages 876–82.

5. COMPLEX VECTORS IN 3-PHASE CIRCUITS, A. Pen-Tung Sah, December 1936 issue, pages 1356–64.

Following the formal presentation of the papers, the sessions were featured by enthusiastic discussions by members and some guests who were invited, because of their particular qualifications, to present informal discussions on the papers. Among the invited discussers was Doctor Banesh Hoffman, of the Institute for Advanced Study, Princeton (N. J.) University, who discussed the papers from the point of view of the mathematician, showing the simplicity of the tensor method by assuming a simple hypothesis in the physics of motion and developing it into a tensor expression. He pointed out the advantages of tensors in distinguishing physical phenomena by avoiding the use of specific coordinate axes and reference frames; however, he expressed the belief that at present electrical engineers are not using tensors as they are known in the realm of pure mathematics, but are using a modified form of tensor theory.

Doctors Oswold Veblen and H. W. Tucker, also of the Institute of Advanced Study, Princeton University, continued the discussion of the purely mathematical aspect of tensors. Doctor Veblen spoke briefly about the controversial aspect of tensor analysis and its introduction as an engineering tool, comparing the present controversy to the disputations aroused by the introduction of quaternions as an analytical aid. He stated that tensor analysis is very valuable to certain branches of science, but that it should not be forced upon the engineer as a universal instrument of analysis, for it is not the most easily applicable method for all types of problems. Doctor Tucker demonstrated the applications of some of the abstract processes of topology to the analysis of electrical circuits.

Professor Karl L. Wildes (A'21, M'29) associate professor of electrical engineering at Massachusetts Institute of Technology, Cambridge, compared the methods of symmetrical components and dyadic algebra in the analysis of unbalanced polyphase circuits, pointing out an advantage in the use of dyadic algebra for solving 3-phase

**After 2 sessions on tensors: E. E. Dreese (left) of Columbus, Ohio, who presided, and K. L. Wildes of Cambridge, Mass., one of the discussers**

circuits with unbalanced impedances. Professor Wildes asserted that engineers should not be too eager to adopt the method of tensors until its field of usefulness is more clearly defined, because the general application of method may be more obscure and devious than the methods now in use.

W. E. Byrne, of Virginia Military Institute, outlined briefly his experiences in attempting to teach the theory of tensors to a special class of senior students. He expressed a need for closer co-operation between the teacher of mathematics and the practicing engineer.

W. H. Ingram, New York, N. Y., based his discussion upon 2 premises: (1) tensors have not been introduced in electric-circuit theory to date; and (2) there is no necessity for using tensors in circuit analysis. He contended that the term "tensor analysis," as used in electrical-engineering literature, is a misnomer and, moreover, that tensors have no direct application in electrical-engineering problems.

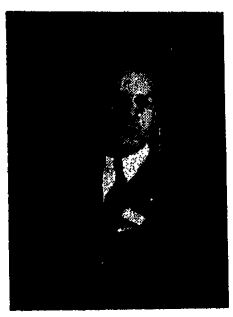
Professor M. G. Malti (M'34) of Cornell University, Ithaca, N. Y., discussed briefly the need for new methods of analysis to deal with the complexities of modern electrical-engineering problems and the suitability of tensors in filling that need. He predicted that the tensor method will be found useful in so many branches of electrical science that its universal adsoption is inexorable, although it may be slow in finding such acceptance. Professor Malti recalled that many engineers bitterly contested Heaviside's operational methods at the time of their introduction, but that those methods have become so widely useful that they can be ignored no longer.

L. V. Bewley (A'27) in his closing discussion emphasized an opinion expressed in his paper: that the tensor method, although extremely flexible, is an inefficient engineering tool, because most problems do not require the mathematical power obtainable by means of tensors. By way of substantiating this assertion, Mr. Bewley described the results obtained by a group of advanced engineering students in determining the best method of analysis in the solution of a great variety of electrical-engineering problems. Each problem was first analyzed to determine the most suitable method of attack, solved by the method chosen, and recorded. Most problems were found to be most easily solved by the conventional vectorial methods; only a relatively small number were advantageously solved by the use of the tensor method.

Following a brief closing talk by P. L. Alger (A'17, F'30) of the General Electric Company, Schenectady, N. Y., who was one of the chief promoters of the tensor sessions, the afternoon session was adjourned by Chairman Dreese; however, several informal conferences were formed for the further pursuit of unfinished problems and arguments. According to Chairman Dreese, the sessions were notably combined meetings of engineers and mathematicians, in which the free interchange of ideas served to inform the mathematicians of new applications of a method of reasoning with which they are already familiar, and to suggest to the engineers some further applications of the tensor method, some necessary revisions in nomenclature and symbols used in engineering papers, and some improvements to provide a more rigorous mathematical treatment of problems involving the use of tensors.

**IES Moves Offices.** General offices of the Illuminating Engineering Society have been moved from the Engineering Societies' Building to the New York Life Insurance Company Building, 51 Madison Avenue, New York. All communications to the society should be sent to room 2100 at the new address.

## Conference Held by Student Branches Committee



Some 40-odd committee members, Student Branch counselors, and other interested persons attended a luncheon conference of the Institute's Student Branches committee, held at the Town Hall Club in New York, N. Y., January 27, 1937, during the recent winter convention. Among those present were Past-President (1902–03) Charles F. Scott of New Haven, Conn.; Past-Vice-President W. H. Timbie of Cambridge, Mass.; Vice-President C. Francis Harding of Lafayette, Ind.; Director R. W. Sorensen of Pasadena, Calif.; and Director F. Ellis Johnson of Columbia, Mo., who as chairman of the Student Branches committee presided.

Chairman Johnson reported that the organization of 3 new Branches had been authorized on January 26, by the Institute's board of directors in accordance with the recommendation of the committee on Student Branches: Tulane University, New Orleans, La.; Northwestern University, Evanston, Ill.; and Columbia University, New York N. Y.

With reference to the organization of future Student Branches, a question was raised concerning the possible influence of the current program of the Engineers' Council for Professional Development in accrediting engineering curricula. Two schools of thought on the subject were evident: (*a*) That the authorization of Branches should not be dependent upon the accrediting of certain technical curricula; and (*b*) that no Branch should be authorized in institutions where electrical engineering curricula had not been accredited. The consensus of opinion was to the effect that for the present, and until ECPD's accrediting program has been carried further, there would be no change in the committee's basis for considering the organization of new Student Branches.
